
The Naval Institute Guide to **WORLD** **NAVAL WEAPONS** **SYSTEMS 1991/92**

NORMAN FRIEDMAN

Comprehensive and totally up-to-date, this guide provides unprecedented coverage of every weapons system in service in ships, submarines, and naval aircraft throughout the world. It is the only single-volume work to offer in-depth information on complete systems, including sensors, fire control, and tracking, as well as on the weapons themselves.

New to this edition are the integrated computer hardware and software that serve naval weapons, with explanations of how they relate to the system's data links, fire control, targeting, and tracking. Descriptions and analyses of combat direction systems and the computers that determine their capabilities are also provided. These include, among others, the current British ADAWS, French SENIT, and U.S. NTDS, along with such emerging systems as the British SSCS and U.S. ACDS.

This edition also offers greatly expanded coverage of airborne sensors, weapons, and countermeasures, together with the latest details on the navalized Su-27 and MiG-29 aircraft being adapted to the new Soviet carriers. In addition, there are incisive descriptions of the state of the art in naval radar, optronic and infrared sensors, lasers, electronic countermeasures, IFF, and missile guidance.

As the most informative assessment available of the complex technological issues affecting naval weapons and their use, this reference has become the choice of sea service professionals, analysts, and engineers around the world.

Some 1,300 photographs and line drawings accompany the text to give the reader a total picture. An addendum notes very recent changes, and a comprehensive index puts all this valuable information at the reader's fingertips.

Other guides published by the Naval Institute Press:

The Naval Institute Guide to Combat Fleets of the World, a biennial guide to the ships, aircraft, and armament of more than 160 navies in the world. Each edition of the book includes more than 1,000 pages and thousands of photographs and keyed line drawings. Edited by A. D. Baker III, this is the English-language edition of Bernard Pr  zelin's *Flottes de Combat* and appears in alternate years with *World Naval Weapons Systems*.

The Naval Institute Guide to the Soviet Navy by Norman Polmar, a triennial reference to the Soviet fleet—its ships, aircraft, weapons, and electronics—that includes an analysis of changes and trends in naval strategy, leadership, shipbuilding programs, and much more. With more than 600 pages and 800 illustrations, each new edition provides thoroughly updated material to keep the reader abreast of important changes.

The Naval Institute Guide to the Ships and Aircraft of the U.S. Fleet by Norman Polmar, a triennial guide to the U.S. Navy's ships, submarines, aircraft, weapons, and electronics, as well as its people and organizations. Each edition of this book contains more than 600 pages and close to 1,000 illustrations.

U.S. Navy Ships and Coast Guard Cutters: A Naval Institute Book for Young Readers by Rear Admiral M. D. Van Orden, USN (Ret.), an introduction to the purposes and general characteristics of U.S. warships and support ships, with 80 illustrations, many of which are in color.

Introduction

As this book goes to press, Western defense policies are shifting radically to take account of vast changes in the international situation. With the threat of land attack in Europe greatly diminished (vanished, if the Soviets are to be taken at their word), large investments in armies and tactical air forces no longer seem wise. It seems possible, however, that the West will not reduce naval forces proportionally. One reason is that these forces sometimes deal with Third World threats that are still real. Another is that, despite the withdrawal of Soviet land forces from Central Europe, the Soviets are still at the borders of the West, deploying their navy on NATO's northern flank. At least through 1990, the Soviets had not reduced naval production commensurate with their claimed reductions in the production of tanks and land-based tactical aircraft. A skeptical observer of foreign policy might well wonder whether the Soviets saw their fleet as a potential means of pressuring the West, e.g., in the event that the U.S.S.R. does not receive sufficient economic aid. Alternatively, Soviet naval production may involve such long lead times that ship building programs may not reflect any decisions to cut for some years.

By early 1991, moreover, there was some question as to whether the Cold War really was over. Faced with severe internal problems, the Soviet government reacted increasingly with classic anti-Western rhetoric, such as a charge that Western banks had caused the collapse of the Soviet economy. Such charges seemed intended primarily for internal consumption, but the Soviet leadership seemed embarrassed that it could no longer separate internal from external messages. Even so, the reversion to past patterns of behavior was not encouraging to the West. There had been some hope that Mr. Gorbachev had made irreversible changes, not only internally but also in Soviet foreign policy, and had admitted that the West was not the problem and that Soviet military forces were vastly overgrown. These admissions justified the deep cuts negotiated during 1990, in the START (for strategic forces) and CFE (for conventional forces in Europe) treaties.

The Soviet military leadership never found the cuts particularly attractive. At first it appeared that the General Staff was going along because Mr. Gorbachev offered to modernize the military's industrial capabilities so that it could match the West technologically. By late 1990, however, it was clear that the General Staff was restive at best. Public statements by Soviet politicians and government officials amounted to a claim that the immense cost of the military, a cost unjustified by any real external threat, had been a major factor in the Soviet economic disaster, and these statements reduced the military's prestige. Deep cuts in European forces translated into unemployed (and often homeless) officers. The withdrawal from Eastern Europe, moreover, looked more and more like the military defeat of a large army that had never actually seen battle, and this defeat was hard for the military to accept because of its technological and economic causes. To many Soviet officers, what they perceived as a capitulation to the Western enemy seemed to be the result of treason committed by the politicians. Senior military officers in Moscow, including some in the Soviet parliament, began to talk about reversing the concessions of 1989-90.

These trends were particularly worrisome because the Soviet administration seemed less and less able to control the Soviet Union, including the Soviet armed forces. In the past, despite nominal lines of control from government to General Staff, actual control often rested with the Communist Party, which formed a kind of invisible government. Largely to modernize the Soviet economy, Mr. Gorbachev tried to break the Party's hold, substituting a real and overt government for the older, informal one. He was no longer pursuing that path by the beginning of 1991, but he was forced to live with a largely discredited Party and with interest groups, including the military, that were openly pursuing their own agendas. The lines of control were frayed at best. This problem extended to all areas of the Soviet system.

There was no mechanism that automatically coordinated the agreements reached by the Foreign Ministry with what was ac-

tually done at the military level. For instance, in December 1990 a Foreign Ministry official claimed that, during the previous year, only four new submarines had been completed, an example of arms reduction. Told by a Westerner that the true number was nine, the official could only reply that the military never quite bothered to tell the Foreign Ministry how many were actually built (the figure of four applied only to nuclear attack submarines and left out such insignificant types as Oscars and ballistic-missile submarines). This was not a matter of clandestine subversion. At about the same time, a writer in a major Soviet newspaper proudly described measures to evade the CFE ceilings, measures that included the nominal transfer of army divisions to naval control.

When Foreign Minister Eduard Shevardnadze resigned late in 1990, he cited a growing fear of dictatorship. He might as well have cited his ministry's declining influence within his own state (or, perhaps, the disintegration of his government). After all, he had negotiated arms-control agreements with the expectation that his military would have to follow them up.

Increased military influence on the course of Soviet policy was perhaps also a consequence of Mr. Gorbachev's desperate need to prevent the disintegration of his empire. Observing the failure of the Soviet economy to respond to his treatment thus far, senior officers were unlikely to accept deep cuts or liberalization as the price of labor modernization. It seemed likely, rather, that they would demand a return to earlier practices, including hostilities with the West, in exchange for intervening in the republics. However, it was becoming increasingly clear that only the West could supply the capital and technology the Soviets needed for modernization (but perhaps the Soviet social/political system could not and cannot usefully absorb that capital and technology).

The result is a very difficult dilemma for whoever governs the Soviet Union, a dilemma clearly illustrated during the crisis over Kuwait. To obtain Western resources and cut running costs, Mr. Gorbachev had to become conciliatory, demonstrating that his country was no longer the wild card of diplomatic poker. He could not, therefore, support Saddam Hussein's aggression, at least not publicly (there is evidence that some of his military felt and acted otherwise). The logical consequence was that he had to support the eventual attack on Iraq. However, that support would have enraged many Soviet client states in the Third World. To acquiesce in the collapse of a former client, Iraq, at the hands of a U.S.-led coalition would have been to lose all the influence the Soviets sought in key areas such as the Middle East. Moreover, a Soviet military increasingly unhappy with the government's conciliatory policy found the strong U.S. presence in the Gulf, so close to the southern Soviet border, worrisome at best. Hence the frantic Soviet attempt to abort the ground attack on Iraq by means of a "peace plan" that would have avoided any punishment for the rape of Kuwait and would have ensured Saddam's survival.

As a result of these developments, Western governments may soon find themselves regretting the drastic reductions announced early in 1990. The great question in 1991 is whether the Soviet Union will manage to hold together over the next few years. If it does, it may well be by internal military control, and the military regime is unlikely to be very well disposed toward the West. Because of the state of the Soviet economy, however, no Soviet regime is likely to be able to continue the current level of military power for much longer. Moreover, enough information has already leaked out to suggest strongly that the current military machine has severe weaknesses. It will probably be some years before they can be repaired, if indeed they can be overcome without considerable liberalization.

Thus, the issue for the West may well be whether to maintain forces suited to combat against the Soviets or to reduce those forces drastically to finance research on new types of weapons. Advocates of stealthy aircraft and missiles could certainly prefer the latter choice. It remains to be seen whether current naval technology is approaching a revolution that would justify such a choice. It may well be that the only revolution in sight is the

advent of much more powerful computers and signal processors, and this would be relatively inexpensive. This book describes numerous existing systems that have been radically improved by the insertion of more powerful computers, often at what must have been limited cost.

In Kuwait, Saddam Hussein very graphically demonstrated the need for Western forces, particularly naval forces, capable of intervention in the Third World. Although the battle inside Kuwait and southern Iraq was fought largely by ground and air forces, that battle could not have occurred at all without the prior and continuing presence of large naval forces. The principal reason is the difference in mobility between land and sea forces.

Naval forces are inherently mobile because they are so nearly self-contained. Before 2 August 1990, no one really expected Saddam Hussein to invade and annex Kuwait. He had had a running border dispute with Kuwait, and he had stationed large forces near the border, but it was generally assumed that the forces were present to exert pressure, not to invade a sovereign country. There was no particular reason for the United States or any other country to intervene in what seemed to be a commercial dispute over oil revenues. For that reason, no U.S. or other Western forces were present in the area when the Iraqi army struck.

At that point there were two immediate issues. One was to deter Saddam Hussein from direct aggression against or intimidation of Saudi Arabia and the small Gulf oil states. The other was to bring pressure to bear to force him to relinquish Kuwait. Neither objective was attainable without the use of force, and the only Western forces that could reach the Gulf quickly were warships. The only available quick-reaction offensive forces were on board U.S. carriers, which soon arrived in the Gulf and in the Red Sea. Carrier attack aircraft and marines using equipment landed from the preloaded Maritime Prepositioning Ships based at Diego Garcia and Guam provided a uniquely valuable deterrent against further Iraqi action. It is true that long-range land-based bombers might have flown into the area, but their only option would have been to attack. Had they flown to bases in Saudi Arabia, they would have been impotent without masses of support equipment and munitions.

The initial pressure to withdraw was also naval, in the form of a United Nations-supported blockade. A blockade was an attractive option because it was a form of pressure that could be applied instantly (as soon as warships could take positions in the Gulf and Red Sea). An instant blockade stopped Saddam from swallowing up Kuwait, laughing off some protests, and publicly claiming that any later military campaign was a completely separate act of aggression against him. He tried to make such claims anyway, but the continuing and highly publicized blockade prevented the international community from appearing helpless. Whether blockade (i.e., economic sanctions) alone would have driven Saddam from Kuwait was another question entirely. Among other considerations was Saddam's probable unwillingness to back down from an operation mounted in part to enhance his prestige, which had suffered badly from the unsatisfactory end of the Iran-Iraq War.

Thus, there was always a distinct possibility that Saddam would not leave Kuwait unless he was forced out. U.S. policy from August 1990 on seemed to have been to prepare for a military option while pursuing diplomacy and applying economic pressure. From this standpoint, one virtue of the blockade was that it reduced the flow of spare parts to the Iraqi military. Before the outbreak of war, it was widely reported that much of Iraq's modern equipment was maintained only by last-minute orders for spares, a practice sometimes called "maintenance by DHL," i.e., by air courier. Much overhaul work had to be done abroad. For example, the United Nations embargo caught much of the Iraqi MiG-21 fleet undergoing overhaul in Yugoslavia. Hussein himself had tried to dissolve Iraq's image of limited industrial capability by staging an arms show in Baghdad in 1989, displaying a variety of purported Iraqi-developed missiles and other weapons. However, close examination of photographs

strongly suggested that many or all of the missiles credited to Iraqi industry were really standard Soviet types with crucial parts removed, or with nonfunctional elements of other missiles added for appearance.

With the embargo, the coalition bought valuable time, during which intelligence about Iraqi defenses was gathered and collated and the force within Saudi Arabia was built up. There was little point in even threatening military operations until forces in Saudi Arabia comparable to Iraqi forces both in numbers and in sustained fighting capability had been accumulated. The mobility of naval and marine amphibious forces comes at a price: because they carry their munitions and spares with them, these forces cannot sustain high-intensity combat for very long without withdrawing for replenishment. Only with time can very large dumps of equipment be built up to support much larger ground-based forces for longer. Because of its weight and bulk, the build-up equipment had to come by sea. Even though the men and the aircraft arrived by air, they could not have done very much without the supporting materiel. As late as November 1990, carrier-based aircraft still represented the majority of U.S. air capability in the theater.

Even after the ground-based aircraft had taken the lead in sustained capability, the mobility of the naval forces remained important because it made Iraqi forces spread out to be ready for all of the many options open to the sea-based attackers. This dilution reduced the opposition that attacking ground or land-based-air forces would encounter. For example, the mere presence of a powerful marine amphibious force off the Kuwaiti-Iraqi coast made it impossible for large numbers of Iraqi troops to quit their positions spread out along the coast to reinforce others along the ground border, yet the marines could not possibly have attacked along the entire coastline. The Iraqis' lack of any maritime reconnaissance complicated their problem: they could not know where the marines were going to land until just a few minutes before the assault began.

This introduction was written during February 1991, and of course all the lessons of Desert Storm had yet to be learned. It was, however, gratifying to see that the claim made in 1990, that U.S. and other Western equipment finally really works, had been so strongly borne out in practice. Visible success is terribly important because any operation in the Third World, such as Desert Storm, is played out not only for its immediate results but also for the edification of other Third World regimes. Conversely, failure (or even expensive success) would tend to encourage other Third World countries to adopt a hostile stance toward the United States and its allies. Many will probably see the success of Desert Storm as the victory of Western materiel and techniques over forces largely, though hardly completely, modeled on and equipped by the Soviet military. That impression cannot fail to improve Western prestige.

The success of the attack missiles, such as Tomahawk and SLAM, was striking mainly because it was so public. Desert Storm was, after all, the first time Tomahawk was used as a precursor to manned air strikes. However, an even greater success was the swift and total destruction of the Iraqi air defenses, which proved to be the key to the air and ground campaigns that followed. At the time of writing it was not clear just how that destruction had been accomplished, and thus just how applicable the operation was to other Third World problems.

It may be that the Allies enjoyed overwhelming but very special advantages, and it remained to be seen whether the abject failure of the Iraqi air defenses was largely the result of incompetence or careful Allied intelligence-gathering over the five months leading up to the attack. After all, the Allied forces almost certainly enjoyed the advantage of information supplied by the purveyors of the air defenses, including the Soviets (who may now rather regret their cooperation). In that case, the lessons of the air-defense-suppression campaign would have little future applicability. However, it may also be that the keys to success were highly accurate missiles, such as Tomahawk, and a command-and-control system capable of coordinating very large numbers of attackers. In that case, it may be much wiser

to invest further in command and control and in antiradar weapons than to produce stealthy aircraft. If, however, the Iraqi air-defense system was very much a special case, then a carrier battle group trying to make a quick strike cannot expect similar success in the future, and special aircraft may be absolutely essential.

Perhaps the greatest question raised by Desert Storm is whether Third World countries like Iraq have been able to make full use of the advanced technology on which they have spent so much of their national wealth. Before the war, Iraq's integrated air defense was often cited as an example of the much increased threat that many future U.S. naval air strikes would have to penetrate. The reality seemed to have been far less impressive.

It seems likely that Iraqi ineffectiveness was largely the result of inattention to command and control, perhaps unavoidable given a lack of educated personnel. Command and control determines just how well weapons can approach their potential destructiveness. The less effective the command-and-control system, the less accurately the published performance figures reflect combat effectiveness. Hence the emphasis in this book on sensors and on command and control. In a land war like that in Kuwait, for example, command and control determines how well a senior commander can perceive the course of a battle and order units to deal with an enemy's moves. The best command-and-control systems provide detailed information in virtually real time and allow a battle to be controlled in detail, enabling a force to react very fluidly. The more rigid and less fluid the command-and-control system, the slower an army is to react to changing events. It appears that the Iraqis failed partly because, whatever the maximum performance of their expensive weapons, they never had a command-and-control system to match, so they were entirely unable to deal with the rapidly moving forces that destroyed them. Although the example is not naval, the lesson clearly extends to all other forms of warfare. It is possible, for example, that the key to destroying or neutralizing Iraq's air defenses was not so much the efficacy of particular Western weapons as it was the flaws of the system that integrated the sensors with the weapons. These flaws, both in technique and in equipment, may have been evident even before the system was fatally stressed. A senior U.S. officer who spent time with the Iraqi forces during the Iran-Iraq War commented that he was not at all surprised that bombs hit Baghdad well before any sirens sounded, i.e., well before the Iraqi national air-defense system was aware of what was happening.

Performance is not, of course, entirely a matter of reliable microchips. Reportedly, the ex-Kuwaiti missile boats operated by the Iraqis failed to engage the Lynx helicopters that sank them because the boats' lightly built structures vibrated badly enough to throw fire-control radars off target. The BEAB pencil-beam radars repeatedly locked on, just to be thrown off by slight helicopter movements. By the time the problem was being corrected, the helicopters' Sea Skua missiles were making it irrelevant. The boats also suffered because their ECM and ESM antennas were so close to the water that they were overwhelmed by multipath effects. One conclusion is that the small but highly sophisticated attack boats so widely touted may be much less effective than is generally supposed. At the very least, such boats would seem to require air-defense missiles (preferably self-guided so that the vibrations of the launching boats do not throw off the missiles' guidance).

One of the surprises of the war, at least as of late February 1991, was the paucity of sophisticated Iraqi weapons, of the sort so publicly but fraudulently displayed in Baghdad in 1989 and also so widely discussed in the Western press before the war. It seems remarkable in retrospect that observers at the time were so credulous, and their willingness to believe official Iraqi statements makes one wonder what other announced Third World weapons and related equipment really does not exist. In addition, many countries may have simply copied Western equipment without permission, paying little attention to Western-oriented intellectual property laws.

Reference books such as this one are largely based, either directly or indirectly, on material released by defense manufacturers, much of it handed out at the many international arms and air shows. Sometimes the weapons advertised are still paper projects, and sometimes claims of sales are false, but it is difficult to recognize sheer fraud. In peacetime, fraud usually does not matter. The run-up to the war in Kuwait was a very different matter. Saddam Hussein badly wanted to deter the West from military action. He believed that his potential enemies, particularly the United States, would shrink from any action entailing large numbers of casualties. It is striking that the whole spectrum of media coverage generally emphasized the fighting power of the Iraqi army, even though by 1990 it was clear that the Iran-Iraq War had ended, not in some sort of splendid victory for Iraq, but rather in mutual exhaustion. Periodically, the press circulated stories of major illicit transfers of technology to Iraq (e.g., fuel-air explosives and cluster bombs), tending not to discover that fuel-air explosives were at best difficult to use and that cluster bombs were fairly ancient. The interesting postwar question is to what extent Iraq orchestrated such stories. Had the coalition perceived that the Iraqi army was essentially war weary and ill equipped at the command-and-control level, would military action not have come much earlier? How much of the public and official image of other Third World military forces is similarly inflated?

It may fairly be argued that professional intelligence agencies would have done (or have done) better. However, three points should be remembered. At least in the United States, unclassified studies of the likely progress of a war with Iraq, based very largely on the published record, had enormous impact in Congress and throughout the Washington community. The reason was that whatever intelligence had been collected could not (or would not) be sanitized for general use. An estimate of, say, twenty thousand American deaths in the liberation of Kuwait had enormous political effect when Congress was considering whether to authorize the use of military force.

Second, at least until very recently in the United States, professional intelligence efforts have been focused almost exclusively on the Soviets. Much of the information about Third World military organizations and particularly Third World military producers is taken from standard unclassified reference materials.

Third, there is little reason to imagine that classified professionals are less credulous than published ones: secret does not always mean true. After all, during the run-up to the ground war, the White House, which had access to all intelligence sources, made no attempt to discredit any of the gloomy scenarios; the President merely argued that Saddam Hussein had to be stopped and that the cost of doing so later would greatly exceed the cost of doing so right now. There is every evidence that Central Command, in its planning, had just as much respect for the Iraqi army as did the civilian commentators in the United States. In each case the impressive paper image camouflaged real Iraqi deficiencies. The allied plan did exploit some major Iraqi weaknesses (particularly in command and control), but the collapse of the Iraqi army seemed to have caught everyone by very happy surprise.

The question for the future is whether that surprise points to some grave deficiency in the U.S. way of evaluating potential enemies. In particular, the United States seems to focus on numbers, whether of ships or of soldiers, and on the nominal or maximum performance of the weapons. Western analysts seem much less capable of factoring in subtleties, such as weak or slow command and control. For example, by now the West is well aware of the characteristics of the MiG-29, which is being tested by the German air force. The MiG-29's aerodynamic performance is exceptional, but its maintainability is apparently quite appalling. Both are easy to quantify. It is much more difficult to quantify another important factor: cockpit layout. A MiG pilot has to shift attention frequently just to flip the switches needed in air combat. "Switchology" like this is not an abstract issue. Early in the recent war, one Iraqi MiG

shot down another because, to save time, the pilot had taped down some of the switches that otherwise would have provided a way to veto the firing of a missile at whatever target the plane had locked onto. What the pilot did was, apparently, standard practice. Clearly, it is difficult to estimate how poor internal arrangement (which may partly result from the absence of an effective central computer) affects the performance of a large number of MiGs flying over Central Europe, for example. It is easier to assume that, apart from some aerodynamic details and missile ranges, a MiG is equivalent to an F/A-18 or an F-15. However, that analysis is worthless if switchology is not merely a detail but a fatal disaster.

In the United States and probably in all or most NATO countries, mathematical projections of combat outcomes determine the course of weapon and force procurement. Abstract mathematical techniques, then, are not a trivial issue. The mathematical techniques are attractive because they provide decision-makers with clear-cut numerical predictions, but they have never really been tested, not even compared with historical evidence to see whether a model predicted events correctly. There is, then, no real evidence as to whether the mathematics has any reality behind it. In the past, mathematical techniques have been criticized because they do not take tactics into account, particularly the way tactics change either during a battle or during a campaign. They may also fail to take into account issues of morale and determination or command and control, all of which were absolutely critical to the outcome in the Iraqi-Kuwaiti desert. There is some evidence that both in the Falklands and in Kuwait, the projections were seriously in error. The West is now cutting many programs, often on the basis of such mathematical projections. Perhaps the most valuable lesson to be learned from events in Iraq and Kuwait is that it is time to notice that this particular emperor is very nearly naked.

One major surprise of the war (as well as of the UN-sponsored embargo preceding it) was the extent to which naval (and other) forces that in the past had been mortal enemies have operated in close coordination. With the wind down of any cold war, the opposing powers do not immediately become close friends. However, they do discard any idea of near-term hostilities. Just this sort of cooperation occurred frequently in the latter part of the nineteenth century, when navies nominally intended to fight one another joined forces to conduct peacekeeping or policing operations in the Third World, where all had much the same goals: stability and a reasonable degree of friendship commensurate with trade. These navies had not discarded the roles they would play in major war, but those roles had been put off.

In 1890 coordination meant little more than a conference among commanders before operations began. All the ships were within sight of each other, and fatal errors cannot have occurred very frequently. Any reader of this book knows that coordination is now far more complex and generally requires the automatic exchange of data, of tactical plots in particular. To say that NATO warships are compatible means that all share Links 10 and 11 and that they carry tactical data systems designed to show a common picture. What happens when NATO forces must operate with neutral navies, or even with the Soviets, who do not share our systems? We need some way to share the linked data on a strictly temporary basis, perhaps by using portable terminals. Such equipment may actually be aboard Soviet warships in the Persian Gulf, in the hands of the U.S. Navy's liaison teams.

Why does real-time data exchange matter at all? In 1890 the main instrument of power projection was the naval gun, controlled entirely by the firing ship. Now the most effective instruments are long-range missiles and aircraft. They are also the best weapons for attacking ships. It is reasonable to assume that outbound aircraft are friendly, but naval air strikes must return to their own ships and would, for example, have to overfly most of the warships in the Persian Gulf. Surviving enemy aircraft may well elect to follow air strikes back to the carriers. If ships find themselves forced to engage any airplane coming within

some predetermined keep-out distance, we will make very few strikes before we lose all our aircraft.

The U.S. Navy found one solution to this problem in 1945, preventing Japanese aircraft from following American strikes home to the carriers by assigning sections of fighters to visually inspect the returning groups of attack aircraft and to shoot down any interlopers. At that time the fleet enjoyed plentiful air resources, and enemy aircraft were relatively easy to identify by sight. Now the fleet has many fewer fighters. Visual identification is much more difficult, partly because aircraft must be engaged at long range, but also because both sides use very similar (or identical) airplanes. For example, both Kuwait and Iraq bought French-built Mirage F-1s.

The only really sure way of identifying aircraft without their cooperation is by following their flight paths. During Vietnam, for example, we stationed an NTDS ship in the Gulf of Tonkin to identify and track all air traffic crossing the area because we did not want to shoot down an airliner, or one of our own aircraft, inadvertently. Because of its relatively limited radar horizon, that ship, and any picket ship, also relied on information from early-warning aircraft. AEW aircraft can, in theory, observe aircraft as they take off from ships or from bases ashore, track them out to the target areas, watch their strikes, and then follow them all the way home. Whether AEW aircraft can conduct this tracking function in practice depends on the capacity of the airborne computers since several hundred aircraft may be airborne at once. Another factor is the precision of the airborne radars, which may find it difficult to distinguish aircraft flying very close together (and which may then erroneously mix friendly and enemy aircraft tracks).

Current naval air-defense systems ought to be reasonably effective, so the critical decision is when or at what to fire. The *Stark* incident taught every CO in the world the lesson that it is better to shoot first than to suffer the consequences of hesitation. In the Soviet navy, in addition, there is reason to believe that ships carry heavy concentrations of antiaircraft weapons because the Soviets credit individual weapons with relatively small kill probabilities. That factor would tend to bias a Soviet commander to engage early. Similar considerations would apply to any other navy with little belief in the efficacy of installed antiaircraft weapons. It always pays to open fire as early as possible. A captain relying entirely on the ship's on-board sensors will almost have to treat every nearby airplane as unfriendly.

These considerations explain the Canadian navy's provision of an ADLIPS tactical data system for its replenishment ship deployed to the Persian Gulf during the run-up to the war.

This discussion may seem far too gloomy in view of the success Allied forces enjoyed during the war against Iraq: hundreds of aircraft flew attack missions for well over a month without encountering any blue-on-blue problems. It seems likely, however, that at least the initial strikes had to be planned very carefully and rigidly to avoid accidental interception. Rigid control probably meant manual planning, and hence less than the most efficient use of the aircraft. That trade-off was perfectly acceptable because of the enormous power available. Moreover, there seemed not to have been an urgent timetable that might otherwise have forced commanders to accept more blue-on-blue risks. In the only projected air campaign of like size, a NATO-Warsaw Pact war in Europe, air operations would have been much more urgent because they would have been aimed at stopping a rapidly advancing enemy army. Because air support of the land campaign is so fluid, it cannot be so rigidly controlled. In the campaign against Iraq, however, the destruction or flight of the bulk of the Iraqi air force greatly simplified the problem. In the absence of enemy air attack, allied antiaircraft gunners had no occasion to develop the usual jitters that lead to the deaths of aviators by friendly fire.

The conclusion is that careful planning can overcome the classis blue-on-blue problem, and that assessment in turn would seem to support current efforts at developing 3D, computerized, air-mission planning systems, such as the projected ISPS, which would combine greater efficiency (and timeliness) with safety.

Such systems have become practicable as computer power has become less expensive and more reliable.

Iraq may well turn out to have been a specially fortunate case. In the Falklands, for example, on at least one occasion, British fighters flew into their own ships' firing zones while the ships were engaging Argentine bombers; to avoid shooting down their own fighters, the ships had to break off the engagements and allow the bombers to penetrate unopposed. Fear of blue-on-blue engagements has been a major factor in the development of U.S. carrier battle-group tactics. Similarly, one of the standard considerations in NATO's war planning during the 1970s and 1980s was the expectation that about 40 percent of all friendly aircraft would be shot down by NATO forces. Neither case involved integrating forces with radically different engagement doctrines or without access to standard data links. Fear of blue-on-blue is so strong that the standard U.S. Navy tactical command system, NTDS, is biased against engaging any airplane labeled friendly. The *Stark* never engaged the Iraqi airplane that attacked her largely because that track had been labeled friendly (there was no label for neutral, only unknown/assumed enemy). The *Stark* could have engaged the track, but an engagement would have required a specific effort to override the NTDS safeguards. This experience will probably motivate ship's commanders to do everything possible to engage approaching aircraft unless they are sure those aircraft are friendly.

Today's commanders would like to rely on IFF for identification, but experience has shown the combat limitations of these systems. Any concentration of ships and aircraft in a very small area, especially along a coast, will cause interference among IFF responses and, thus, identification and tracking difficulties. In neither the Falklands nor Lebanon was identification complicated by the presence of friendly forces that did not share tactics, data links, or IFF systems, so operations in the Persian Gulf had even greater potential for confusing the IFF picture.

If the intervention in the Persian Gulf were a special case, the identification problem would probably be an acceptable risk. But history suggests that the crisis over Iraq's invasion of Kuwait is the prototype for many future interventions, almost always by mixed forces. How well the Gulf peacekeeping force coordinates operations now will not only affect the outcome of this crisis but will also serve to deter, or encourage, future aggression.

The experience of war in and around the Gulf tends to reinforce another point made in the previous edition, that modern weapons are often less lethal than imagined and that damage assessment is too often overlooked. It is quite clear that modern weapons can be directed to particular points in enemy territory, but it is difficult to keep in mind that a bomb hitting or even penetrating a bunker does not necessarily destroy either the bunker or its contents. Bomb damage can be repaired, and with a sufficient gap between bombing and post-strike coverage, it can be faked to protect other targets (which may appear to have been hit). The Iraqis certainly resorted to decoying, both simulating vehicles and simulating bomb damage. For example, the roof of the notorious dual-use bunker on the outskirts of Baghdad had several false bomb holes painted on it. They seem to have been less than effective, partly because the attack schedulers knew the building had not been hit prior to the raid that destroyed its insides.

Readers will be painfully aware that existing reconnaissance systems, some of which are described in the Strike/Surface Warfare section, are inferior to earlier ones, such as that carried by the RA-5C Vigilante. Superior systems are still under development. The best existing U.S. system, on board the mothballed SR-71 Blackbird, was not available for the war. As a result, commanders in the theater had to wait much too long to assess the effects of strikes. Such delays may be entirely acceptable during a campaign against fixed targets, but they greatly detract from attacks on mobile targets such as tanks.

The lethality gap was particularly evident at sea, where Sea Skua missiles disabled Iraqi surface combatants, such as ex-

Kuwaiti fast attack boats, by hitting their superstructures. The boats were not sunk, and they were the targets of later strikes because no one could be sure that they had been rendered entirely ineffective. Experience seems to show that modern Western antiship missiles just do not have sufficient destructive power to kill most warships. In a protracted campaign, a ship or fast attack boat tied up at the pier will probably attract additional attacks. Because of the limited number of weapons available, any unnecessary attacks would prevent more productive uses of the weapons. Much the same might be said of a tank burned out inside but appearing intact. It is useless except as a decoy, but its usefulness as a decoy is high.

Lethality has another aspect. Readers will notice that virtually no air-delivered weapon weighs more than about 2000 lb. All carrier aircraft in the world carry their weapons externally, as do most land-based aircraft. External carriage imposes severe limits on a weapon's length, diameter, and weight. The current limit is perfectly acceptable as long as the targets are those common in the major U.S. scenario of European war: vehicles and reinforced-concrete aircraft hangarages. In Iraq, however, there was another class of target, the deeply buried command bunker. It could have been argued that the only really effective deterrent to Saddam Hussein would have been a weapon capable of hitting and killing him in his bunker, about 40 ft below ground level. At the very least, the threat of such attack would have forced Mr. Hussein to use surface facilities, in which he would have been much more vulnerable to the fury of his compatriots, and thus would have contributed materially to his downfall.

Ironically, this problem was solved half a century ago. During World War II the RAF introduced "earthquake" bombs, heavy-cased weapons that, falling at supersonic terminal velocity, would penetrate so deeply into the earth that they would explode below their targets, destroying them with shock waves. They were enormous bombs: 12,000-lb Tallboys and 22,000-lb Grand Slams. The Addendum describes the 4700-lb GBU-28 developed during the recent war specifically to penetrate deep Iraqi bunkers. It was delivered by an F-111F and is probably somewhat too long for carrier aircraft (nor can it be delivered by B-1 and B-2, which can carry nothing larger than a Mk 84).

This second edition of *The Naval Institute Guide to World Naval Weapons Systems* is substantially larger and more complete than the first, and it has been almost completely reillustrated.

The most obvious new feature of this edition is a detailed account of combat-direction systems (CDSs), such as the British ADAWS, the French SENIT, and the U.S. NTDS, and also of the computers that ultimately determine the capabilities of these systems. CDSs mediate between sensors and weapons, not only on board ships but also in an increasing number of naval aircraft. The sensors and weapons determine the ultimate combat potential of a ship or aircraft, but the CDS generally determines the extent to which that potential can be met.

Automated CDSs are needed to keep track of many different targets. The requirement to track multiple bogeys automatically first emerged in air warfare. However, as sonar (particularly passive sonar) range has increased, it has turned out that ASW participants, too, require computers to track and target multiple contacts. ASW actions may move much more slowly than air engagements (hence the witticism "awfully slow warfare"), but they are intricate and must sift an enormous amount of data: the U.S. SQQ-89 system requires about twice as much computer program as Aegis.

Most of the naval CDSs are intended to make combat itself more manageable, and they have little influence on combat plans. Now new systems intended for precombat planning are beginning to appear. They permit a commander to see the likely effects of various, alternative approaches, much as spreadsheets allow financial analysts to try alternative investment strategies. The naval problem is, of course, infinitely more complex, but

in both cases the benefit of comparing different tactics is much the same. Perhaps the most extreme examples are the new planning tools for the deployment of tactical aircraft. Systems such as the French Circe 2000 and the developmental U.S. ISPS allow quick comparison of the virtues and defects of alternative routes for air attacks against land targets. The new U.S. Afloat Planning System for land-attack Tomahawk missiles (see the Addendum) is a simpler equivalent of these systems. In the case of the Afloat Planning System, the line between planning and combat is blurred because the machine sends its data directly to the missile. There is no realistic manual alternative. With tactical air forces, however, manual strike planning is a well-established process.

The tactical planning systems replace vast amounts of staff work traditionally applied to "what-if" questions. The need for automated CDSs has long been obvious, and enormous sums have been spent on them. It remains to be seen whether the promise of the new tactical planning systems will make them attractive enough to survive the post-Cold War drawdown.

As in the past, the single major gap in our knowledge of CDSs is the Soviet Union's systems. Published or publishable information is virtually nonexistent. However, there is still reason to believe that the Soviets lack Western-style integrated combat systems and still rely heavily on manual (grease-pencil) compilation of a tactical picture. For example, the proliferation of short-range air-defense weapons on board most Soviet warships probably indicates an inability to react quickly enough to engage incoming attackers at long range, i.e., it probably indicates a lack of automation. If so (presumably as a consequence of the relatively primitive condition of the Soviet computer industry), then the Soviets' very impressive weapons cannot currently perform up to anything like their full potential: Western navies enjoy an enormous, if ill-defined, advantage because of their CDSs. But that advantage may be a fleeting one. As export controls are relaxed, it may be possible for the Soviets to buy the commercial equivalents of the elements of Western-style combat systems.

This is not to say that Soviet naval capabilities will surge as soon as the first few personal computers or workstations arrive in Leningrad. CDSs are much more than a few computers: they require elaborate software (not to mention human engineering) and careful integration with existing weapons and sensors. Software testing generally entails the creation of one or more land-based test sites. Merely plugging computers into existing manual systems can be disastrous (the U.S. cruiser *California* literally did not function on her initial trials because of software problems in her incompletely integrated system; she took a year to fix).

In the past, computers of all types were extremely expensive, and only major warships could be fitted with automated CDSs. Other ships had to make do with the manual systems developed during World War II. However, since the late 1960s computer costs have fallen so dramatically that even many current fast attack craft have on-board computers. At the same time, relatively few ships built without computerized CDSs have been fitted with them, partly because such systems function effectively only when they are fully integrated with their sensors and weapons. Consequently, the ships of the world's navies still fall into pre- and post-computer classes.

That distinction becomes more significant as older ships, either entirely without computers or with early low-performance units, are retired. For example, the U.S. Navy plans to lay up (or, more likely, sell) the entire *Knox* class. These ships never had automated CDSs of any type. The consensus is that without such systems, ASW ships cannot hope to track multiple targets passively. Thus a nonautomated ship cannot make full use of her towed-array sonar. All later U.S. ASW ships either have, or are having installed, an automated ASW CDS in the form of SQQ-89. One conclusion is that the retirement of the *Knox* class represents a far less significant loss of capability than bare numbers would suggest. Another is that any navy buying

these ships would probably want to fit them with some type of automated CDS.

Although the cost of civilian computers has fallen and their reliability has improved, their ability to directly replace their much more expensive military counterparts remains in question. On the one hand, some commercial-grade computers are at least as rugged as their military counterparts. For example, the Canadian navy tested a new sonar algorithm by using a commercial PDP computer and discovered to its surprise that this machine outlasted the standard military computers during that cruise. Because commercial machines are not subject to elaborate procurement practices (sometimes denoted by the shorthand of "Mil-Spec"), they have very much shorter development times and, thus, can embody more advanced technology at a relatively low price. The U.S. Navy has adopted some commercial workstations (desktop computers, or DTCs), which bring down the cost of some important tactical improvements. They do not, however, conform to full military specifications. Procurement has, therefore, been limited to what are called tactical decision aids (as opposed to mission-essential devices), on the theory that a ship can fight even though her decision aids may have been disabled.

Buying commercial computers carries a hidden cost. Military computers change very slowly, and the customer can demand strict control of their configurations. Software that works perfectly on one UYK-7 will work identically on a UYK-7 made ten years later. The world of commercial computers is very different. Machines with identical designations may embody engineering changes that affect software performance in subtle but important ways. Hardware that is sold as perfectly compatible or equivalent may have differences that users quickly notice, often to their misfortune. This problem is by no means insurmountable, and it ought not to deter any Western navy from increased reliance on commercial computer products. However, navies will need to take a different approach to procurement and testing.

The U.S. Navy's next generation computer resources program (NGCR) may have already developed the appropriate approach. NGCR will accept commercial components that are fully compliant with stated software requirements. The question will be just how well the navy can test that compliance. Readers who bought extra boards for their open-architecture personal computers (such as IBM PCs and their clones) know that on occasion the supposedly fully compatible boards caused problems because they handled software just a bit differently from the original computer. The problems were by no means common, but their naval equivalents would have been unfortunate in combat. The navy will have to avoid the strong temptation to regard all nominally equivalent components as truly equivalent and should refuse to choose simply on the basis of price.

This edition includes considerably expanded coverage of airborne sensors, weapons, and countermeasures because the main threat to naval forces throughout much of the world is still from land-based air forces. In addition, accounts of Soviet air weapons and sensors have been expanded to take account of the capabilities of the Su-27 and MiG-29 fighters that the new carrier *Admiral of the Fleet Kuznetsov* and her successors will carry. There is still no public information concerning possible successors to the heavy air-launched antiship missiles, the AS-4 and AS-6, that the Soviets introduced during the 1970s. Given Soviet progress in other areas, it is difficult to imagine that no successors exist.

It has been possible to provide much fuller accounts of some of the weapons and sensors described in the previous edition. For example, this edition describes the different versions (Mods) of many U.S. systems in detail. In many cases, different Mods of the same device or system are so different that we might legitimately consider them different systems.

The Addendum, which was current as of the end of March 1991, includes a detailed description of I-2000, the bunker-attack bomb first used in the war against Iraq. The Addendum

also includes the most complete list yet published of Soviet communications antennas, substantial new material on current and planned U.S. and NATO data links, and some recently declassified material on the origins, rationale, and development of the NATO SOSUS system.

To compensate for the additional entries, and also for the greater detail in some sections, I have deleted some historical material. That includes descriptions of some abortive systems that were interesting for their connections to current projects. Interested readers should consult the first edition of this work. However, I have not deleted any weapons systems or naval sensors in current service or in reserve, and I have added some older systems still in service but inadvertently omitted in the previous edition. The goal of this edition, and all future editions, will be to include all existing naval weapons systems.

Dimensions are given, wherever possible, as diameter $\times$ length (wingspan or fin span as a separate item). For radars, the first dimension is the horizontal one, which determines the horizontal beamwidth. Dimensions are generally in the units (English or metric) used by the country of origin. Where that is metric, English units are given in brackets. Dimensions for some Soviet systems are given in English units (feet and inches), even though the weapons have certainly been designed in metric terms, because the published data come from U.S. sources and are surely approximate rather than exact. Ranges are in meters and yards (sometimes in thousands of yards, or kiloyards, abbreviated kyd). Although a nautical mile is 6080 feet (6053 feet in British measurement), it is commonly approximated to 2000 yards, so that a range of 17.5 nautical miles is probably actually 35,000 yards.

An important note on sources. Readers should keep in mind, above all, that this is an UNCLASSIFIED book, a compilation of information from the open literature, from declassified documents, and from brochures provided by the manufacturers of the equipment. I have chosen data on the basis of the plausibility of the source, and also on the basis of their conformity to the known characteristics of similar weapons for which data are better established. In some cases I have identified equipment from available photographs. Official documents generally are not declassified for some considerable time after their origination, typically at least twelve years in the United States, but often as long as thirty in Britain. Because systems change (not only to be improved) over time, data correct at the time the documents were compiled are often only approximately correct when the documents are declassified. Data should, therefore, be taken as typical rather than precise. Virtually all unclassified data on Soviet systems are limited both in accuracy and in completeness. Hopefully, readers with access to better data may find comparisons with Western systems useful.

ACKNOWLEDGMENTS

I could not have written this book without considerable assistance. I am particularly indebted to A. D. Baker III, the editor of the companion volume, *The Naval Institute Guide to Combat Fleets of the World*; to Chuck Haberlein; to David Isby; to Steven J. Zaloga; to Raymond Cheung; to Fu S. Mei; to Mark Wertheimer; to Eric Grove; to Lon Nordeen; to Anthony Preston (editor of both *Naval Forces* and the invaluable newsletter *NAVINT*); to Dr. Jan Breemer; to Stuart Slade; to Dr. Geoffrey Till; to B. Bruce-Briggs; to Jim Burke; to Alan Raven; to Capt. Philip Orvis, USN (Ret.); to Dr. Tam Melia; to Sue Fili; to Dr. R. S. Scheina; to David Steigman; to Jürg Kürsener; and to C. C. Wright. The U.S. Navy Office of Information provided invaluable information on current systems. I am also grateful to the Freedom of Information Office of the U.S. Army Communications-Electronics Command, which answered numerous queries concerning standard U.S. electronic equipment. The U.S. Navy Operational Archives and the British Public Record Office provided invaluable historical material, which remains

relevant because a great number of the systems described here have been in service for so long. Many of the manufacturers represented here have been extremely generous with material, both factual and photographic. I would emphasize, however, that the descriptions and analyses of equipment are my own, and that the manufacturers should not be held responsible for the conclusions I have drawn.

I would like to thank my in-house editor, Anthony Chiffolo, for his effective and measured approach, which made this edi-

tion possible; and Linda Cullen, for her often-successful efforts to find illustrations.

I would like especially to thank my wife, Rhea, for her loving support, her encouragement, and her direct assistance.

Any book of this type is inevitably incomplete, and some inaccuracies will slip in. Additions and corrections for the next (1993/94) edition are most welcome; please submit them to the author c/o Naval Institute Press, Annapolis, MD 21402.

PREFATORY NOTES

RADAR

Radar is described at the beginning rather than in a separate section because radars appear in both the surface and air warfare sections.

Radars are generally described by their frequency bands, peak power, pulse width, and pulse repetition frequency (PRF).

Frequency (which is inversely proportional to wavelength) determines how precise the radar beam can be, since beamwidth (in radians) is approximately equal to the inverse of the antenna size in wavelengths. The larger the antenna, the narrower the beam. Moreover, the larger the antenna, the higher the gain: the larger the fraction of the returning echo the radar will detect. Frequency (or wavelength) also determines the kind of technology required to produce the radar signal, and the extent to which that signal will be absorbed by the atmosphere, e.g., by rain.

There are two quite distinct systems of coding frequency bands. One, developed during and after World War II, describes the physical characteristics of the signals and is almost certainly mnemonic. It is used in this book. A second, more recent system is a more systematic division of the possible radar bands. It was developed for electronic intelligence, and it reflects the fact that other nations (particularly the Soviets) use radar frequencies very different from those common in the West. It is used in this book primarily to describe ECM equipment. Details of both systems are given in Table 1.

The original wartime radar-band system consisted of a metric P-band (P for pulse, as in the U.S. APS and SPS designations), and an S-band for short (or centimeter) wavelengths (about 10 cm). An X-band (for exotic) was added during World War II for a newer generation of 3-cm radars. After the war, the P-band was temporarily abandoned in favor of a long centimetric wave-

Table 1: Radar Frequency Designations

The boundaries between bands in the classic radar system have changed over time, but the approximate positions of the bands do not. 1000 MHz is 1 GHz, and older references use cycles rather than Hertz, i.e., Mc/s instead of MHz.

FREQUENCY	U.S. RADAR DESIGNATIONS	ECM BANDS
30-250 MHz		A
100-150	I-band	
150-225	G-band (World War II IFF)	
225-390	P-band	
250-500		B
390-1550	L-band	
500-1000		C
1000-2000		D
1550-3900	S-band	
2000-3000		E
3000-4000		F
3900-6200	C-band	
4000-5000		G
5000-8000		H
6200-10,900	X-band	
8000-10,000		I
10,000-20,000		J
15,250-17,250	Ku-band	
33,000-36,000	Ka-band	
20,000-40,000		K (K-band embraces Ku through Ka)
36,000-46,000	Q-band	
40,000-60,000		L
46,000-56,000	V-band	
56,000-100,000	W-band	
60,000-100,000		M

NOTE: In radio parlance, HF extends up to 30 MHz; VHF is 30-300 MHz; UHF is 300-3000 MHz; SHF is 3000-33,000 MHz. These boundaries approximate wavelengths of, respectively, 10 m, 1 m, 10 cm, 1 cm, and 1 mm.

length (L-band, about 20 cm), and a new compromise band (C, about 5 or 6 cm) was developed. The advantage of the C-band was that it could be used in conjunction with a small antenna (like X-band) but could penetrate rain better than X-band. There was also K-band (about 1 cm), a designation left over from an abortive wartime attempt to rationalize band designations. Some radars are also characterized as UHF, meaning a frequency range somewhat higher than P but lower than L (the term UHF is used slightly differently in radio).

As a rule of thumb, the beamwidth of a linear array, such as a slotted waveguide, is about 1 divided by the array length (in wavelengths), in radians. A similar consideration applies to a circular antenna, uniformly illuminated. At X-band, the beamwidth (in degrees) of such an antenna is about 70 divided by antenna diameter in inches. Many such antennas use tapered illumination, which gives a slightly wider beam but much lower sidelobes; in that case beamwidth is about 85 divided by antenna diameter.

Naval radar operation is much affected by the fact that signals reflect off the sea. At low frequencies (e.g., P-band), reflected and direct signals interfere constructively and destructively, forming a lobe pattern. The lowest lobe can be at an elevation angle well above the sea surface; as a result, P-band radars generally cannot detect low-altitude targets. On the other hand, at higher altitudes, interference can be constructive, and radar range can be greater than it might be in free space (or, for that matter, over land). The lobing phenomenon itself causes targets to fade in and out of detection as they approach; the ranges at which fading occurs are a crude measure of target altitude. At higher frequencies, lobing is much less significant because the areas of constructive and destructive interference are very narrow and tend to wash out as a ship rolls.

The naval environment poses a special problem for the operation of radars. Because a ship is relatively small, and because it must carry numerous antennas in close proximity to its superstructure, its radars may often be affected by reflection off both the ship and other antennas. The effect is particularly noticeable in the sidelobes. For example, a whip antenna vibrating near a radar antenna may impose a modulation on the radar signal. Such effects may limit the extent to which a naval radar can rely on, for example, doppler information extracted from the details of returning echoes.

Quite aside from lobing, radars are affected by back-scatter off the sea, particularly when they are used to detect low fliers. At 0 elevation, with a beam of 2 deg and a pulse of 2 microsec, the radar typically sees a patch of sea about 0.05 nm² at 10 nm. Back-scatter, in m²/nm² at 8–10 nm is:

	RADAR BAND			
	P	S	C	X
<i>Sea State</i>				
0	—	.003	.005	.01
1	—	.03	.05	.1
2	—	.1	.25	1
3 (moderate)	.001	.3	2	10
4 (rough)	.003	5	20	100

Thus in a rough sea, an S-band radar will see 5 m² of back-scatter at 8–10 nm, and any radar return from a small sea-skimmer (typically of 0.1-m² radar cross section) will be altogether swamped.

At very high frequencies, molecules (mainly oxygen and water) in the atmosphere absorb most radiation. There are, however, 3 windows:

35 GHz (8-mm wavelength)—Ka band

94 GHz (3.2-mm wavelength)—M band in the ECM system

140 GHz (2.3-mm wavelength).

The current upper limit on reasonable radar power generation is probably 94 GHz. Millimeter-wave radar touches the far infrared part of the spectrum. In the infrared, which is closer to light, there are windows at

8–14 micrometers (0.008–0.014 mm) and

3–5 micrometers (0.003–0.005 mm).

(The term micron is typically used instead of micrometer, i.e., one-millionth of a meter, or one-thousandth of a millimeter.)

Visible light wavelengths are an order of magnitude smaller, around 0.5 micron, or 0.0005 mm.

Radar power determines how well the radar is able to detect an individual echo. Because detection is cumulative, a large number of relatively weak echoes will have the same net effect as a small number of strong ones. Moreover, the detectability of an individual echo depends not only on its peak energy but also on how long it lasts. Thus maximum radar range is commonly equated to average radiated power, i.e., to the product of peak power, pulse duration, and pulse repetition rate or frequency (PRF). The product of pulse duration and PRF is the duty cycle, the amount of time, as a fraction or percentage of the total time, that the radar is transmitting. For example, a radar transmitting pulses of 1 microsec at a PRF of 500 pulses per second has a duty cycle of 0.0005; if peak power is 1 MW, average power is 500 W.

The radar's ability to distinguish objects at different ranges depends very much on pulse width (pulse duration) and on PRF. Because a radar measures distance by measuring the time between sending and receiving a pulse, it cannot distinguish a distant echo, returned after the next pulse has been sent, from a close-in echo, returned soon after that next pulse has gone out. Because of this second-time-around (STA) problem, unambiguous or maximum radar range is commonly equated to half the time interval between pulses, i.e., to the inverse of the PRF. This is not the same as the range the radar will actually achieve on a given target, but it is often the figure listed as radar range. Since the radar designer maximizes the probability of detection by maximizing PRF, a designer will generally try (but possibly fail) to match PRF-range with a realistic range on the target of greatest concern.

Some radars eliminate many STA echoes by jittering the PRF around an average value. The apparent range of STA echoes will vary with PRF. Thus, such echoes can easily be eliminated. Jittering cannot, however, eliminate the STA echoes of large objects, such as land masses. So PRF remains a measure of effective range.

Radar signals travel at about 186,000 miles/sec (about 162,000 nm/sec, or 300,000 km/sec), so the unambiguous range for a 1000-pps radar is about 81 nm (162 nm between pulses, for a pulse to go out and return). Thus 2000 pps corresponds to about 40 nm, and 500 pps to about 162 nm.

There is 1 important exception to this idea. Pulse-doppler radars use very high PRFs and typically detect targets at ranges considerably beyond their unambiguous range (because actual detection range depends on the average power sent out, i.e., on the product of peak power, pulse width, and PRF). In effect, pulse-doppler radars compromise between operating at a pure frequency (i.e., in a continuous wave, CW, mode) and pulsing. They use variations in the frequency of the target echoes to measure target velocity.

Just as a pulse radar can be limited in its unambiguous range, a pulse-doppler radar is limited in its range of unambiguous velocities. The radar signal is a mixture of pure signals of different frequencies spaced around the nominal radar frequency; each such subsignal is doppler-shifted by the velocity of the target toward or away from the radar (radial velocity). The shift in frequency is given by target radial velocity as a fraction of the speed of light. The different subsignals are separated in frequency by the PRF of the radar. Just as the radar cannot distinguish echoes that return after the next signal has been sent (i.e., whose delay times exceed the pulse repetition interval), a pulse-doppler radar cannot recognize velocities whose doppler shifts exceed the PRF. For example, a velocity of 1000 km/hour (620 mph, 540 kt) shifts an X-band signal (10,000 MHz) by about 9200 Hz. Typically the first speed that cannot be distinguished is called the first blind speed. These considerations explain why

doppler radars often use extremely high PRFs, e.g., 20 kHz (corresponding to an unambiguous range of only 4 nm).

The higher the PRF, the worse the associated ambiguity in pulse range. High-PRF radars typically measure range by varying their carrier (radio) frequency with time, associating a particular range with a particular frequency. For example, frequency can rise up to a maximum, then fall back to the initial frequency. The frequency shift associated with range is mixed with the frequency shift associated with target doppler, and the radar must sort between them. One solution is to insert a constant-frequency segment at the end of each period of changing frequency; the frequency shift of this segment is the target doppler shift. Another is to vary frequency smoothly up and then down. The target doppler adds to the rising frequency on one half cycle and subtracts on the other. This scheme also uses a flat (constant-frequency) segment to measure target doppler.

Doppler data may be important in itself if the radar is being used to predict target motion. It is also the most important means by which the radar distinguishes among multiple targets. Given measurements of the target dopplers, the radar can associate the appropriate rising and falling frequency segments for the different radars (de-ghosting). Since a target must be detected on all 3 segments of the frequency cycle, maximum detection range is shorter than in the pure-doppler case. Fighter radars, therefore, generally have a separate velocity-search mode, operating at a pure high PRF. They can switch to a range-while-search (FM-ranging) mode.

Some fighter radars, such as the AWG-9 of the F-14 Tomcat, have an additional raid-counting mode. Beyond some particular range, several aircraft will fit within each radar resolution cell. Raid counting protects a fighter from locking on to the raid as a whole and, hence, losing the ability to deal with any particular airplane before it is too late. Between search scans, the radar spotlights (scans narrowly) the radar target(s) representing the raid for precise doppler measurement. Several aircraft flying together will have slightly different doppler shifts, and the spread in the radar return is measurable. A multiple-aircraft symbol appears on the display. As the range closes, and the target covers a larger angle, the radar automatically widens the spotlight scan.

FM-range accuracy is limited by the precision with which the frequency of the returned signal can be measured, i.e., by the width of the filters (real or mathematical) making up the doppler filter bank; that width in turn is limited by the integration time, the length of time during which frequency ramps up or down (this time interval is also a measure of maximum unambiguous range). The total extent of frequency change is limited by the requirement that the lowest-doppler targets be distinguishable from clutter. All of these considerations greatly limit the accuracy of FM ranging for a high-PRF (doppler) radar.

High PRF is attractive partly because it can give a high probability of target detection even at a relatively low peak power. (Radar detection is a cumulative process, each pulse having some probability of being picked up, so detection depends on average power, not peak power, and average power can mean many relatively weak pulses per second.) Since counterdetection generally depends on the strength of the particular pulse picked up by the target's radar detector, the high-PRF/low-peak power solution may amount to a somewhat stealthy radar.

Anywhere near the ground an airborne radar will pick up the echo of its sidelobes (and, in cases in which the radar points down, its main lobes). Suppression of this clutter becomes a major radar design objective, particularly for radars intended to operate over land (which scatters much more of the signal back toward the radar; the sea tends to scatter the signal forward, away from the radar). Because the main lobe looks toward the ground, it encounters very strong STA echoes, which can entirely overshadow the echo from a target. The target echo can, however, be separated out by means of its doppler shift, since the ground (as seen by the airborne radar) may have a very different doppler shift, reflecting its very different velocity.

The ground will reflect a variety of radar lobes, both main

and side. For a radar pointing down at a shallow angle, the sidelobes all see the ground at relatively short range. The main lobe sees the ground at a much greater range, closer to the range of any potential target. Thus a radar giving unambiguous range information (i.e., at low PRF) can exclude much sidelobe clutter by avoiding short-range targets, but the radar may not easily distinguish the strong echo of the main lobe from a real but very low flying target (this distinction depends on pulse width, i.e., range resolution).

The alternative is to use relative doppler shifts. The sidelobes, striking the ground at different angles, give different radial-velocity components, corresponding to a range of doppler shifts, from very low frequency (associated with the lobes pointing almost directly at the ground) up to the main lobe, whose image of the ground may show a shift corresponding to a large fraction of the airplane's speed over the ground. The shift will be strong but relatively narrow in frequency. The sidelobe clutter will be weaker, but it will extend over a very wide range of frequencies, corresponding to everything between 0 and the actual velocity of the airplane over the ground.

An airplane flying nose-on toward the radar will have a very high relative velocity and a large corresponding doppler shift, well away from the shifts of the ground clutter. The plane can, therefore, be detected at long range. On the other hand, an airplane flying away will have a very small relative velocity, hence a small doppler shift, and that plane may be swallowed in the ground clutter. Modern fighter radars typically operate at very high PRFs (often hundreds of kHz) so that they can effectively and unambiguously detect nose-on (closing) targets. At very high PRFs, it is difficult to resolve range ambiguity, and available methods reduce the detection range. For this reason, for example, the longest-range mode of the AWG-9 radar (used to control the Phoenix missile) is velocity, i.e., doppler search.

A medium-PRF mode is often available as a compromise to permit detection of tail-aspect (low-relative velocity) targets. Both range and doppler are ambiguous. The strong main lobe peaks in frequency are far enough from one another (because the PRF is great enough to keep the signal components well part) that target signals can be distinguished. On the other hand, there is still enough range precision to separate the close-in sidelobe clutter. Range measurement in general is easier than with high PRFs. Both high- and low-speed targets still have to compete with sidelobe clutter.

The doppler blind zones are eliminated by shifting among several quite different PRFs, each maintained for a brief period. Such switching limits maximum range because there is never very much time to integrate over numerous pulses. One common scheme is 3:8, the cycle consisting of 8 PRFs covering overlapping doppler ranges, any 3 of which must be clear for detection. An earlier alternative is to use 3 widely separated "major" PRFs. Each is flanked by 2 "minor" PRFs. Range ambiguity is avoided by switching from the major PRF to the 2 minor ones in succession (one for resolution, the other to eliminate ghosts). The problem is that because the minors are close to the major, their blind zones may be adjacent. Using a cycle of widely spaced PRFs (without minors) eliminates the problem.

Most shipboard radars exemplify the low-PRF case, and the big airborne early-warning radars also employ low PRFs, for long unambiguous range. Fighters generally use high-PRF transmitters that can switch to medium PRF. Radars for close-in weapons such as Phalanx are generally high-PRF pulse-doppler types.

Pulse width determines resolution, the ability to distinguish between 2 targets that are close together. Radar signals travel at about 300,000 km/sec, so a pulse length of 1 microsec corresponds to a distance of about 300 m. Resolution is generally slightly greater than the length associated with 1 pulse length, since the radar cannot quite distinguish 2 pulses end-to-end.

Waveguides and other radar components can carry only a limited amount of energy. If that limit is exceeded, they break down. For example, an overloaded coaxial or waveguide may arc (spark), so that no signal at all is transmitted. Since radar range

depends on average power rather than on peak power, 1 alternative is to spread that power over a pulse varying in frequency (a chirp). The returned echo can be compressed ("pulse-compressed") into the equivalent of a very energetic short pulse. Pulse coding is another approach to the same problem. Different portions of the extended pulse are differentiated, e.g., by polarization. The resulting pulse bears, in effect, a coded signature that can be distinguished from the surrounding noise. In either pulse compression or pulse coding, the key is that the radar can distinguish between different parts of the long returning pulse, so that it can be made equivalent to a much shorter pulse.

Pulse compression or coding has another advantage: stealth. A pulse-compression radar spreads its energy over a series of frequencies, using a short pulse in each. Although total average energy may be considerable, there may be relatively little peak energy in any one pulse; therefore, a countermeasures receiver may find such pulses difficult to detect. The longer the train of pulses, the lower the peak power (for a given average power, i.e., for a given detection range). Recent pulse compression radars with very low peak power, such as the new Canadian SPS-503 and the French DRBV 26C, are designed specifically for low probability of intercept. Ultimately the pulse train (extending across different frequencies) could occupy nearly all the time between initial pulses. Such a radar could be described as frequency-modulated continuous wave (FMCW) or as spread-spectrum (for low probability of intercept), and the only current public example is PILOT (see Sweden in the Antiaircraft Warfare section).

Radar beam dimensions are horizontal $\times$ vertical; the horizontal dimension measures how accurately the radar can locate a target in bearing without concentrating on that particular target (e.g., by beam switching or monopulse techniques). Antenna dimensions are, similarly, width $\times$ height. Scan rate or data rate is the rate at which the antenna spins and, therefore, the rate at which data about the location of any particular target are renewed. The faster the scan, the higher the target speed with which the radar can cope. On the other hand, the faster the scan, the shorter the time during which the radar dwells (stares) at any particular target and, therefore, the lower the probability that a target will be detected.

Typically, a distinction is drawn between search and tracking radars. A search radar scans continuously. A pure tracking radar follows a particular target, using some technique of beam switching or beam comparison (e.g., monopulse) to detect target motion. Any scheme for associating successive target locations (as detected by a search radar) to establish an approximate target track blurs this distinction. The quicker the scan, the more accurate the track. Very quick scanning radars with the appropriate associated memory are, therefore, described as track-while-scan (TWS) radars. As more and more search radars are associated with computers for automatic detection and tracking (ADT), and as more information is extracted from radar echoes, TWS operation is becoming more universal.

Some further points deserve brief mention here. Radar tracking generally requires the radar to compare several beam positions, i.e., to measure when it is off the correct direction. One method is conical scanning (conscan), in which the beam spins. Each position of the spinning beam is somewhat off the proper radar direction, but the beam is symmetrical about the direction at which the radar antenna is pointed. Thus, if the radar return is constant while the beam spins, the radar is pointing right at the target. If 1 beam position shows a higher return, then the radar is pointing off, and the point in the scanning cycle at which the return is greatest can be used to show the appropriate correction. The 2D equivalent of conscan is a nodding radar, pointing its beam alternatively to left and right (or above and below) the target. Conscan is simple to design, but it is subject to a relatively simple countermeasure. If a strong signal is sent back out of sequence, the tracker may pick it up in a sidelobe. In this way a jammer mounted on the target can appear to the tracker to be well off to one side; it can capture the tracker and

lead it astray. This technique is called angle-stealing or angle-gate pull-off.

The usual counter is monopulse, a technique in which the radar continuously and simultaneously puts out multiple beams, continuously comparing their signals. Since there is no cycle associated with this sampling, there is no way that a point jammer can insert a deceptive signal out of sequence. The tracker can be led astray only by signals from several distinct sources, separated in location, a technique called "cross-eye."

Three current technical developments deserve brief mention here. One is the rise of solid-state transmitters (see, for example, the French DRBV 26C, the British AWS-7, and the U.S. SPS-40). This trend is distinct from the much earlier movement from vacuum-tube to solid-state technology for radar control and data processing. That left one big vacuum tube, the radar transmitter, which had to be cooled and protected. Now solid-state transmitters are powerful enough to be used, in combination, in place of the tubes. The solid-state transmitters are more reliable; they require less power (and emit less heat); and they cannot burst. Moreover, since numerous transmitters are used together, the failure of any one of them does not put the entire radar out of action. For the U.S. Navy, the first major solid-state transmitter is that replacing a klystron in some SPS-40 radars. This transmitter is expected to achieve a mean time between failure (MTBF) of 10,000 hr, and it will probably be followed by an SPS-49 solid-state transmitter. The SPS-40 unit uses 112 2500-W modules, each of which uses eight 400-W peak-power transistors working in parallel.

A second major technical development is the appearance of better and less expensive means of electronic beam forming and movement. In the past, phase shifters were expensive and unreliable, and many electronically scanned radars used frequency-scanning (in one dimension) instead. That method was effective, but it limited the extent to which a radar could hop among frequency bands, since the angle of elevation of the radar beam depended entirely on the wavelength of the signal. Now phase shifters are much less expensive, and newer radars tend to employ them rather than the older technology of frequency-scanning. The next step is the active-array radar, in which the elements of the antenna themselves transmit the signal. There would then be no need to apply a phase shift to a signal produced by a separate unitary transmitter. The new Japanese OPS-24 is the first active-array radar to have entered operational service (see the Addendum).

A third development is software-controlled transmission. In most radars, pulse characteristics are determined by hard wiring. They are extremely difficult to change. There may be special wartime operating characteristics, but they, too, are hard-wired; and even when compromised, they cannot easily be changed. However, a number of current airborne radars, such as APG-65, are software controlled, so that their signal characteristics are quite easily changed. This ability will potentially allow the system to counter current methods of radar recognition by pulse analysis. It may still be possible to recognize a radar by the detailed structure of its pulses, but that type of recognition is several orders of magnitude more difficult.

The major types of radar scope in current use are:

A-scope Range vs. signal strength, with range measured horizontally. This was the first type of radar display. The great remaining advantage of the A-scope is that jamming can more easily be distinguished from a real signal, both appearing as spikes.

A/R-scope Precision A-scope, typically for fire control. A precision sweep is a magnified version of the main sweep, its range notch corresponding to a range step on the main sweep. The range step can be moved to the target. When the range notch of the precision sweep is on the target, the target range is gated for tracking.

B-scope Range vs. bearing, distorted so that all signals at a given

bearing are in 1 vertical line. This reduces the spread of signals at long range and is often used for gunfire control.

PPI Plan position indicator, the classic maplike radar display. Usually the ship or airplane is at the center, but PPIs can be off centered. A PPI is, in effect, a rotating A-scope in which the spikes of the former are replaced by brightening on the face of a CRT.

RHI Range-height indicator, in effect a PPI showing range and altitude instead of range and bearing. It is the natural display for 3D radars.

OPTRONICS AND INFRARED DEVICES (PHOTONICS)

An increasing number of naval sensors operate passively, either in the visible band (optronics) or in the infrared. Optronics is the combination of optics and electronics, as in a television; optronic devices are sometimes also called electro-optical (EO) for the means by which they convert light signals into usable electronic ones. Optical and infrared technology have enough in common to be treated together, although there are important differences. Since both optronics and IR generally involve the detection of photons (which produce electrical signals by knocking electrons from one energy level to another), optronic and IR devices are sometimes lumped together under the heading photonics, as in the coming generation of submarine masts.

An optical device detects radiation, reflected from an object. Generally that radiation is sunlight, although there is an important class of image-intensifiers that provide passive night vision based on reflected starlight or moonlight. Typical wavelengths are about 0.4–1.1 microns (commonly 0.7–0.95 microns).

Unlike an optical device, an IR detector is concerned mainly with heat radiated by an object, such as the hot plume of exhaust gas, aerodynamically generated heat, or even a person's body heat. IR technology includes both seekers (as in air-to-air missiles such as Sidewinder) and thermal (night) imagers, the latter working on much smaller signal-to-noise ratios (i.e., on much smaller differences between target temperature and background temperature). All objects hotter than their surroundings emit some heat, and the wavelength at which the maximum radiation is emitted varies with the temperature: the hotter the object, the shorter the wavelength. The shape of the curve of emissions also changes, so that the ratio of the strength of emission at one wavelength to that at another will also change. The farther apart the 2 readings, the more drastic the change in their ratio as the temperature changes. The emitted spectrum generally contains a line structure characteristic of the object, but this structure is generally too complex to be used operationally.

There are 2 classes of IR detectors, cooled and uncooled. The cooled detectors respond to individual photons striking them; cooling is necessary to reduce the amount of extraneous activity. Most current missile seekers and imagers fall into this category. There are also uncooled detectors, generally measuring the heat difference between an object and its surroundings (pyroelectronics). At present they are used primarily in short-range low-resolution devices, such as the detectors firefighters sometimes use to search rubble for survivors. For the future, however, they are attractive because they can operate without bulky cooling systems. Moreover, since they need not wait until they cool to operational temperatures, they can (at least in theory) be used in faster-reacting missiles. The distinction between cooled and uncooled is not altogether precise, however, since even uncooled detectors of standard types can often function to some extent against hot enough sources, such as jet engines.

Current imagers, which work against relatively cool heat sources, must be cooled to well below ambient temperature. Their technology, then, includes not only that of the detector and related signal processor, but also the cooling mechanism. In air-to-air missiles such as Sidewinder, the cooling source may be a bottle of liquid gas that cools by expansion; in

many optronic/IR detectors, the mechanism is a closed-cycle refrigerator.

IR radiation is defined as wavelengths too long to be visible, i.e., from 0.8 or 0.9 microns up. IR devices operate in a few "windows" through which radiation easily passes: 1.5–1.8, 2.1–2.4, 3–5, and 8–14 microns. The last 2 are the most commonly used in military and naval systems. The different windows are sometimes called different IR "colors," so that a 2-color IR device generally works at both the 3–5- and 8–14-micron bands. Typically the 3–5-micron range is defined as mid-IR (MIR), and the 8–14-micron band as LWIR (long-wave IR). The hotter the source, the shorter the wavelength at which it provides maximum radiation. Thus devices intended to detect very hot objects, such as jet engines and active guns, often operate in the mid-IR; they include missile seekers. Imagers intended to detect cooler sources operate best in the LWIR region, although many operate in both bands.

Compared to radar, photonic devices suffer much more severe weather limitations. Generally they cannot penetrate clouds or rain, although IR signals will penetrate haze better than visible light. Variations in temperature and water vapor in the atmosphere will tend to bend both visible light and IR radiation. Generally longer-wave IR will suffer less than shorter wave in haze and fog. Some typical transmission factors are

Visible Light	3–5 Microns	8–12 Microns
1.00 (no fog)	1.0	1.0
0.5 (fog)	0.87	0.97
0.10	0.36	0.66
0.01	0.01	0.22

That is, when only 1% of the light is penetrating, 22% of the LWIR radiation is still available.

Typical IR detectors are lead sulfide (1–3 microns), indium antimonide (3–5.5 microns), mercury-doped germanium (8–13 microns), and mercury cadmium telluride (2–14 microns; photoconductive at shorter wavelengths and photovoltaic and photoconductive at longer ones). Lead sulfide cuts off at about 3 microns when uncooled and at 4 microns when cooled. Indium antimonide does not extend its range when cooled but does become more sensitive. For shorter wavelengths, silicon is effective at 0.4–1.2 microns. Television cameras typically use antimony sulfide (0.4–0.7 micron).

A jet pipe radiates most strongly at 3.75 microns, and early air-to-air missiles homed on this radiation. Because an airplane's jet pipe is visible only within about 30 deg of dead astern, violent maneuvers often sufficed to break the locks of such missiles. The hot plume of exhaust gas radiates most strongly at 3 microns (carbon dioxide) and at 4.2 microns (water vapor), and extension of the seeker to these wavelengths greatly enlarges the area astern within which a missile seeker can operate. This is still a signature visible largely from astern, although someIRSTs (such as the French VAMPIR) can detect the rising plume of a missile exhaust from ahead. A fast airplane or missile is heated aerodynamically, and its skin will glow in the infrared; it can, therefore, be detected from ahead. A supersonic target, flying at Mach 1.25 at low altitude, will radiate most strongly in the 8.6-micron range, although some radiation will spill over into the upper end of the 3–5-micron range. The figures above show why indium antimonide was so much more effective than lead sulfide, since it could detect not only a hot jet pipe and exhaust radiation, but also the shorter-wavelength radiation from aerodynamic heating.

Aerodynamic heating is not the only source of forward-aspect IR detection. Sunlight will glint off glass and even aircraft structure, and the IR portion of this glint can be detected.

Thermal imagers will generally have to detect relatively cool heat sources, all of which will radiate at relatively long wavelengths. Typically they will detect temperature differences as small as 0.1°C, and differences of about 10°C will be detectable at ranges as great as 10–20 km. In contrast, a missile seeker

will be looking at hot tailpipes, with temperatures of hundreds of degrees, and even an aerodynamically heated wing leading edge may be 65°C hotter than its surroundings.

Devices divide into point detectors for tracking (such as the seekers of most air-to-air missiles) and imagers, such as television cameras. A point or spot tracker cannot distinguish different IR sources (of the same character) within its field of view; thus, it is vulnerable to flare countermeasures. The simplest counter-countermeasure is to examine the characteristics of the detected target, e.g., to compare its image in 2 different wavelengths so as to measure its apparent temperature. That comparison may be done in 2 portions of the same color (2 shades) or in 2 colors (which generally requires 2 separate detectors). Such processing greatly complicates the design of an IR decoy, since the decoy generally relies on sheer power (often generated at a temperature quite different from that of the target) to provide sufficient brightness. Two-shade or 2-color processing will also make it easier for a seeker to distinguish the sun from an appropriate target.

Generally a reticle, a series of openings in an otherwise opaque screen, is spun in front of a point detector. The reticle defines a beam pointing slightly off the missile axis, and the overall effect is much like that of a conically scanning radar. If the missile is pointing directly at the heat source, the signal does not vary with time, since the spinning beam always intersects the source in the same way. Otherwise, the signal strength varies as the reticle spins, and the variation is used to generate the correction signals that point the missile (or, more precisely, the tracker) at the target. Because the tracker associates a particular direction with a particular point in the scanning cycle, it is vulnerable to countermeasures in which the apparent target signature is flashed; it can mistake the flashing signature for time variation due to its own scanning.

Rosette scanners reduce this vulnerability by adopting a more complex scanning pattern, in which the scanned point covers more of the available area. It swings back and forth as well as in a circular path. A spiral scan is a simpler variation on this theme. Alternatively, the reticle can spin off-center to produce a signal whose frequency varies over time. In each case, because the association of direction with time is no longer simple, a simple flashing signal will no longer necessarily convey directional information, and thus will no longer serve to throw off the missile seeker. This immunity to countermeasures is purchased at the cost of greater complexity in the missile scanner; some arrangement of prisms and mirrors must replace the simple reticle of the circular-scanning seeker.

The alternative to a scanning seeker is a staring seeker, consisting of an array of point detectors. Such an array might be considered broadly equivalent to monopulse, as opposed to conical-scanning operation, with the same immunity to a time-varying countermeasure. Such detectors are sometimes described as offering IIR performance.

Imagers generally form their product by sampling the brightness, either in the optical or in the IR spectrum, of an image formed by one or more lenses. In a standard television camera, the image is formed on a plate inside the imaging tube, and this plate is electronically scanned; tube output voltage is proportional to the brightness of the portion of the plate hit by the scanning electron beam.

Alternatively, the pickup device may be a CCD (charge-coupled device), a matrix of photosensitive sites on the surface of a solid-state device. The electric charge at each site is proportional to the amount of light (the number of photons) striking it; a typical silicon device will respond to wavelengths 0.4–1.1 microns, with peak response at 0.7–0.8 microns. The charge at each site is turned into an electrical signal, and thus the image focused on the CCD array can be read out electronically (the individual charges are read out in sequence, just as the electron beam reads the image off a photocathode). Depending on the material of which it is made and the character of the array elements, a CCD array can be designed to function either in the visible or in the IR spectrum; the CCD camera is a focal-plane

array device. A CCD array can be considerably more sensitive than a conventional video tube, and thus a camera incorporating it can function at low light levels.

The conventional television detector is a fully analog device, in the sense that the position of the sampling electron beam will vary continuously over the width of the plate in the tube. The CCD imposes some quantization, since each diode is separate.

In a television camera, the electron beam scans horizontally across the image to form a line, and the lines are displaced (rastered) vertically down the image to form a complete frame. Resolution is measured by the number of lines per frame. Although picture brightness will vary continuously along each line, the system is generally arranged so that resolution is the same vertically and horizontally. Picture shape is defined by aspect ratio (or one might say that the appropriate aspect ratio is the one for which horizontal resolution matches vertical resolution). For example, the standard U.S. television frame employs 525 lines, and the aspect ratio is 4:3; it follows that each line consists of 700 picture elements ($\frac{4}{3}$ times the number of lines). The entire scene is represented by a total of 367,500 pixels. The television displays 30 such pictures (frames) each second. Just as in radar, this type of sequential scanning defines a data rate that determines just how well the television can detect rapid motion, in this case rapid angular motion.

A television-type sequential or serial scanner splits its image into a series of lines, so that picture elements that are close together vertically will be far apart in time. It is, therefore, much easier for the system to compare elements close together horizontally, since they lie along the same scanning line.

Low-light-level television (LLTV) interposes some form of light intensification between the optics and the viewing screen. In the simplest such devices, starlight scopes, the incident light falls on a photocathode, which releases electrons. These electrons can then be processed to produce a stronger signal. Vietnam-era starlight scopes used very large voltages, typically 10 or 30 kV, to accelerate electrons given off by the photocathode. The electrons in turn struck a phosphor screen, which glowed. Such voltages required bulky equipment and large power supplies. In particular, Vietnam-era starlight-scope technology would not be suitable for NVGs, which are now common on board airplanes and helicopters.

The key to compactness is an electron multiplier, a micro-channel plate (MCP). The initial electrons are accelerated over a short distance via an electrostatic lens. The MCP is an array of glass capillaries (channels) down which electrons are accelerated. They collide with the channel walls, which are coated with secondary electron emissive material. As in the original starlight scopes, these electrons in turn are used to produce a brighter secondary image, typically on a phosphor screen that glows when it is struck by electrons. The MCP does not distort the form of the image, and the entire device can be quite compact. In a typical modern set of aviator's NVGs, the accelerating voltage is 1–3 kV, the typical light gain is 30,000, and the spectral response is over the 0.3–0.91-micron band, covering the ultraviolet to the near infrared. Distortion is about 7%, and magnification is close to 1, i.e., the final image is very nearly the same as an image of the scene in natural light. The same technology can create an electrical signal corresponding to the amplified image, and this signal in turn can be displayed on a television screen.

MCP devices are considered second and third generation light intensifiers, the difference being the use of gallium arsenide photocathodes in the third generation, replacing tri-alkali materials such as sodium potassium cesium antimonide. The new material increases electron emission, for a given light level, by a factor of about 10. These materials also differ in their response to different wavelengths of light. A second-generation tube is most sensitive at 0.5 micron, but a third-generation tube works at 0.6–0.9 micron, so that its range extends well into the near infrared. That extension is useful because the night sky provides much of its illumination in the near-infrared region (the day sky

is lit mainly in the visible range). Thus the third-generation tube not only makes better use of what it receives, it also receives much more energy in the first place. Third-generation tubes first appeared in the 1970s.

In each case, the initial very weak image is converted into electrons, which are then amplified either by acceleration (which makes the individual electron more energetic) or by a combination of some acceleration and multiplication; the electrons are then used to create a secondary image on a phosphor screen.

There are three kinds of LLLTV. One uses a starlight scope as the input to a conventional television image tube. Another uses a CCD as its imager, since a CCD can be much more sensitive than a conventional video tube. Finally, the combination of a starlight scope image intensifier and a CCD detector can provide an image under conditions of very low light.

There is no IR equivalent of the television electron-beam imaging tube. Instead, an imager will generally use a rapidly rotating (5–10,000 rpm) mirror, whose sides are at slightly different angles, to break up the image in the focal plane, illuminating one or more detectors at a time. Until about 1960 there were only single-element detectors, so scanning always had to be 2D, one mirror scanning in each direction. By the early 1960s there were linear arrays, which were characteristic of Vietnam-era FLIRs. 2D arrays of discrete detectors appeared in the late 1970s.

A typical imager uses multiple detectors, across which the image of the scene may be scanned. For example, a FLIR imager typically uses a vertical array of detectors, which scan across the scene. Unlike a television, a FLIR produces all of the lines across the scene simultaneously. They are multiplexed to produce lines in sequence for television viewing. Since it generally cannot accommodate as many detectors as a standard television provides lines, the FLIR image will often not be of television quality. In some cases, even though the detecting array is linear, scanning is not only horizontal but also vertical, so that a smaller and lighter array can still cover a wide field of view.

The U.S. common module FLIR uses 180 detectors in its vertical linear array, scanning across 480 pixels horizontally. Two horizontal scans are interlaced, so that in effect there are 360 vertical positions. The sampling rate per channel is $480 \text{ pixels} \times 30 \text{ Hz (frames/sec)} \times 2 \text{ (interlacing)}$, for a total of 29 kHz. An equivalent serial scanner would scan at a rate of 5.2 MHz because the head would have to cover all 360 vertical positions as well as the 480 pixels; the associated mirror system would have to scan at more than 60,000 rpm. The same performance could also be achieved by a hybrid device, with several detectors in both the serial (horizontal) and parallel (vertical) directions; in this case scanning would be slower, and the use of several detectors in the horizontal direction would improve the signal-to-noise ratio.

There are also 60- and 120-element U.S. common module detectors (DT-591 and -594), both operating in the 7.7–11.75-micron band. Hughes produces a standard 160-element parallel-scanning FLIR module.

Current naval aircraft common module FLIR systems are AAQ-16 for the V-22, AAR-50 for the F/A-18 (navigational FLIR), AAS-36 in the P-3, AAS-38 in the F/A-18, and OR-263/AA in the S-3.

Many British systems use TICM (thermal-imaging common modules), which are serial scanners using SPRITE (signal processing in the element) detectors. SPRITE is a linear array that is mathematically equivalent to a point detector: the output of each element is added up, with an appropriate time delay, for a net improvement in signal-to-noise ratio. A vertical array of SPRITEs would be equivalent to the arrays in current U.S. FLIRs, scanning a scene in parallel. TICM was first proposed in the mid-1970s and thus represents a later technology than the U.S. common modules. Class I is a man-portable direct-viewing system made by Thorn-EMI; Class II is a mid-performance module, made by GEC-Marconi (which defeated Barr & Stroud). The Class II TICM is to be used on board U.S. AV-8B Harrier IIs.

FLIR is sometimes distinguished from DLIR (downward-look-

ing IR), a line-scan device used for reconnaissance. A DLIR scans a few IR detectors across an airplane's line of sight, using the forward motion of the airplane to provide the other scanning direction. The resulting images are recorded either on film or on magnetic tape. As in the somewhat analogous case of airborne synthetic-aperture radar, the image is viewed on the ground, but a slightly time-late version can be displayed in the air.

Both FLIRs and DLIRs first entered service during the Vietnam War, where they were important sensors. Both were means of viewing a scene in reduced illumination, and both therefore competed with, and complemented, light intensification devices.

Post-Vietnam developments were generally in detector sensitivity. In many modern systems the individual detectors of the vertical array are replaced by linear arrays. The individual elements of such a subarray see the scene one at a time, and their outputs can be integrated (using suitable time delays) to produce a better and less noisy result.

The ultimate detector development is a staring array (focal-plane array) on which the image is focused. The image is self-scanned, i.e., its subelements are sampled electronically. No mirror is needed, and the system is physically very stable, so that signals can be integrated over a long time to eliminate noise. Such a system may, therefore, be able to operate without much cooling. However, the staring array will rarely be able to cover a very wide area (field of regard) at a reasonable level of resolution. Typically its designer will have to accept either limited resolution or else some mechanical means of stepping to scan over a wider area. In the latter case, the staring array is, in effect, a better version of the linear detector already described. Since the array itself is stepped, it cannot move very quickly, and frame time may be lengthy. Scanning systems tend to be best for wide field coverage; staring systems provide more sensitivity.

Because the array stares continuously at a scene, it can easily register change from frame to frame. If the array stares continuously at the scene, then in theory elements of the scene can be read off in any desired order. Elements that are close together in the scene are also close together in any electronic representation of the scene taken from the array.

A focal-plane array is a 2D detector array on a single chip, with the preprocessor integrated into the same chip. Analog outputs are multiplexed, so that there is a single output into the analog-to-digital converter. This output is equivalent to the output of the imaging tube of a television. The alternative is a series of discrete detectors, each feeding into an analog-to-digital converter and multiplexer. The effect of the large number of elements of the focal-plane array is to improve field coverage; their small size makes for better resolution and better signal-to-noise ratio; and on-chip processing makes for less noise and also for faster readout. Typically the scanning (multiplexing) algorithm is built into the processing chip, so scanning within the array is always sequential. Such arrays can be arranged to stare at a scene, or they can be used as elements scanned across an image. A typical current chip accommodates as many as 512×512 individual detectors in a 12-mm square, 16 mm thick. Individual detector elements are tens of microns across.

Signal processing in the focal-plane array is a development of the mid- to late-1980s. At present the U.S. DoD is seeking the development of large inexpensive focal-plane arrays using mercury cadmium telluride, platinum silicide, and extrinsic silicon detectors. The goal is to match the cost and capability of current television CCD focal-plane arrays; the projects include on-chip preamplification and multiplexing.

Work is also proceeding on better uncooled detectors. In 1986 Plessey displayed a lightweight 64-element linear array of pyroelectric detectors; the company offered a 128-element array, suitable for use in a FLIR. At this time it also offered a 16×16 -element staring array and expected a 64×64 -element array, with sufficient resolution for its operator to recognize a tank, to be ready for production in 1990. The company expected

to have a 256×256 array, sufficient for an air-to-air missile, in 1992. By 1995 Plessey hoped to be able to duplicate TICM II performance with pyroelectric detectors.

The great current challenge is to manufacture focal-plane arrays at low prices. In 1990 a 64×64 -element indium antimonide array cost about \$50,000 (in FY86 dollars, the cost per pixel is about \$10). This price is far too high to realize the potential advantages of focal-plane arrays in tactical weapons. In 1986, for example, a DoD estimate showed a need for more than 340,000 64×64 -element arrays between 1991 and 1996, which in turn would cost about \$17 billion. A producibility program, the Infrared Focal-Plane-Array Initiative, was, therefore, proposed (and funded by Congress in 1989); its goal is to reduce the cost per pixel to 10¢, i.e., to 1% of the 1986 figure. The companies involved are Rockwell, Hughes, and Fairchild, and the materials are indium antimonide, mercury cadmium telluride, and platinum silicide. Foreign equivalents to this initiative include the French SOFRADIR (primarily for a new antitank missile, Trigat) and a Japanese program.

Two other important developments should be mentioned. One was the discovery that a tracking circuit could be applied to a television image. If some part of the image could be defined clearly enough, then the tracker could keep pointing the camera at it and thus could guide a missile or a fire-control system. This development applies to daylight television, LLLTV, and also to thermal imagers. It was the basis of Vietnam-era electro-optical "smart bombs" such as Walleye and their successors.

The other discovery was that appropriate circuitry or software could be made to notice important features in a television scene, alert operators to their presence, and then track them. This development is the basis ofIRST devices, such as the French VAMPIR and the Canadian-U.S. SAR-8. AnIRST scans a scene, for example, turning through 360 deg, and searches for particular features.

In both cases, signal processing and image recognition are necessarily relatively primitive. The most obvious criterion for object recognition is relative contrast, which shows up as a sudden change in signal strength pixel to pixel, or from one portion of a scanning line to another. In each case, the primary operation in tracking is comparison of the image from frame to frame.

Contrast trackers typically follow the centroid of a dark area or an edge. In centroid tracking, an area of the overall scene is defined by gates above and below and to either side. The tracker breaks the gated area into quadrants, calculating the total intensity of each. The intensity is treated like the output of one channel of a monopulse seeker, the tracker pointing toward the most intense quadrant. An edge tracker is a variation on this theme: the edge is detected and then tracked by centroid techniques.

The other, more sophisticated option is correlation tracking. If a sufficiently varied area of the television image is chosen, then the tracker can compare the complex profile of that area with alternative areas on the next frame. In many cases, the human operator points the seeker or tracker at the target by enclosing the area to be tracked within gates; the gates define the area of the next frame that must be searched.

Each of these techniques has its advantages and disadvantages. Spot or centroid tracking is simple, although it may become confused if the target passes near some alternative dark object. Edge tracking is simple, and an edge will not change very rapidly as the missile approaches its target and the scale changes. On the other hand, the missile may tend to slide down the edge and onto another dark object should the target merge with any alternative target. High-contrast spots and lines are the easiest objects to recognize and are, presumably, often the basis for missile detection inIRSTs. Both centroid and edge tracking are most effective against extended targets. Centroid tracking is only fair against point targets (it is easy to confuse because it calculates a centroid over a wide area), and edge tracking is useless in such cases (a point target has no discernible edge).

Correlation tracking is potentially far more stable than the

other alternatives, since the signal being tracked contains much more information and, thus, is much more difficult to swamp in optical noise (i.e., in false targets). However, correlation also often (though not necessarily) involves much more processing than edge or spot tracking. Typically a correlation target must be inserted by a human operator. However, the search function of anIRST is in some ways a correlation function since theIRST is always comparing the contents of its search area with the contents seen on the previous scan. Correlation tracking is a special case of contour matching.

The tracking techniques can be realized using fairly simple analog circuits, by comparing the lines within the gates of one frame with the corresponding lines of the next. Overall target location would be determined by averaging out the target location given by each line. Such operation avoids processing the picture pixel by pixel, but it also precludes any recognition of the target as an entity since the lines must be handled separately and sequentially.

Signal processing can, of course, be much more elaborate on a pixel-by-pixel basis. There now exist computer programs for limited image recognition by shape. Images may also be classified, at least tentatively, by their measured temperature (apparent color), their apparent size, and their measured speed. Because the image is very rich in detail, any substantial processing entails very great computing power. The numbers are much like those encountered in television: a signal rate of 5 million pixels/sec might well be encountered. The processor would form images based on whether each of those pixels was above or below some selected threshold, and thus it would have to examine each one every second. Threshold crossings must be correlated from pixel to pixel to decide whether individual pixels were isolated points or were parts of extended images. Moreover, clutter, which may resemble real targets, must be eliminated. Such processing entails the use of numerous parallel channels.

Photonic detectors suffer from 2 inherent defects. First, the overall scene they observe tends to be much richer in detail than the scene observed by, say, a radar. It may, therefore, be much more difficult for an automatic system, such as a missile seeker or anIRST, to separate out the limited number of features of interest, such as the target itself. The earliest electro-optical devices succeeded because a human operator could select out a sufficiently distinctive aiming point for the tracking circuits to distinguish as the missile flew. However, currentIRSTs are worthwhile precisely because they can recognize particular targets before human operators can do the same.

Second, these devices are all passive; therefore, none can measure range to a target. Optronic/photonic fire-control devices often incorporate a ranging laser, whose weather-penetration capability is broadly comparable with that of the passive tracker.

LASERS

Lasers are already very widely used for range finding (as range-only radars) and for target designation; they are beginning to be used for communications and for weaponry. All follow the same basic principle, but at very different wavelengths and power levels. In most cases, the value of the laser lies in its very pure coherent light, easily distinguishable against a very noisy background and thus capable of carrying substantial information. Purity means not only purity of wavelength (frequency), but also coherence: the laser beam is pure in phase as well as in overall frequency. In effect, the laser beam is a single very strong light wave, rather than the usual incoherent mixture of many beams with different phases. This coherence shows in the characteristic speckled (spatial interference) pattern shown by a laser beam in air.

The beam is narrow because it is coherent. If the laser aperture were infinitely wide, the beam would not diverge at all. As with radar, the laser beam diverges (has some width) because the aperture through which it emerges is only a finite number of wavelengths wide. However, because light has so short a

wavelength, a laser beam is often only a few mrad in width, so that it is still fairly narrow at a great distance.

Although it is commonly claimed that a laser has no side-lobes, in fact there is inevitably some leakage of radiation to the side, so that a laser link cannot be entirely covert. In one embarrassing case, a laser target designator operated in the infrared so as to avoid optical detection. Unfortunately, the likely targets were tanks, which normally used their FLIRs even in the daytime; in this particular case the IR bandwidth of the FLIRs included the laser frequency, and the presence of side-lobes ensured that tanks other than the intended victim could detect the designating laser.

Laser operation can produce very short light pulses, in the case of a laser producing a range of wavelengths simultaneously. Such energy concentration in time can be considered an alternative to concentration (purity) in wavelength or frequency (color). As in radar, the shorter the pulse, the wider its content in terms of frequency. The purer the frequency, the longer the pulse.

The basis of laser operation is that atoms (and other atomic systems, such as semiconductors) have well-defined and well-separated energy levels. When they fall from level to level, they can emit photons, whose frequencies (wavelengths) are proportional to the difference in energy levels. Moreover, the probability that an excited atom will emit a photon of a particular energy and phase increases in the presence of another photon of just that energy and phase. Hence the coherence of a laser. The laser medium is pumped up into an excited but fairly stable (metastable) state. Then an atom decays to a lower energy level, emitting a photon. That photon causes another atom to emit a second, and the process avalanches. Typically the laser medium is enclosed by mirrors so that the photons (quantized light waves) reflect back and forth, causing further emission. In the simplest arrangement, 2 flat mirrors are at either end of a solid laser rod; the 2 mirrors must be an integral number of half-wavelengths apart to form what amounts to a resonant cavity. There are also other mirror arrangements, better suited to gas lasers. In any case, 1 of the 2 mirrors is partially (typically 1%) transparent; the laser beam exits through it.

The laser can fire spontaneously (one of the metastable atoms will soon decay), or it can be fired by a master pulse sent through it, along its optical axis, perpendicular to the mirrors.

A laser uses several of the energy states of its medium. Atoms are pumped up into an unstable state above the metastable state, and they decay rapidly down into the metastable state. Without these multiple levels, the laser cannot populate the metastable state because the pumping radiation also stimulates radiation out of the metastable state. The population of the metastable state is said to be inverted because normally it would be so much smaller than that of the ground (lowest-energy-level) state; this relationship is inverted by the pumping action. The initial quick decays consume some of the pumping energy, turning it into incoherent radiation. Not all of the pumping energy is absorbed by the laser material, and atoms can decay without radiating the laser photons. Lasers are, therefore, relatively inefficient converters of energy, with efficiencies of no more than a few percent.

Solids, liquids, and gases can all be used as lasing materials, provided they have appropriate energy-level structures. The pumping process in a solid tends to heat the solid, and that heating in turn limits the power such a laser can develop to about 1 kW/m of length. Really high power demands a flowing medium, which can dissipate the pumping energy. Each atom or molecule of the flowing medium is active while it passes through the open laser cavity.

Most lasers are pumped by broad-band lamp (optically) or by electrical discharge (through the laser material). The choice depends on the nature of the lasing material. Typically, solid and liquid lasers are optically pumped. Semiconductor and gas lasers are electrically pumped.

Three pumping schemes have been proposed for high-energy laser weapons: gas-dynamic lasers, electro-discharge lasers, and

chemical lasers. A gas-dynamic laser uses collisions between its hot molecules to place them in metastable states. The chemical laser uses an energetic reaction, typically producing hydrogen fluoride; the product, which is in the metastable state, is suitable for laser operation. In all of these gas lasers, the gas streams through the laser cavity, perpendicular to the line along which the laser beam resonates and projects. High-powered chemical lasers present special problems for shipboard installation because their exhaust gas is often quite toxic.

Some typical laser materials, with their dominant wavelengths, are

Alexandrite	0.7–0.82 micron. Typical repetition rate 40/sec; typical of many tunable crystal lasers. Used as target designator.
GaAs	0.850 micron (semiconductor laser). Power conversion efficiency can be as high as 57%. Used for signaling in fiber optics and as seeker head.
GaAlAs	0.8–0.95 micron. Used as seeker head.
Ruby	0.694 micron. Typical repetition rate 6/min; now obsolete for military applications. Used as range-finder.
Nd: Glass	1.06 microns. Typical repetition rate 10/min; now obsolete. Pulse energy 10 times that for ruby. Used as range-finder, target designator.
NdYAG	1.064 microns. Typical repetition rate 20/sec; low energy (range-finder). Also used as target designator and weapons-guidance data link and as decoy for laser-guided bombs.
CO	4.9–5.7 microns. Typically used as a laser jammer. Output power of 100 kW and efficiency 60+ % demonstrated.
CO ₂	10.6 microns (gas laser). Typical repetition rate 2/sec; pulse energy 40 W in a burst. Can tune 9.6–10.6 microns. Uses: range-finder, target designator, beam-rider, LADAR, laser jammer, laser decoy, high-energy laser (HEL).
DF	3.6–4.2 microns (chemical laser). Used as jammer and HEL.
HF	2.6–3.3 microns (chemical laser: hydrogen fluoride). Typical HEL.
XeCl	0.31 micron (blue-green).
XeF	0.35 micron.

A real laser material inevitably offers a range of transition energies. The laser spectral line is said to be broadened. For example, electrons in a solid occupy bands of energy, and they drop from one band to another. In a gas, lines are broadened by collisions between atoms. In a disordered material, such as a liquid or a glass, individual atoms will be surrounded by varied numbers of other atoms, so their energy levels will differ slightly.

At low levels of pumping energy, this natural broadening results in a broad range of stimulated emission. Above a threshold level, however, the resonant character of the laser cavity or solid selects out a narrow range of wavelengths, and the characteristic very narrow range of laser frequencies results.

The principal current naval laser applications involve relatively low energies, for target designation, for range-only radar (range finding), for LADAR, and for signaling (as in the case of the experimental air-to-submarine channel, and also within fiber-optic systems). Typically, current laser range-finders operate at 0.6 to about 1 micron; laser designators, in the 1.4–1.8-micron band, and laser trackers at longer wavelengths, in the mid-infrared (3–5 microns).

Typically a laser will fire raggedly and spontaneously, spreading the energy of its pumping pulse over time (in a typical example, a pulse with a peak power of 1 kW might be spread over 130 microsec). However, many laser applications require that the laser be pulsed over much shorter times, which in turn can be achieved by sealing the laser cavity completely except for a

short pulsing time. The pulsing technique is called Q-switching; given the same laser characteristics as those above, it can produce a 15-nanosec pulse with a peak power of 10 MW (the total power is of course the same).

Q-switching opens and closes the laser cavity; when the Q-switch is off, no light leaves. When the shutter is opened, the stored energy is suddenly released as a strong, short pulse. One such technique is a Pockels cell, which responds to an electric current passing through it. Alternatively, a saturable absorber can be inserted into the cavity. The absorber precludes laser action until a threshold has been crossed; then it is saturated and ceases to prevent lasing. In this case, the combination of pump, laser, and absorber sets the pulse rate. Semiconductor-diode lasers are unique in that they do not require Q-switching.

A typical LADAR might use a pulse rate of 20/sec, the beam being 1 mrad wide. A 120×120 -deg field of regard (FoR) then represents 693,600 laser positions or lasels, and given the PRF, each frame requires 578 min (116, which is still far too much, at 100 pulses/sec). These figures show that laser radar is really practical only when the beam scans over a very limited FoR (or when multiple beams are used in parallel). For example, in a 2×1 -deg FoR, there are only 578 lasels, and frame time (equivalent to data rate in a conventional radar) is 29 sec at 20 pulses/sec. Existing LADARs (which are sometimes also called LIDARs) generally operate at either 1.06 or 9.2–10.8 (nominally 10.59) microns, with a very narrow field of view (based on the considerations above).

Blue-green lasers present particularly interesting possibilities because they can penetrate considerable depths of seawater. As early as the mid-1960s, such beams could reach down as much as 400 ft, and for a time it seemed likely that a shallow-water submarine-hunting LADAR was practicable. The effort was abandoned because insufficient return energy was available, probably because too much was lost to internal reflection when the beam passed through the water surface on the way up. More recently, analogous downward-looking LADARs have been used for shallow-water surveying and for mine location (ALARMS).

The press has carried references to LADAR in connection with torpedo defense. If the main problem in the early LADAR was in fact losses due to reflection at the surface of the water, then a LADAR totally immersed should be more practicable. Up to short ranges (perhaps a thousand yards), it should be able to detect objects more reliably than a sonar, providing it can scan rapidly enough (or, more likely, providing it scans over many sectors simultaneously). Such a LADAR would be a natural complement to a very high speed underwater projectile.

It has been possible to generate very high laser energies for some time, but laser weapons (other than the recent British "dazzler") are still almost as far away as they seemed two decades ago. There are two problems, propagation and actual damage to the target.

The atmosphere is not homogeneous, and the beam bends as it passes through. The beam director, therefore, must adapt to changing atmospheric conditions, some of them caused by the beam itself. At least at present, beam directors for high-energy lasers are quite massive. In addition, the atmosphere absorbs the beam. Water vapor is a particular problem for a beam directed close to the sea surface. As it heats, the air changes its index of refraction, and it bends or spreads the beam (blooming).

The beam can transfer energy either continuously or in a short pulse. A continuous-wave laser heats its target, and there is always some question as to whether evaporation from the target will carry away energy quickly enough to protect it. Alternatively, a short pulse will transfer energy very quickly, almost like a kinetic-energy projectile, smashing into a target. Such a laser has the additional advantage that it may be so short that the air will not heat enough to bloom it as it passes through.

ECM

Electronic countermeasures figure in several sections of this book, and these notes will be limited to items common to all

warfare areas. ECM splits into passive devices, electronic support measures (ESM), intended to detect and identify characteristic emissions, and countermeasures (ECM), intended to disrupt hostile sensors or communications. Some of the basic alternatives are worth mentioning.

An ESM device has to determine the main parameters of the emitter: direction, intensity, frequency, pulse width, PRF, and scan rate or pattern. There are several approaches to this problem.

One is the broad-band (crystal video receiver or CVR) receiver, which can respond to any of a very wide variety of signals within its bandwidth. It identifies a signal by frequency band, but it cannot tell where in the band that signal is located. CVRs are relatively simple and lightweight, and they are normally used in radar-warning receivers (RWRs) and in small ships' ECM systems. They may be matched with devices that detect and measure the pulse width and PRF, and these use these data to identify an emitter.

A second approach is the tunable receiver (scanning superheterodyne receiver or SHR). A narrow tuning band sweeps through the receiver's bandwidth. If the sweep is very rapid compared to the duration of the signal, then such a receiver will probably detect and identify the signal. However, if the signal is brief enough, the tuner may well miss it. Typically, a mechanical tuner may sweep a few GHz per second, and an electronic tuner may improve this to a GHz per microsecond. However, typical radar pulse widths are also on the order of microseconds. SHR performance can be improved by breaking down any given frequency band into narrower channels.

Finally there are instantaneous frequency measurement (IFM) receivers, which have a high probability of intercepting a signal because they are always open to the entire frequency band. They tend to be less sensitive than the SHR because they have to respond to so broad a range of frequencies. IFM is becoming common in shipboard systems, but it is rarely used in aircraft. The main drawback of IFM is that it may be unable to deal with several signals in close succession, since it requires a finite time to process each signal. This is not an unsolvable problem, but it does increase the complexity of the equipment.

Sensitivity is generally inversely proportional to channel width; the wider the channel, the less sensitive the receiver. Thus an IFM is less sensitive than an SHR.

The most important distinction within ECM is probably the difference between simple noise jamming, which seeks to blot out a signal, and deception. Noise jamming can cover a wide range of frequencies (barrage jamming), or it can be directed to a particular, narrow frequency band (spot jamming). The best counter to noise jamming is frequency agility (the signal's frequency moves away from the jammer's). The higher the basic frequency, the broader the range of frequencies a barrage jammer must cover.

Because radars have finite sidelobes (i.e., cannot concentrate all of their energy or their reception in one direction), jamming signals can always enter via those sidelobes and appear (to the radar) to be coming from the direction in which the radar is pointing.

Deception generally depends upon some measurement of the radar PRF, scan rate, and pulse width, since the jammer must send back a false echo. The echo may confuse the radar in range (e.g., range-gate pull-off) or in bearing (via the sidelobes). Consequently, jittered or varied PRF is a counter-countermeasure because the radar may reject signals that do not conform to the precise pattern of its variation in PRF.

Jammers are often described as responsive or as repeaters. A responsive jammer measures the frequency of the received signal and sets an oscillator. The frequency data are, therefore, typically stored and processed digitally. The response can continue after the pulse has ceased. It need not be at precisely the received frequency. For example, if an enemy frequency-hopping radar is known to execute a particular pulse pattern, the responsive jammer can be programmed to match it. The response of such a jammer is limited by the finite time it takes

the associated oscillator to reach the appropriate frequency. Current linear hyperabrupt transistor oscillators can tune over 25 GHz/microsec, over a total bandwidth of 4.5 GHz, with a settling accuracy of 2 MHz in 100 nanosec. Total response time is longer; current technology can provide a response accurate to within 2 MHz within 250 nanosec.

A repeater is a simpler analog device. It simply amplifies the received signal, with or without a time delay; the incident pulse fires its TWT at the appropriate frequency. Because no frequency measurement is made, the response can be extremely quick, typically in 100 nanosec. A repeater is, therefore, a natural counter to a tracking radar, with its high pulse rate.

Repeaters are often built around frequency memory loops (FMLs), which store an exact replica of the received pulse. The storage device is often a coaxial, a waveguide, or an acoustic delay line. The radar pulse is fed into the line, whose memory switch closes a set time after the beginning of the pulse is detected. The pulse energy then circulates within the delay line. It picks up noise on each circulation, and thus the information in it is gradually lost. The jammer taps it and amplifies it to produce a replica signal. A typical FML has a frequency range of 8–16 GHz, carrying a signal accurate to within 3 MHz (distortion would be introduced by the characteristics of the delay line), with a duration of 7.5 microsec. The line itself is 150 nanosec long (duration measures how quickly a signal in the line would decay to uselessness). There are also dual-delay memory loops. A typical example can switch between lengths of 150 and 300 nanosec, with a 15-microsec duration.

Effective jamming operation typically requires that jamming energy be concentrated on the target; jamming antennas are, then, typically paired with target trackers. In some cases, as in Scimitar, the tracker (receiver) antenna is identical to the jammer antenna. SLQ-32 is probably unique in using the same antenna for initial detection, target tracking, and jamming. More generally, although the tracker can function as a search antenna, it has too narrow a beam for efficient search. Ships, therefore, generally have separate coarse direction-finders for initial detection. Soviet systems are unusual in using an intermediate tracker to cue the tracker associated with the jammer. Such operation is analogous to the combination of broad-beam search radar, narrow-beam target indication radar, and very narrow beam fire-control tracking radar in many warships.

Finally, it is useful to distinguish between a variety of direction-finding or tracking techniques used by ESM and ECM systems: interferometric, monopulse, and (single) directional antenna.

An interferometric direction-finder consists of a series of omnidirectional antennas. Each detects a signal with a slightly different time delay, the amount of the delay depending upon the direction from which the signal comes. This technique is used in some airborne systems (such as the U.S. sonobuoy reference systems) and in such submarine sonar systems as PUFFS (BQG-4). The classic interferometer is the Adcock, consisting of 2 pairs of vertical antennas, each half a wavelength wide, at right angles. Crossed-loop direction-finders also fall into this category.

The direction of the signal can be read off in several ways. The entire antenna can be rotated; the elements of the array can be sampled by a rotating goniometer; or the elements of the antenna can be grouped into 2 subantennas with patterns at right angles. The 2 groups can drive the 2 pairs of plates of a CRT, showing the angle of any intercepted signal instantaneously. The latter technique was invented in the 1920s by Robert Watson-Watt, who also invented the British form of radar (others independently devised other forms of radar in other countries virtually simultaneously).

A rotating loop takes about 10 sec to find a direction; a rotated goniometer takes about 3. World War II experience showed that an instantaneous CRT system could cut direction-finding time to half a second or less. That capability was particularly important after the Germans drastically reduced the duration of their signals to defeat conventional direction-finders, and, of

course, it would be important in a direction-finder attempting to deal with short radar pulses. A modern system would replace the CRT with a computer comparator and would do better because the computer would sense the presence of a signal much more quickly than a human operator.

The stage beyond the Watson-Watt system is to form more than 2 beams, using what amounts to a phased array. The first major application of this principle was the German Wullenweber circularly disposed array of World War II; coincidentally the Germans applied much the same technique to their wartime GHG passive sonar. It was adopted postwar by both the Soviets (as Krug) and the United States. Compared to an Adcock, a Wullenweber provides better directivity because its more numerous elements give a much narrower beam pattern. In the Wullenweber, about a third of the elements were used at any one time, the relative delays being fixed to form a narrow beam. A goniometer selected the appropriate third and applied the delays; it rotated among the elements of the array. This operation was exactly analogous to the use of a commutator in early scanning sonars. As in a scanning sonar, this technique suffers from the weakness that it does not stare in all directions simultaneously. A modern array would use preformed beams; it would sample all directions simultaneously and would form beams in all directions at the same time, via a computer memory.

A monopulse direction-finder compares the strength of the signal as it is detected by a series of antennas pointing in different directions. The antennas are often spirals or broad-band cones. Examples are shipboard wide-open ESM systems and aircraft RWRs. Monopulse is usable only when the wavelength is short enough that individual antennas can be sufficiently large (in wavelengths) to have fairly narrow (at least not overlapping) beams. On shipboard, then, it cannot be used at HF or VHF frequencies and is limited to radar direction finding. Interferometry is used at lower frequencies.

Although both interferometers and monopulse direction-finders can rotate to focus on a particular signal, both techniques are more commonly used in fixed form. Their beams are formed, in effect, electronically.

In contrast, a directional antenna, such as a dish, has a narrow pattern. Typically, it scans, passing its beam over the direction of the incoming signal. For a given total size, a directional antenna generally provides much greater gain (hence longer range) and much greater accuracy, but its coverage of a given signal is necessarily intermittent. In recent years, then, the tendency has been to use monopulse rather than spinner antennas for radar direction finding. High gain has been reserved for trackers used to direct jammers, as in the Signaal Ramses or the Soviet Side Globe.

Electronically scanned antennas can provide some of the virtues of a highly directional antenna but at a high scanning rate; the Hughes SLQ-17 is an example. A lens antenna, such as that used in SLQ-32, is a more monopulse-like alternative, providing the equivalent of a large number of high-gain antennas producing adjacent beams simultaneously.

IFF

Because IFF (identification, friend or foe) applies to so many radar systems, it seems best to treat it here. Since the middle of World War II, the standard system, both in the West and in the Soviet Union, is the interrogator-transponder. A radar is fitted with, or associated with, an interrogator with approximately the beamwidth of the main radar. The interrogator sends a coded pulse or pulse train in approximately the same direction as the main radar, but at a different frequency. The transponder on the target sends back a reply, at a third frequency. Generally, the reply is coded to indicate the details of the target's identity. Over the years, frequencies have increased, and interrogators have become more directional; in some cases, the text gives details for the interrogators associated with particular radars.

All of the many interrogators on board a single ship (not to mention in, say, a fleet) are entirely independent, so that all may interrogate the same incoming target. As a consequence,

the transponder of any particular target may be unable to reply to all of them, since it can send its code to only 1 interrogator at a time. The only current exception to this problem is the single integrated IFF antenna used in conjunction with the U.S. SPY-1 radar (see that entry in the Antiaircraft Warfare section): it limits a single ship's interrogations.

Moreover, the interrogator-transponder system can be a liability in combat, since an enemy with access to the interrogation codes can use them to trigger transponders aboard approaching targets and thus can use IFF itself to track targets. That makes the coding of interrogators particularly important, and this requirement in turn makes for relatively complex systems.

IFF is not a universal identification system; it is a means of positively identifying some radar targets, leaving all others unidentified (and hence either neutral or foe). Moreover, because a potential target may not reply to a particular interrogator (for example, because it is replying to others at the same time), IFF errors can occur even for friendlies. Additionally, the more complex the coding for security, the better the chance of error. It is commonly assumed that in wartime large numbers of aircraft will fall victim to IFF errors, on both sides of any conflict.

There is also a danger that a nearby ship will receive the reply intended for another, either through the main lobe or through a sidelobe. Such false replies are called "fruit," and they are eliminated or "defruited" by assigning each interrogator its own pulse repetition frequency (PRF): special circuits eliminate any reply with a different PRF. It is also possible for a single target to receive interrogations from 2 radars in line, so that the reply intended for 1 is received by the other, and thus is associated by the other radar with an entirely different, nonreplying target. Multiple interrogation signals can also overlap and confuse a transponder.

The current NATO system, Mk 10, was introduced during the Korean War. There was no Mk 9; Mk 10 was developed as Mk X, the X standing for the future system (it replaced Mk V of 1945). This system interrogates at 1030 MHz and replies at 1090 MHz. A coded Selective Identification Feature (SIF) was added in the mid-1950s. Capacity is 4096 identification codes, in 3 modes (1, 2, and 3). This system is used for both military and civil aircraft, and the responses typically carry coded information. Civil aircraft provide flight call sign and altitude. Military aircraft provide a basic IFF response plus other data. Mode 3 is military, Mode A is joint military/civil (often called Mode 3/A), Mode B is civil (identification), and Mode C is civil (altitude reporting). A further Mode D is not currently used but is available for expansion of the system.

Mk 10A has an Automatic Code Changing (ACC) capability, with more code combinations. Because Mk 10A and the civil ATC system use the same message format, there is always a possibility that an enemy will find it relatively easy to fabricate false Mk 10A messages.

Early in the 1960s the United States added a cryptographic facility, Mode 4. The interrogator as well as the transponder is coded to prevent an enemy from tracking by using a false interrogator to trigger transponders. Mk 10/10A plus Mode 4 is designated Mk 12, which is now standard in much (though not all) of NATO. Mk 12 has never extended throughout NATO partly because it is much more expensive than Mk 10 and partly because its greater degree of coding makes the system as a whole more vulnerable to jamming, which might confuse the codes.

In the early 1970s, NATO set up a working group to define a NATO Identification System (NIS) that would replace Mk 10/12. By 1981 Britain, West Germany, and the United States were all developing prototypes. Britain and West Germany favored a higher-frequency (S-band) system, the United States and France an L-band system compatible with Mk 10/12. In April 1985 NATO agreed to adopt the U.S. solution. Britain and Germany had claimed that L-band was too crowded but accepted the L-band system when the United States agreed to add a radar interrogator mode (i.e., interrogation at radar frequencies in the S- and X-bands to supplement the previous standard of 1090

MHz; however, as at present, responses would still be at the standard frequency of 1030 MHz). This scheme meets a requirement stated by the European NATO partners, allowing interrogation by a radar not fitted with a separate interrogator.

This new system, called Mk 15, will use two types of interrogation, one using spread-spectrum interrogation, the other a radar mode using pulse-position keying. Where possible, the radar mode will be integrated directly into weapons systems.

In a larger sense, identification must be based not only on electronic replies but also on observed behavior. For example, schemes for air operations in Europe commonly involve special corridors, including altitude, along which returning strike aircraft can expect to return without being shot down. To avoid funneling enemy strikes into the same areas, the corridors are changed very frequently. Similarly, a fighter returning to a carrier would not only "squawk" or send the proper IFF reply but would also behave in a particular preassigned way. Otherwise, the fighter would probably be shot down. Systems based on flight profiles can help to allow for possible electronic failure or battle damage, but they cannot be perfect.

These inherent problems have prompted considerable work on noncooperative means of identification, using the physical characteristics of the approaching target. In the past, at least in the United States, the most popular have been the measurement of the rates of rotation of jet engines' compressor blades (since the blades make prominent radar returns), and the direct imaging of an approaching airplane. Neither has ever been implemented.

A third alternative is positive tracking of all the aircraft in an area. That was done in the Gulf of Tonkin during the Vietnam War, when a computer-equipped ship tracked literally all air contacts. In theory, much the same thing could be done by an Aegis ship in, say, the Mediterranean. However, identification by tracking requires the cooperation of neutrals, who in effect must identify themselves when they take off. If they do not, identification must fall apart—as in the *Vincennes* incident of 3 July 1988.

The shooting down of the Iranian airliner by the USS *Vincennes* illustrates these points. Because the airliner was not a U.S. military aircraft, it could not send an appropriate IFF signal. The signals it did send seemed to correspond to those that the Iranians had used earlier for F-14s, but that was a deduction from observed Iranian behavior, not necessarily a positive identification. After all, the Iranians might well change their own IFF codes quite often. Thus the captain of the *Vincennes* could not be sure what the IFF return meant. He tried to contact the airliner by radio but received no reply, and the airliner itself did not swerve away, as Iranian airliners had in the past. He did not shoot, however, since the negative information he was receiving did not necessarily mean that the airliner was hostile. Then he was told (incorrectly, as it turned out) that the aircraft had begun to descend, to dive. To the captain, that was a positive signal of hostile intent. This reading in turn was based on a series of known Iranian threats and an expectation that the Iranians might well try a suicide attack. Apparently, the error in reporting the height was partly caused by an inconsistency in the display of target data: height was given in digital (numerical) form, whereas the track of the airplane (range and bearing) was shown graphically. Under the stress of combat (the ship was swerving to keep her after 5-in gun bearing on 2 Iranian gunboats), it was apparently too easy to misreport numbers.

The incident well illustrates the central problem of identification: one might be able to determine the physical character of an approaching target, but how can one interpret the intent of the target's operator? Although Captain Rodgers undoubtedly believed he was facing an Iranian F-14, in fact his ship could have been crashed just as effectively by an airliner. A system that merely told him what type of airplane was approaching could not have sufficed. This problem will most likely recur in other areas, where several countries might be operating the same or similar equipment.

MISSILE GUIDANCE

There are 3 basic types of missile guidance: inertial, command, and autonomous.

Inertial guidance systems measure the motion of a missile through space, sensing and integrating accelerations to find the missile's velocities. Inertial systems were initially used only in long-range ballistic missiles because these systems were so expensive. There are 2 types: a hard-wired system, in which the missile attempts to fly a precomputed path, correcting whenever the missile deviates; and a computer-based system, which constantly recomputes the necessary flight path based on the actual flight of the missile. The latter requires less fuel for correction, and thus is suited to greater ranges. It allows for operational flexibility, since only the launch location and the target need be entered into the computer. In the absence of such a system, a missile must be fired at a single preassigned target from a preassigned site.

In recent years inertial sensors, such as gyros, have become much cheaper, and some form of mid-course inertial guidance is now quite common. Often it is described as strapdown, which means that the inertial sensor lacks the full range of measurement, i.e., cannot measure pitching motions. That is acceptable in a short-range missile, or in a missile constrained by a radar altimeter to fly a flat path.

Command guidance may be of several forms: commands may be sent through a wire or fiber-optic cable or a radio link; or the missile might be a beam-rider, controlled by the movement of a radar beam (in at least one case, a laser beam). The basic attraction of command guidance is that the intelligence of the weapons system can be concentrated in a director that need not be limited in size or cost, rather than in an expendable missile of very limited size. The main limitation on command guidance is the loss of accuracy as the range increases. An advantage of beam riding is that it is somewhat difficult to jam: the missile's antenna that senses the beam faces rearward instead of forward, toward the target. The jammer must, therefore, concentrate on the more distant (and more sophisticated) tracker, rather than on the nearby missile. That is why Bofors advertises its laser beam-rider, RBS 70, as unjammable.

Much depends on whether the beam tracks the target itself. In most early beam-riders, such as the British Sea Slug and the U.S. Terrier, a single tracking radar generated the beam, and the missile, therefore, continuously pointed at its target. Because it had to follow target maneuvers, it could lose a good deal of its energy along the way. On the other hand, in the contemporary U.S. Talos (now extinct), the beam motion was programmed so that the missile flew along an energy-efficient up-and-over path. It homed semiactively only as it approached the target.

Autonomous or self-sensing guidance takes many forms. It does make the missile more accurate as it approaches its target; on the other hand, the missile seeker is of limited size, and it may not be able to deal with countermeasures. Moreover, it may be difficult to design a seeker that can distinguish some kinds of targets.

Usually missiles incorporate some compromise between these elements. In the case of antiaircraft fire, semiactive homing is quite widely used. Semiactive homing is a type of command guidance, to the extent that the missile director tracks the target. However, the missile actually tracks the radiation reflected from the target (usually radar, sometimes laser). The missile's estimate of target position, therefore, becomes more accurate as it approaches the target. The greatest drawback to semiactive homing is that the tracking radar must be powerful enough to provide the missile with sufficient reflected illumination from the moment that it is launched. This requirement limits effective range. One alternative is to use command guidance or inertial guidance (i.e., a preset autopilot) to bring the missile relatively close to the target before turning on the semiactive seeker. That is the solution chosen in the U.S. Aegis and Phoenix systems.

Missile guidance determines missile flight path. Here command guidance has an advantage, since it can bring the missile

along the most efficient flight path possible. Any form of full autonomous homing or semiactive homing results in a less energy-efficient path and, therefore, in a shorter range for a given missile.

The simplest and least efficient path is pursuit because the missile turns to fly along the line of sight to the target. The missile's rate of turn equals the rate of turn of the line of sight, and quite violent maneuvering may be required as the missile approaches its target. Pursuit is effective against slow targets, or against targets approached from the rear (e.g., by IR-guided missiles). It is also effective at very short range. Missiles using command-to-line of sight guidance (such as the French Crotale Navale and the British Sea Wolf) follow pursuit paths that limit the system's effective range. For missiles launched from shipboard, command-to-line of sight is effective for point defense but not really for defense against crossing targets. To the extent that major Soviet systems such as SA-N-1 and SA-N-3 appear to employ command-to-line of sight guidance, they are effective for the defense of individual ships but not of formations of ships.

Proportional navigation requires the missile to measure the rate of change of the line of sight and to maneuver at some fixed or variable multiple of that rate of change. The navigation ratio may change during flight to optimize missile performance. Proportional navigation systems require the missile to compare the direction to the target with the direction in which it is flying. That is sometimes done by a doppler comparison between the reflected energy from the target and a broad reference beam from the launcher. In such cases the missile requires a set of rearward-facing reference antennas. The reference beam has to be broad because the missile generally is not in the tracking beam itself. Proportional navigation improves missile range performance, and also improves performance against a maneuvering target, since the missile need not maneuver violently to follow the details of target motion. In effect, proportional navigation aims the missile not directly at the target but at a computed interception point ahead of the target.

Proportional navigation can also be applied to IR missiles. In these cases the reference is an internal gyroscope. The missile tracks the forward edge of the target. As a consequence, it tends not to be distracted by decoys (flares) dropping away to the rear of the target. The French Mistral is the only publicized example, but for some years Sidewinder has been credited with the ability to hit the forward portion of its target. That suggests that it, too, employs proportional navigation, and that this form of guidance is an important anticountermeasure feature. Presumably the only way to decoy a proportional-navigation missile would be to fire the decoy ahead of the target.

In contrast, command guidance generally involves some quite different flight path. The main alternatives are:

- A constant-bearing or collision course, which requires the missile to be fired with a sufficient lead angle to meet the predicted position of the target.
- A fixed lead angle path.
- A line-of-sight path, which requires the missile to follow the line-of-sight from launcher to target (as in a beam-rider).

These concepts apply not only to missiles flying through the air but also to torpedoes. A straight-running torpedo is inertially guided. Lightweight torpedoes are self-guided, although they may have inertial (preset) run-outs before their homing devices are activated. Most heavy torpedoes are command (wire) guided, until they reach a homing basket. In a few cases they are wire guided all the way.

DIGITAL VS. ANALOG EQUIPMENT

One of the major themes of this book is the displacement of analog equipment by digital types. Although many navies still operate old analog equipment (which suffices for their purposes and which would be expensive to replace), analog equipment is no longer being manufactured (at least in the West). Digital technology has triumphed in the last quarter century. Cheaper and more reliable digital computers have made digital methods

much more attractive than analog, and in turn the pressure to adopt digital methods partly explains the need for greater and greater computer capacity. A comparison between digital and analog methods gives some idea of the limits that current computer capacity imposes.

Initially, the impetus for adopting digital techniques was largely their precision and flexibility. However, digital operation provides something much more powerful. All signals (raw and processed) are carried in the same memory, and in the same form, so they can be compared directly. It is easy to run the same signal through several parallel processes since the signal can be copied without any loss of precision. Most important of all, the program that runs the processor is carried in the same memory. It can easily be changed. And as the program runs, it can modify itself; more accurately, it can determine which of many different possible paths the machine takes, based on the results of earlier computation and, often, of external inputs during computation.

This sort of flexibility is impossible in an analog machine because the analog processor is literally a physical equivalent of a mathematical operation or series of operations. Change means physical change, by adjusting some part of the processor. It is possible to imagine some self-adjustment, but only at the cost of great complexity.

In some very primitive sense, a programmable digital computer can be aware of the data passing through it; it naturally makes decisions based on these data, and then applies those decisions to its own operation.

CDSs are a case in point. The early analog types, such as the U.S. EDS and the British ADA, handled each track separately (in effect, each track had its own analog memory channel), bringing them together only in a summary plot. The system could not in itself use the summary character of the plot; only a human operator could compare tracks to decide which targets to engage. Digital systems such as the U.S. NTDS and the British ADAWS carry all their track data in a single memory. They can compare tracks to decide which represents the greatest threat, and they can correlate track data with data supplied by external sources. These data can also be fed directly into WDSs.

Flexibility does carry a cost in processing speed. In some special cases, therefore, specialized microchips with fixed programs are used. The most important case is the series of FFT chips used in sonar and radar processing. Early digital computers (valued for their speed and precision) did not always have sufficient memory space for elaborate programs and so were sometimes provided with fixed (hard-wired) programs. Hence the contrast, common in the literature of the 1950s and 1960s, between digital and general-purpose digital computers. Even these machines, however, did not require the manufacture of mechanical components specific to particular sets of ballistics, such as specially shaped cams, which were common in earlier electro-mechanical analog computers.

Flexibility carries one other great drawback. It is difficult to ensure that none of the possible paths through a program will have unfortunate unintended consequences. The more complex the program, the more possible paths through it, and the more possible sets of inputs that can cause the system to travel those paths. Hence the enormous current emphasis on software testing, often carried out at a special site designed to simulate operational use, including operator errors. Such error testing is sometimes called "Murphy testing."

The potential for error increases as the software defines not only operations inside the machine, but the meaning (to the machine) of the buttons available to the operator. That is quite common; users of personal computers soon discover that the software enables the machine to recognize, e.g., that the pressed key (marked "A") corresponds to an A in the machine's memory. Specialized software can be bought to change the significance of the keys, as in converting the standard QWERTY keyboard to the more efficient Dvorak. The important military use of this sort of software is in making all or most of the keys multifunction so that a board of manageable size can be used

to control a whole sequence of operations, or different operations depending on the role the console fills at any particular time. Much, therefore, depends on whether the system correctly interprets the significance of any particular key at any particular time. There are also human factors. Most typists make occasional errors, but that is acceptable if the computer shows them what they have typed and allows for corrections. However, some systems may not provide this sort of feedback. Even though the software is, in theory, flawless, it may still succumb to Murphy's law.

Software development and testing is often done on standard commercial machines, more readily available than the specialized naval computers that will actually run it operationally. Many naval computers are, therefore, designed to run programs that can also run on major commercial computers. The first example was probably the IBM System/4 Pi series, whose programs could run on standard System/360 machines.

The difference between analog and digital systems is in how signals are represented so that they can be processed. Signals come from the external world (such as the image falling on a FLIR, or radar or sonar echoes) or from devices within a ship (such as inputs and outputs of fire-control devices). Ultimately, they are processed so that decisions can be made on their basis. These decisions may be mechanical (the pointing of a gun) or they may be more complex (the decision that a FLIR image represents a friendly airplane). Whenever some sensor or device intervenes between a raw signal and a human or mechanical decision maker, signal processing must occur.

Analog systems construct a mechanical, electrical, or electronic equivalent to the signal (including the accompanying noise). That is not to say that the analog will reproduce the real signal precisely; there will always be errors of translation. An analog system displays the world in what amounts to continuously varying shades of gray. However, some very light grays may be represented as too white, and some very dark grays may seem too black or too light. This sort of nonlinear distortion is inevitable. It adds noise to the noise that every signal carries with it. Further analog processing introduces further distortion and further noise, if only because no physical device is entirely linear, i.e., none handles all signal strengths (and, usually, all frequencies) in the same way.

In a mechanical fire-control system, for example, target bearing is introduced by rotation of a shaft, driven by a synchro that in turn is driven by an operator following the target visually. There is inevitably some slip in the synchros at each end. The input shaft cannot be entirely rigid, and its twist must distort the input slightly. Similar slippage occurs within the computer; the more complex the calculation, the greater the slippage. Further slippage occurs in transmitting the product of the calculation to the gunner.

A digital system operates very differently. It approximates the physical signal varying over time by a series of discrete samples (represented by numbers) taken at close, regular intervals. No such representation can account precisely for variations occurring between sampling times. However, if the samples are taken close enough together, and if the signal varies smoothly enough, then signal behavior between sampling times can be accurately estimated by interpolation.

The signal can be imagined as a combination of signals of different constant frequencies; their strengths are calculated by Fourier transform of the original signal. Those components with frequencies much higher than the sampling rate will account for portions of the signal that cannot be estimated accurately by interpolation. If they are small enough, interpolation will be reasonably accurate. A signal with a maximum frequency can be represented exactly by a series of samples taken at twice that maximum. Thus, in theory, the output of a passive sonar receiving signals of up to 1 kHz in frequency could be represented precisely by samples taken at a rate of 2 kHz, i.e., by 2000 samples/sec. This sampling theorem indicates the information content in a given signal or, alternatively, the processing requirement that a given signal entails.

In practice such precision cannot be realized; higher sampling rates are needed. For example, since each sample takes a finite length of time to collect, the real system loses some accuracy in sampling. The maximum data rate of the system may be imposed by some physical limitation, such as the capacity of the associated data bus, and it may be insufficient to deal with really rapidly varying signals. This consideration helps to explain pressure for higher-capacity data buses.

Sampling considerations determine the load a sensor imposes on its processor. A passive array sonar, for example, may receive signals with noticeable frequencies of up to 1 kHz, so it must sample at a rate of at least 2 kHz. If the sonar has 100 transducers, the processor receives data at the rate of 200 kHz: 200,000 samples/sec. Processing will often occur in 2 steps: beams will be formed, and then each beam will be broken down by frequency, in hopes that the target will be stronger than the noise in a narrow beam and within a narrow frequency range in that beam. Each beam requires 1 multiplication and 1 addition per transducer (i.e., per sample), 400,000 calculations/beam/sec. A mere 25 beams require 10 million calculations/sec before frequency data are extracted. Each beam is represented by 2000 samples/sec.

Frequency (spectral) analysis is by FFT, numerous samples being combined to search over a narrow frequency range. The greater the number of samples, the finer the resolution of the FFT, but also the greater the processing load. Typical FFTs are taken on 1024, 2048, or 4096 samples. Successive FFTs generally overlap, e.g., a new 2048-point FFT might start every 1024 samples. A 2048-point FFT requires 70 operations/sample, and ancillary operations add more. In practice a processor might run several parallel FFTs to cover different narrow frequency bands. These FFTs would have to be conducted for each beam. The final processing load would be hundreds of thousands of operations per beam per second. That is why sonar processors have to be so powerful.

Sampling also explains the need for preprocessing, which generally means analog reduction of the complexity of the signal (filtering) before it is reduced to digital form. For example, a radar signal may be received at a frequency of 10 GHz, but the important information in it, the rate at which echoes arrive, is superimposed at a rate of tens of kHz. In this case preprocessing strips away the 10 GHz carrier signal so that the digital signal processor is not swamped by irrelevant information.

Display is the inverse of sampling; the results of digital computation must be displayed to the operator. In this case the important frequency is determined by the human eye, which cannot register very rapid changes. The eye thus interpolates between successive images (as in a movie). It also retains an image, so that the very rapidly moving single dot of a television suffices to produce a complete image. Typically, a television screen is refreshed 30 times/sec, to produce what seems like continuous movement.

A TV picture represents a vast amount of data, so much so that televisions are still analog devices. In the United States, for example, a television picture consists of 525 horizontal lines. The picture has an aspect ratio of 4:3, so that for equal resolution in both the horizontal and vertical directions, each horizontal line can be equated to 700 picture elements (pixels), i.e., each picture consists of 525×700 pixels, or 367,500 in all, or 11,025,000 elements/sec (actually only half as much information is transmitted because each signal element can be considered a wave producing both a positive and a negative peak on each cycle). The human eye distinguishes no more than 9 brightness levels, i.e., 4 bits/pixel, so that the total screen equates to a little less than 22 Mbits/sec.

These figures apply to the monitors that display weapons-system outputs. They explain why, until recently, radar monitors were always analog devices. However, to digitize such a monitor is to gain enormously. Each pixel of the screen can be processed separately, e.g., to emphasize some important ones, to add further data, or to distort the scale. Modern systems that can superimpose different radar pictures, or which superimpose

radar and other video, often gain this performance by using digital processing, albeit at a very high cost in processing power.

Digital processing may also buy the ability to make decisions based on the content of particular pixels, since each pixel is assigned a numerical value. For example, a keep-out zone may be shaded in red. The system computer keeps track of the area of the zone by examining the red pixels in turn. The screen itself is now a 2D, digital (i.e., processible) analog of some physical situation. The underlying processor can also use these data in some other way, e.g., by conducting some geometric transformation on the points.

Many systems still use an intermediate step, the cursive display, in which the electron beam paints particular patterns at preset points on the screen. A typical cursive computer screen may display 24 lines of 80 characters each, a total of 1920 characters. Each can be any 1 of about 64 alternatives, hence represented by 1 byte. The typical cursive screen is equivalent to fewer than 2 kbytes. Many displays combine analog video with cursive character generators.

Users of personal computers will appreciate the difference in processing power between a cursive display and a fully digital one: the latter is generally associated with a special graphic board. Even so, it takes up so much processing power that images on screen cannot be made to move very rapidly.

Digital operation requires some physical representation of numbers. Thus far, such representations have always been binary, i.e., in the form of 0s and 1s represented by switches that are either off (0) or on (1), each equivalent to 1 bit of data. Current memories are typically organized in bytes (units of 8 bits each), sufficient to represent the numbers 0–63. Programmers find it convenient to work in half-bytes ("nibbles"), sufficient to represent 0–15; often numbers are expressed in hexadecimal (base-16) form. A byte is then equivalent to 2 hexadecimal digits (which are written using letters for values 10–15).

Even very limited memory capacity requires numerous bits, i.e., numerous switches. Each must be easy to set, read, and unset very quickly. The earliest digital computers used vacuum tubes (which are, literally, switches) in circuits that could adopt 2 alternate stable electronic configurations. They were both cumbersome and unreliable, and memory was lost when power was turned off. Digital equipment first became really practical with the advent of magnetic cores or drums, numerous examples of which remain in service. In contrast to the vacuum tubes, the magnetic core or drum retains its polarization (its 1 or 0) whether or not computer power is on. The current standard memory device, the semiconductor, reverts to the earlier pattern of carrying its 0 or 1 as a stable electronic configuration. Like its vacuum tube predecessor, its information content is lost whenever the power is turned off.

No matter how large the memory, it is of finite size, so all numbers must be approximated by a limited number of digits. Nothing can be quite exact; the system is always rounding off as it calculates. For example, each number might be represented by only 3 digits, so that the fraction $\frac{1}{3}$ would be carried as 0.333. In this case, multiplying by 3 would give 0.999 rather than 1.0. That might have little significance, but squaring the result would give only 0.998 instead of 1.0, and errors would increase as the calculation became more complicated. Systems are typically designed to round off as they calculate, to limit errors, but even so they must suffer as calculations become lengthier.

Digital machines represent numbers in 1 of 2 ways. They can be in the form of fixed numbers of digits (fixed-point operation). For example, an 8-digit machine might carry $\frac{1}{3}$ as 0.333333, and 15.75 as 15.750000. It would have to carry one-billionth as 0, however, because it cannot accommodate more than six 0s after the decimal point. Similar problems arise with numbers greater than 99.999999. The alternative is floating-point operation, in which numbers are represented as products of significant digits (called the mantissa) and a power of 10 (the exponent). For example, $\frac{1}{3}$ might be represented with a mantissa of 0.33333333 and an exponent of 0; one-billionth might be 0.10000000 with

an exponent of -8 . The machine gains enormously in dynamic range, but at the cost of more complex processing (each arithmetic operation now involves 2 sets of numbers, exponents and mantissas).

The rounding-off process, by which real-world numbers (which cannot generally be represented by a limited number of digits) are reduced to the limited numbers of digits in a machine, in effect mixes those real signals with noise. The mathematics of information associates a particular signal-to-noise ratio with a particular number of bits used to represent the samples that in turn represent signals. The greater the number of bits per sample, the less the rounding-off noise. Alternatively, it might be said that, given a particular signal-to-noise ratio, there is no point in using more bits per signal than would be needed to keep the rounding-off noise at the same level. The number of bits increases only logarithmically with the signal-to-noise ratio. Using 1 bit/sample is equivalent to accepting a signal-to-noise ratio of 3 (4.7 dB); 4 bits is equivalent to a ratio of 255 (24 dB); a byte (8 bits) is equivalent to a ratio of $>65,000$ (about 58 dB).

These figures all apply to a system in which all the samples are normalized (divided by the largest possible sample size) for easy comparison and translation into fixed-point form. If each is represented by 1 byte, then that means that each must be represented by a number between 0 and 255. The intervals have to be wide enough so that noise will only rarely boost a signal across an interval, or subtract enough to drop a signal to the level below. Hence the relationship between noise strength and the number of bits representing a given signal.

In a real system, the level of representation chosen is based on the physical capacity of the system (e.g., the size of the words the computer can handle). For example, early digital sonars used clippers, which turned each data point into a 0 or 1, simply because they could not accommodate more detailed data.

A digital system must contend, then, with the effects of rounding off numbers as they are passed through more and more stages of computation. An analog system suffers from physical noise introduced as signals representing numbers pass from devices representing any one operation to devices representing another; it may also suffer from imprecision in translation from one kind of physical analog to another, as in an electro-mechanical computer. The digital system overcomes physical noise in transmitting the signals representing digits by adding extra check bits, such as parity bits; changes in the parity bits alert it to errors in transmission. There is no analog equivalent.

The great advantages of digital operation are fully realized only when data from all of a ship's sensors can be processed together and used together to drive displays and weapons. That in turn entails precise timing and rigidly defined signal standards. All the signals are discrete, and all of them have to be kept distinct. That is easy within a computer, but a ship whose combat system is built around a digital computer must use data from many different sensors and sources, each with its own analog-to-digital converter. When digital computers began to appear in U.S. naval weapons systems in the 1960s, problems were encountered in tying together devices that had never been designed to work together. This experience explains some of the pressure to develop new, fully digitized versions of radars and sonars. It also explains why it is relatively difficult to fit an existing ship with a fully integrated digital CCS. Even combinations of different digital machines may encounter timing problems.

DESIGNATION SYSTEMS

AUSTRALIA

Australia uses the U.S. triservice (AN) designation system, but numbers are in an 800 series, e.g., the Barra sonobuoy is SSQ-801.

CANADA

The Canadian government uses the U.S. triservice (AN) designation system, but numbers are in a 500 series. Thus SPS-501 is the first, not the 501st, Canadian naval radar.

FRANCE

The French government uses a unified triservice electronic designation system, similar in spirit to the U.S. AN system. Each piece of equipment is designated by four letters (the quadrigramme) and a number, with a letter suffix to indicate modifications. The first letter indicates the main function; the second, the process employed; the third, the normal mode of installation; and the fourth, the particular function of the system. In contrast to the AN system, the third and fourth letters can change depending upon the main function.

In addition, in at least some cases, letters are assigned in blocks that further describe the equipment.

Radars in the 10-19 block are X-band; the 20-29 block indicates either L- (20 cm) or P- (2 m) band; the 30-39 block indicates X-band; and the 50-59 block indicates C-band (5 cm).

Sonars in a 20-series are hull mounted; sonars in a 40-series are towed fish; sonars in a 60-series are towed arrays.

MAIN FUNCTION LETTERS (FIRST LETTER)

A	electronic warfare
B	test equipment
C	switchboard (commutation)
D	detection
E	transmitters (emitters)
F	electric generators
G	mine countermeasures
H	not used
I	information processing
J	imagery (electro-optics)
K	not used
L	not used
M	measurement
N	navigation
Q	miscellaneous, not covered in other categories
R	receivers
S	fire-control systems
T	transceivers
V	guidance (for weapons)

PROCESS LETTERS (SECOND LETTER)

A	artillery (fire control)
B	chemical energy (batteries, etc.); ballistic missiles (fire control)
D	doppler
E	wind generators; electricity (measurement)
F	wire (<i>fil</i> , in French)
G	gyroscopic; gas generators
H	magnetic
I	infrared and light intensification
J	inertial; bombing (fire control)
L	laser; mechanical generators
M	mixed; missiles (fire control)
N	nuclear and radioisotope
P	fluidic, hydraulic
R	radio-electric or electronic
S	sound; solar generators
T	thermal generators; television and CRT; torpedoes (fire control)
U	ultrasonic; electric
X	other processes
Z	satellite communication

SPECIAL PROCESS LETTERS FOR INFORMATION PROCESSING (SECOND LETTER)

A	analog
B	magnetic band
C	magnetic card
D	magnetic disk
E	magnetic memory element
G	magnetic drum
K	punched card

- M analog/digital
- N digital (numerical)
- O microfilm; optical memory
- P paper
- R punched tape
- S semiconductor memory
- T cathode-ray tube

MODES OF INSTALLATION (THIRD LETTER)

- A aircraft
- B surface ship (*bâtiment*)
- C man-carried (*cadre*)
- D vehicles and man-portable
- E missile
- F fixed
- M mobile
- N surface ships and submarines
- P man-portable (*portatif*)
- R submerged
- S semifixed
- T portable
- U submarine
- V vehicle

PARTICULAR FUNCTIONS (FOURTH LETTER)

- A analysis (identification); countermeasures; signaling device; attack (sensors and imagery); in generators, 400 Hz; self(auto)-protection (mine warfare); measurement of voltage and current; landing (*atterrissage*) in navigation; amplification; direction (*asservissement*) in fire control
- B jamming; in generators, direct current for battery-charging; in mine warfare, buoys; non-electrical measurements (e.g., acoustic); information processing (fire control)
- C multiplex; fire control; generator control; in mine warfare, classification; calculation (computing); positioning in curvilinear coordinates (navigation) (i.e., Loran-like systems); vector control (fire control)
- D surveillance—alert; detection; power distribution; in mine warfare, sweeping (*dragage*); coding (computing); detection (imagery); distance measurement (navigation)
- E listening; emission (in test equipment and in guidance); scouting; in generators, 50 Hz for electronic equipment; writing-recording (computer); standards of measurement; illumination (navigation); engagement (fire control)
- F frequency measurement; facsimile; telephone-telegraph (test equipment)
- G direction finding (goniometry); graphics; in generators, 50 Hz for general use; mine warfare (test equipment); signal generators (measurement); electrical distribution (fire control)
- H radio; in generators, 60 Hz for general use; printing (impression) for computers; hyperfrequency measurement (spectral analysis, envelopes, noise factors, etc.); vertical measurement (navigation)
- I identification
- J interception; information transmission; in mine warfare, immunization; accelerometry (navigation)
- K calculator; radioactivity (sensors and imagery); in generators, energy conversion; data conversion (computers); guidance (including autoguidance and wire guidance) in fire control
- L deception; security; in mine warfare, localization; reading (computers); measurement of semiconductor tube and crystal characteristics; localization and pursuit in fire control
- M mixed; also mines; in mine warfare, mine-hunting; input/output (computers); oscilloscopes (measurement); modems (miscellaneous equipment); management (fire control)

- N navigation; also teletype; in mine warfare, neutralization; bearing measurement (navigation); control of nuclear explosives (fire control)
- O in mine warfare, obstruction (antisweep)
- P telephony; in generators, production of direct current for various purposes; perforation (computers); pursuit (imagery); bridges for electrical measurement; position in polar coordinates (navigation)
- R localization, reception; missile guidance (sensors and imagery); reproduction (computers); marking (navigation); reception (fire control)
- Q indicators for measurement (galvanometers, magnetometers, etc.)
- S weapons system; also position—altitude (sensors and imagery); translation (computers); analysis of low-frequency signals (measures of distortion, phase, wave analysis, etc.); altimetry (*sondage*; navigation)
- T transceiver; teleprinters; terrestrial objects (sensors); sorting (triage) for computers; marking (imagery); test or multifunction equipment (measurement); position in geographical coordinates (navigation); launching or firing (fire control)
- U regulation of direct current; general functioning (fire control)
- V guidance (command); television; surveillance (*veille*, in sensors); in mine warfare and in computers, imaging (visualization); speed measurement (navigation); display of the tactical situation (fire control)
- W propulsion, energy; visiphone; meteorology; in mine warfare, surveillance; verification (computers); power measurement (wattmeter)
- X special; testing (fire control)
- Y teletype; information storage (computers); miscellaneous, special (fire control)
- Z training

GERMANY (WEST)

West Germany follows the U.S. AN designation system for shipborne sonars, except that all are prefixed D (Deutsch), as in DSQS-21. The serially assigned numbers do not coincide with U.S. numbers and are assigned in blocks (e.g., in sonars, the 11-series for minehunting sonars and the 21-series for search sonars).

ITALY

For naval radars, Italy uses the U.S. triservice (AN) system of designators, with the prefix MM (Marine Militare), with a 700-series, e.g., MM/SPS-768. There are also company designators. It appears that blocks of numbers within the overall series are reserved for special applications, as some of the numbers are too high to reflect a single sequence. It also appears that all naval radars and other electronic equipment, whether air- or shipborne, are in the same single numerical sequence.

Air force electronic equipment is designated in a 200-series.

JAPAN

Japan uses the U.S. triservice (AN) system of designators, except for different platform letters:

- E other
- H aircraft (sonobuoy and dipping sonar applications)
- L land-based fixed
- O surface ship
- R small, portable
- Y general use
- Z undersea (submarines, but also minehunting surface ship sonar)

The prefix N (as in NOLR-1) indicates a combination of other equipment. In many cases with electronics, the U.S. system is used with the prefix J, as in JVRC or JAN/GRC for a radio transceiver. In some cases U.S.-supplied (or license-built) equipment retains its U.S. designation; in others, it is redesignated with a J prefix.

In some cases a Type number system is used, e.g., Type 1 fire-control system. However, most Type numbers indicate the date of designation (not production) in terms of Japanese Fiscal years. Thus Type 63 is a designation adopted during Japanese Fiscal Year 1963. The Japanese fiscal year runs 1 April–31 March and is designated by the calendar year in which the FY begins (e.g., JFY63 began on 1 April 1963). This system corresponds to British practice and is 6 months away from the U.S. fiscal year (which runs 1 October–30 September).

Finally, equipment under development is given a serial designation, with a prefix: G for torpedo, K for mine, S for sweep gear. Thus a torpedo developed as G-9 was adopted for service as Type 73.

NETHERLANDS

Dutch naval electronic systems are generally developed by Hollandse Signaal Apparaten (HSA), and it is not altogether clear whether the HSA designations are imposed by the Royal Netherlands Navy. Radars are divided into

DA target indication (*doels aanwijzing*)

LW air search (*lucht waarschuwing*)

ZW sea search (*zee waarschuwing*)

Fire-control systems, both for surface ships and for submarines, are designated by the letter M and by a number; in some cases the combination WM is used. The numbers are not in sequence of development, but often indicate alternative (and roughly contemporary) levels of capability.

TAIWAN (GRC)

Taiwan uses the U.S. AN system, except that equipment is prefixed CS, as in CS/SPG-24; CS stands for the equivalent of the U.S. Defense Advanced Research Projects Agency.

USSR

All Soviet equipment is developed by design bureaus, and each bureau maintains an internal designation series. In addition, equipment accepted for service use is given a service designation. The chief example is aircraft designations. Published histories of Soviet aircraft design provide numerous examples of internal (bureau) and service designators, e.g., Tu-95 and Tu-20 for the same bomber (Bear). A recent Polish history of the MiG bureau provides a few internal numbers for air-to-surface missiles, and there is reason to believe that the practice is universal. Many Soviet weapons seem to have acquired names, either as covers for designations or as popular references. Finally, Soviet economic planning requires that each product within the economy be assigned what amounts to a national part number, identifying the item by producing ministry. Few of these numerical designations have ever been made public.

Very few of these internal Soviet designations, of whatever type, have become public knowledge. Typically, therefore, NATO has assigned reporting names and numbers. The numbers are in a NATO-generated sequence and may not include prototypes or, in some cases, weapons fielded in small numbers or covertly. Since they reflect the dates on which weapons are first observed, the sequence of the numbers may not reflect the development sequence. The chief series are:

AA air-to-air missiles

AS air-to-surface missiles (both strategic and tactical)

SS surface-to-surface missiles (both strategic and tactical).

Some reporting designations may or may not reflect Soviet practice. For many years Soviet unguided antisubmarine rockets have been designated RBUs, the number indicating the nominal range. These are probably actually the Soviet designators. The few reported Soviet torpedo designators seem to reflect Soviet rather than NATO practice, but some of them do not really fit any obvious system.

NATO's reporting names for Soviet electronic equipment often reflect either signal characteristics or physical appearance. For most naval systems, they combine an animal's name with some physical characteristic.

UNITED KINGDOM

The Royal Navy uses a Type Number system, originally adopted for radio sets. Equipment is designated in blocks, e.g., 900 for naval radars (1945–65, roughly). There is some evidence of blocks within these series, so that numbers are not sequential. For example, Type 992 was developed well before Type 967. In addition, some numbers are left blank, either to allow for improvements or for security purposes. When a block is exhausted another is designated. Modifications are indicated by suffixes but not all letters are used. Nor are they necessarily in alphabetical order. Typical radar modification letters are M, P, Q and R.

Some aircraft-related systems are designated in the NATO triservice AN series, in a 900 block (e.g., the AQS-903 acoustic processor).

The chief current blocks are:

1–99	radios, etc., through about 1945
100	sonars, up through the 1960s
200	World War II naval radars and IFF
600	radio transmitters and jammers
700	hydrophones
900	radars, post-1945
1000	radars, from the 1950s on
1200	VHF/UHF radio transceivers (recently opened)
2000	modern sonars

From 1945 on special designations were used for complete weapons-related systems (with sequence numbers, to indicate versions). Some of the following are obsolete, but most survive in one way or another.

ADAWS	Action Data Automation Weapon System
CACS	Computer-Assisted Command System (ADAWS successor)
CDS	Comprehensive Display System (analog predecessor to ADAWS)
DPT	Digital Plot Transmission (predecessor to Link 10/11)
FPS	Flyplane Predictor (computer) System (gunfire control system, including radar and director with Flyplane computer; replaced by MRS)
GDS	Gun-Direction System (now obsolete)
GSA	Gun System Automation
GWS	Guided Weapon System. The GWS series is divided into blocks:
GWS 1	area defense (Sea Slug)
GWS 20 series	point defense (Sea Cat, Sea Wolf)
GWS 30 series	area defense (Sea Dart)
GWS 40	ASW (Ikara)
GWS 50	antiship (Exocet)
GWS 60	antiship (Harpoon)

Subsystems are designated by the overall GWS designator, e.g., Sea Slug used a Mk 1 missile launcher, but Sea Cat (GWS 20 series) used Mk 20, and Sea Dart, Mk 30.

LRS	Long-Range (gun) System (defunct)
MDS	Missile-Direction System (MDS 1 for Sea Slug)
MRS	Medium-Range (gun) System
TCS	Torpedo-Control System (surface ship)
TCSS	Torpedo-Control System (submarine), now superseded by computer systems
UCS	Underwater Control System (for mortars, torpedoes)
WSA	Weapon System Automation (e.g., gun and missile)

Electronic *outfits* are designated by 2 or 3 letters, the first letter indicating the role. The second letter indicates the category within the role. Second letters were not assigned sequentially; in some cases they are mnemonics (e.g., AWA, for a wide antenna). Third letters (if assigned) are sequence letters within the series. The main examples are:

- A antenna (radio and radar), as in ANU
- C radio receivers, e.g., CUH; includes COMINT (HF, VHF)
- D computer system; DB series for surface ships and DC for submarines. This prefix is also used for decoys (DL series).
- F radio direction-finders; FH series for HF, FM for MF, FV for VHF, in each case with a numerical suffix, as in FH-4. Radar (SHF) direction-finders are prefixed U, as below.
- H teachers; but HO indicates a Hull Outfit (sonar dome), always HO with a number
- K distribution control (internal communication switchboard), e.g., Outfit KMY in a Type 23 frigate
- L radar track extractors (e.g., LFA for Type 996 radar of a Type 23 frigate)
- J radar display, with 1 or 2 additional letters
- Q some displays
- R data link (e.g., Outfit RBB for helicopter transponder; Outfit RJL(1) is the LAN for the Type 23 frigate command system); also sound recorders and reproducers
- T transmitters, when part of a larger system
- U ESM, with 1 or 2 additional letters, e.g., UAP
- Y electronic subsystems

In many cases, particularly in electronic countermeasures, the system has a code name, and it is not always clear whether there is any associated designation. More generally, most British weapons have names rather than numerical designators. However, some are described by their Naval Staff Requirement (NSR) or Staff Target (NST) or corresponding Air Staff designators, generally a four-digit figure. Reportedly, these numbers are applied randomly; presumably they are required for computerized accounting. With the amalgamation of service purchasing under a unitary Ministry of Defence, practice has changed and now there are Staff Requirements (Air) and (Naval) (and corresponding Staff Targets), each with a three-digit suffix.

UNITED STATES

U.S. electronic equipment is designated by 3 letters in an AN (triservice, originally army-navy) series. The first indicates the platform, the second the type of equipment, and the third the function. Numbers run in sequence within each designation, so that there can be both an SPS-49 radar and an SQS-49 sonar. In each case, the full designation is prefixed by the letters AN (multiservice), e.g., AN/SPS-49; the first 2 letters will generally be omitted. In a very few cases, examples of an earlier system survive: Mark numbers applied to fire-control radars (e.g., Mk 13 on board the battleships). These numbers fit the postwar SPG-series, with Mk 49 becoming SPG-49, for example. However, they were never retroactively identified within the AN series.

Experimental versions of equipment are indicated by a 2-letter code denoting the developing agency. Thus SPS-49(XN-1) would be the first Navy Department (i.e., contractor) prototype of the SPS-49 radar. The other major navy suffixes are XB, for the Naval Research Laboratory; SG, for the Naval Ocean Systems Center in San Diego; XJ for the Naval Air Development Center, Warminster, Pennsylvania; XU for the Naval Underwater Systems Center, New London; XAN for the Naval Avionics Center, Indianapolis; XCA for the Naval Weapons Center, Crane; XCL for the Naval Weapons Center, China Lake; XDV for the Naval Surface Weapons Center, Dahlgren; XGS for the Ground Support Division (Naval Air Engineering Center), Lakehurst; XIH for the Naval Ordnance Center, Indian Head; XMG for Point Mugu; XUC for the Naval Undersea Center, San Diego; XPC for the Naval Coastal Systems Laboratory, Panama City; XWH for the Naval Weapons Station, Earle; and XWO for the Naval Surface Weapons Center, White Oak. The suffix XZ was used for the old Bureau of Naval Weapons.

Different versions of systems are indicated in 2 ways. Originally, each version had its own suffix letter, e.g., SPS-6C as

compared to SPS-6B or -6D. More recently, a distinction has been made between variable systems, which differ by deletion or addition of subcomponents, and modifications that are interchangeable with earlier versions. Variable systems are indicated by (V) plus a number, as in SPS-49(V)5. Modifications are indicated by suffix letters, as before.

Parts of systems, or subgroups of equipment, receive 1- or 2-letter designators, e.g., CP for a computer or OL for an indicator. Sometimes the designation is written out to include the designator of the associated system, e.g., TB-16/BQQ is a towed body that is part of several BQQ-series submarine sonars. Typically, parts of systems are distinguished from subsystems (groups), but both are designated in this way.

U.S. missiles and rockets are also designated within a triservice (3-letter) system, but in this case each number is used only once. In some cases, such as Harpoon, the 3-letter designator is actually changed to reflect a different application of the same basic weapon. In recent years weapons' designators often have not been made public until very late in the development process (for example, veterans of the Sea Lance program cannot recall ever having seen a standard designator). This practice may have been adopted to conceal gaps in the list denoting highly classified ("black") programs such as stealth weapons. Code names are published, for budgetary reasons, but without any indication of their significance, and one name may cover several weapons (or vice versa).

U.S. aeronautical equipment (such as bomb guidance units, missile launchers, and warheads) is designated within a system developed by the U.S. Air Force in 1960. Although it superficially resembles the missile designation series, that air force system is entirely different, having been designed to embrace not only equipment carried on board aircraft but also ground-based materiel such as tractors and fuel tanks. This system does not include jet and rocket engines or photographic equipment. As might be expected of so broad a system, it is cumbersome (the air force initially wanted to expand the AN system to cover all aeronautical items, but the Office of the Secretary of Defense rejected that as unwieldy). Equipment is denoted by an initial letter A/, then by a 3-item code. Aircraft components are designated by 3 letters, the last of which is K. Aircraft-associated units are designated by 3 letters, the last of which is U. In the case of ground equipment, the designator consists of a letter indicating the type, a 2-digit number, and a letter indicating function, e.g., A/S32P-5, the fifth self-propelled (S), mechanical (32), protective (P) device (in this case, a fire truck). The only example in this book is A/N37U, a sweep-control device.

In the case of aircraft or missile units, the first 2 letters form a code, and designations include a letter after a slash to indicate the installation. The most important 2-letter codes and installation codes are indicated below.

This system was not applied retroactively, so designations such as Bomb Mk 82 survive.

Finally, in accordance with older procedures, U.S. naval weapons (and many systems' components) other than missiles themselves are organized by Mark number. Marks are applied, for example, to fire-control systems (and, separately, to gun directors), to gun mounts (in sequence whatever the caliber), to missile-launching systems (and, to add to the confusion, to the launchers proper), to rocket motors, to torpedoes, to warheads, and to weapons systems (built around unified control systems) as a whole. Examples of the latter are Mk 7 for Aegis and Mk 15 for Phalanx (see the table below). In at least some cases, Mark series were blocked to differentiate underwater from surface systems, e.g., Mk 101 was an underwater fire-control system, not the 101st fire-control system. However, when the original series reached 100, it continued interleaved with the special underwater series.

In addition, all U.S. nuclear weapons are assigned Mark numbers (by the Department of Energy, formerly the Atomic Energy Commission). Any application of a weapon is indicated by a prefix letter, e.g., the B77 bomb would be a bomb version of the Mk 77 warhead, and W77 would be the same weapon configured

as a missile warhead. Similarly, all reentry vehicles seem to have Mark numbers in a single series.

1. ELECTRONICS (THE "AN"-SERIES):

◆ Platform Letter

A	airplane
B	submarine ("boat")
C	air-portable (obsolete)
D	missile ("drone")
F	fixed
G	ground use (general)
K	amphibious
M	ground-mobile
P	man-portable
S	ship (or water surface)
T	ground-transportable
U	universal (land/water)
V	ground (vehicular)
W	waterborne (surface/submarine)
Z	piloted and pilotless airborne vehicle combination

◆ Type of Equipment

A	infrared
B	pigeon (obsolete)
C	carrier (wire)
D	radiac
E	nupac (obsolete)
F	photographic (not for U.S. use)
G	telegraph, teletype
I	interphone or public address
J	electro-mechanical or inertial wire covered
K	telemetry
L	countermeasures
M	meteorological
N	sound in air
P	radar (pulsed)
Q	sonar and underwater sound
R	radio
S	special, magnetic, etc. (or combination)
T	telephone (wire)
V	visual
W	weapons
X	facsimile or television
Y	data processing (integration of sensors)

◆ Function

A	auxiliary equipment (e.g., antennas, displays)
B	bombing
C	communications (transceiver)
D	direction finding, surveillance
E	ejection or release
G	fire control (gunnery) and searchlight direction
H	recording/reproducing
K	computing
L	searchlight control (obsolete)
M	maintenance and/or test
N	navigational
P	reproducing (obsolete, use H)
Q	multifunction or special
R	receive (passive detection)
S	search
T	transmit (e.g., jam)
W	weapons control
X	identification (IFF)
Y	multifunction (phased-array radar)

GROUP INDICATORS

OA	miscellaneous
OD	indicator
OE	antenna
OG	amplifier

OH	simulator
OJ	consoles
OK	control (used in towed-array reeling equipment)
OL	data analysis and data processing
OM	modulators, demodulators
OP	power supplies
OR	receivers
OT	transmitters
OU	converters
OV	generators
OW	terminals
OX	coders, decoders, interrogators, transponders
OY	radar sets (not to be used if more specific indicators apply)
OZ	radio sets (not to be used if more specific indicators apply)

COMPONENT INDICATORS

AM	amplifier
AS	antenna
AT	antenna (now obsolete)
BA	battery (primary)
BB	battery (secondary)
CA	computer (auxiliary parts)
CD	controlling device
CP	computer
CU	coupler
CV	converter (e.g., from frequency to frequency, or medium to medium)
CW	radome
DA	dummy load
DT	detecting head (e.g., hydrophone)
F	filter (electrical or electronic)
FR	frequency measurement
G	generator
GO	goniometer (DF device)
J	interface
KY	keying device (used for cryptographic devices)
LS	loudspeaker
M	microphone
MD	modulator, demodulator
ML	meteorological device
MU	memory unit
O	oscillator
OC	oceanographic device
OS	oscilloscope
PL	plug-in unit
PP	power supply
PT	mapping and plotting unit (electronic)
PU	power equipment
R	receiver
RD	recorder-reproducer
RL	reeling machine
RO	recorder
RP	reproducer
RR	reflector
RT	receiver/transmitter
SA	switching unit
SB	switchboard
SG	signal generator
SM	simulator
SU	optical unit (electro-optical)
T	transmitter
TA	telephone
TB	towed body (e.g., in towed array or MAD)
TD	timing device
TF	transformer
TG	positioning device
TH	telegraph
TR	transducer
TT	teletype, facsimile
V	vehicle

2. MISSILE-ROCKET DESIGNATIONS:

◆ Launch Environment

A	airplane
B	multi-environment
C	coffin
F	infantry
H	silo-stored (fired from surface)
L	land (fixed silo)
M	mobile
P	soft pad
R	ship
U	underwater

◆ Function

D	decoy
E	special electronic
G	surface attack
I	intercept (antiaircraft)
Q	target drone
T	training
U	underwater attack
W	weather

◆ Type

M	missile (guided)
N	probe
R	rocket

3. AIR EQUIPMENT DESIGNATIONS:

◆ Two-Letter Code

BB	explosive items (not warheads)
BD	bombs, simulated (dummy)
BL	bombs, aircraft (live)
BN	buoys
BR	bomb racks, shackles
BS	munitions stabilizing and retarding devices
CB	cluster bomb unit, consisting of a clustering device or dispenser (SUU) and bomblets (BLU or BDU); may function on board the airplane or after it is dropped
CD	clustering device containing bomblets to be dispensed from an SUU; may or may not be required to make the BLU/BDU compatible with the dispenser (SUU)
CP	computer
CY	cartridge case
DS	target detector (e.g., in proximity fuze)
DT	timing device (e.g., intervalometer)
FM	fuze, munitions
GA	gun, aircraft (e.g., in gun pod)
GB	guided bomb
GD	dummy guided missile (for training)
GP	gun pod (GA plus SUU)
GT	gun turret (excludes gun pods)
GU	guns, non-aircraft
KA	unfilled clustering device
KB	simulated cluster bomb unit
KD	simulated clustering device
KM	miscellaneous kits (used for early "smart" bombs)
LA	launcher, aircraft (e.g., missile rails)
LK	links, ammunition
LM	launching mechanism, ground
LU	illumination (light) (e.g., searchlight)
MA	miscellaneous armament
MJ	countermeasures munitions (e.g., bombs containing chaff or flares)
ML	miscellaneous live munitions
PA	external munitions dispensers (e.g., pods, tanks, clip-ins or other devices mounted externally)
PG	gun ammunition
PJ	projectiles
PW	internal munitions dispensers

RB	rocket and launcher units (combination of LAU and conventional rockets, RLU; excludes CBU)
RL	rocket, live (e.g., FFAR, HVAR)
RV	reentry vehicle (dummy or practice type)
RW	reentry vehicle (live)
SA	sights, gun-bomb-rocket
SP	self protection (as in the SPU-1/W Magnetized Orange Pipe for aerial minesweeping)
SU	suspension and release unit stores (munitions dispenser); may provide a clustering device (CD) to provide compatibility with the ordnance being transported; also may be a CBU less its BLU's
TD	target devices
WA	warhead section
WB	body section
WC	control section
WD	loaded warhead
WE	empty warhead
WG	guidance section
WP	propulsion section
WT	training or dummy warhead

◆ Application Code

A	aircraft or missile
B	aircraft or missile transported (mission expendable)
C	combined air and surface
E	ground (not fixed)
F	ground (fixed)
M	ground movable
N	aircraft or missile transported (not mission expendable)
P	personal use
S	ground, self-propelled
U	multi-installation
W	waterborne (surface or submerged)

4. WEAPON SYSTEM MARK NUMBERS

Mk 1	Weapons Control System (Typhon; abortive)
Mk 7	Aegis
Mk 15	Phalanx (CIWS)
Mks 20-24	TAS (Target Acquisition System; only Mk 23 entered service)
Mk 31	RAM (RIM-116 missile)
Mk 32	Tomahawk (ABL launcher)
Mk 33	DD 963 5-in-gun system using guided shells
Mk 34	DDG 51 class 5-in-gun system
Mk 35	SEAL boat gun system (abortive, for SWCM boat) using 25-mm gun in EX-90 mount, with remote sighting and control
Mk 36	Tomahawk submarine-launched missile system (Mk 44 launching system) using SWG-2 control
Mk 37	Tomahawk vertically launched missile system, using SWG-3 control
Mk 38	Dragon III assault missile, for marines
Mk 39	Iowa class 5-in/38 gun system
Mk 40	Iowa class 16-in/50 gun system

Many of these designations were applied ex post facto for convenience in referring to the system as a whole.

ABBREVIATIONS

A-Scope	radar display (range only)
AA	antiaircraft, also active adjunct (sonar)
AAC	antiaircraft common (ammunition)
AAM	air-to-air missile
AAW	antiaircraft warfare
ABF	advanced bomb family (U.S.)
ABM	anti-ballistic missile
ABRS	assault ballistic rocket system (U.S., by LTV)
ACINT	acoustic intelligence

ACLS	automatic (aircraft) carrier landing system	ASIC	application-specific integrated chip
ACM	antiarmor cluster munition	ASLCM	advanced sea-launched cruise missile
ACQ	acquisition	ASM	air-to-surface missile
ADA	new U.S. standard military computer language	ASMD	antiship missile defense
ADAC	French airborne radar designation; also U.S. all-digital attack center (in submarines)	ASMP	French air-launched strategic cruise missile
ADAR	adaptive receiver for horizontal line array (HLA) sonobuoy (U.S.)	ASP	airborne signal processor; also advanced signal processor
ADAWS	action data automation weapons system (British)	ASPJ	airborne self-protection jammer (U.S.)
ADF	auxiliary detonating fuze	ASROC	antisubmarine rocket (U.S.)
ADI	air-defense initiative (U.S.), complement to SDI	ASSM	abortive multinational antiship missile project of the 1970s, forerunner of the current ANS project
ADT	automatic detection and tracking	ASTAB	automatic status board
ADVCAP	advanced capability (version of EA-6B aircraft)	ASUW	antisurface (ship) warfare
AE	active enhancement (U.S. sonobuoy program)	ASW	antisubmarine warfare
AEM	adaptive energy management	ASWS	advanced standoff weapons system (U.S.)
AERP	active emission receiver processor (U.S., for sonar)	ATA	advanced tactical aircraft (U.S. A-12)
AEW	airborne early warning	ATB	advanced technology bomber (U.S. B-2)
AGC	automatic gain control (ECCM measure)	ATC	air-traffic control
AGPB	advanced general-purpose bomb	ATD	automatic target detection
AGPO	angle-gate pull-off (ECM technique)	ATF	advanced tactical fighter (U.S. F-22 or F-23)
AI	artificial intelligence	ATI	airborne tracker-illuminator
AIMS	IFF Mk XII system (U.S.); also advanced integrated MAD system (Canadian)	ATLIS	French laser designation pod
AIO	action information organization (British term for CIC)	ATT	automatic target tracking, also acoustic target tracker
AIWS	advanced interdiction weapons system (U.S.)	AUWE	Admiralty Underwater Weapons Establishment (British)
AJ	antijam (communications)	B-Scope	radar display (rectangular plot of range vs. bearing)
ALCM	air-launched cruise missile	BAC	British Aircraft Corporation
ALFS	airborne low-frequency sonar (U.S. program)	BAe	British Aerospace
ALWT	advanced lightweight torpedo (U.S. Mk 50)	BB	bottom bounce (sonar)
AM	amplitude modulation (as opposed to FM)	BBC	broad-band chaff
AMCM	airborne mine countermeasures	bbl	barrel (e.g., of a gun)
ammo	ammunition	BDF	base-detonating fuze
AMRAAM	advanced medium-range air-to-air missile (U.S. AIM-120)	BDI	bearing-deviation indicator (for target following in sonar)
AMTI	airborne moving target indication	BGAAWC	battle-group AAW coordinator (U.S.)
AM-X	joint Italian-Brazilian attack aircraft	BHP	brake horsepower
ANL	automatic noise leveling (ECCM technique)	BIT(E)	built-in test (equipment)
AP	armor piercing	bit	binary digit (0 or 1)
APAM	antipersonnel/antimatériel	BL&P	blind-loaded and plugged (inert target ammunition)
APDS	armor-piercing discarding sabot (ammunition)	BN	bombardier navigator
APFDS	armor-piercing fragmenting discarding sabot (ammunition)	BPDMS	basic point-defense missile system (U.S.: Sea Sparrow)
APFSDS	armor-piercing fin-stabilized discarding sabot (ammunition)	BT	bathymograph, to obtain a temperature profile of the sea
APHE	armor-piercing high-explosive (ammunition)	BVR	beyond visual range (in air-to-air combat)
APHE-SD	armor-piercing high-explosive self-destruct (warhead)	byte	hexadecimal digit (eight bits, i.e., base-64 digits)
API	armor-piercing incendiary (ammunition)	ca.	circa
API-T	armor-piercing incendiary tracer (ammunition)	C ²	command and control (C-squared)
approx	approximately	C ³	command, control, and communications (C-cubed)
ARBS	angle-rate bombing system (U.S. AN/ASB-19)	C3I	command, control, communications, and intelligence
ARE	Admiralty Research Establishment (British)	CAAIS	computer-assisted action information system (British)
ARM	antiradar missile	CAD	computer-aided design
ARP	antiradar projectile	CAINS	carrier aircraft inertial navigation system
ASAM	advanced surface-to-air missile, generic U.S. term	CAIR	countermeasure, airborne, IR
ASALM	advanced strategic air-launched cruise missile (U.S.)	CAM	computer-aided manufacture, often combined with CAD (in CAD/CAM)
ASAT	antisatellite (weapon)	CANE	computer-aided navigational equipment (British)
		CANCASS	Canadian command-activated sonobuoy (CASS)
		CASS	command-activated sonobuoy system
		CATIC	China Aero-Technical Import and Export Corp.

CBU	cluster bomb unit	dBm	decibel-milliwatt (measure used in ECM)
CCD	charge-coupled device (electronic component)	DC	direct current, also depth charge
CCS	combat-control system	DCAN	Direction Construction Armes Navale (French)
CCTV	closed-circuit television	DCN	Direction Construction Navale (French)
CDC	command-display console	DCU	distributed computing unit
CDS	combat-data system	DECM	defensive (also deceptive) electronic countermeasures
CEM	combined effects munition	deg	degree
CEP	circular error probable (half of all shots will fall within this radius)	DELEX	destroyer life-extension program (Canadian)
CFA	crossed-field amplifier (radar transmitter)	DEMON	demodulated noise (ASW signal-processing technique)
CFAR	constant false-alarm rate (in radar)	DF	direction finding
CIC	combat information center (U.S.; equivalent to operations room [British])	DFT	discrete Fourier transform
CIGARS	console internal generation and refresh system, modification to U.S. UYA-4 console of NTDS system	DGA	Delegation Generale pour l'Armement, the French government organization responsible for weapons development for all 3 services
CIWS	close-in weapons system	DICANCASS	Canadian DICASS sonobuoy (ASW)
CLOS	command to line of sight (missile guidance)	DICASS	directional command-activated sonobuoy (ASW)
CMOS	complementary metal-oxide-semiconductor (type of computer-chip technology)	DIFAR	directional LOFAR (in ASW)
CNO	chief of naval operations (U.S.)	DIGISMAC	digital scene-matching (cruise-missile guidance); also abbreviated DSMAC
CO	commanding officer	DIMUS	digital multibeam steering (ASW)
CODAR	correlation display analyzing recorder (ASW), to obtain position data by correlating the outputs of 2 or more passive sonobuoys	DLC	down-link communications
COMINT	communications intelligence	DLIR	downward-looking infrared
conscan	conical scan (in radar)	DMA	direct memory access
COOP	craft of opportunity program (generally in minesweeping)	DMCC	dual maintenance of close contact (sonar)
CORT	coherent receive/transmit (in radar)	DME	distance-measuring equipment (passive; U.S.)
CPA	closest point of approach	DMT	dual-mode tracker
CPIC	coastal patrol and interdiction craft (U.S.)	DMTI	digital MTI
CPMIEC	China Precision Machinery Import/Export Corp.	DND	Department of National Defence (Canadian, Australian)
CRBFD	close-range blind-fire director (British)	DoD	Department of Defense (U.S.)
CRT	cathode-ray tube (display)	DOP	Development Options Paper (U.S.)
CRZ	controlled-reaction zone	DP	dual-purpose
CP	command-plotting/plotter	DRAI	dead-reckoning analyzer/indicator (submarine)
csc ²	coscant-squared, a typical vertical shape for radar beams; it provides constant power at a given altitude at all ranges. The expression "30 deg csc ² " means a beam that has cosecant-squared shape up to 30 deg of elevation.	DRAM	dynamic random-access memory
CSDC	combat system display console (U.S.)	DRARM	dual-role ARM
CSEDS	combat system engineering development site (U.S.)	DRT	dead-reckoning tracer
CSLC	coherent sidelobe-canceling receiver	DSARC	Defense System Acquisition Review Council (U.S.)
CSU	compact sonar for submarines (U-boats) (German)	DSCS	Defense Satellite Communications System (U.S.)
CU	control unit	DSMAC	see DIGISMAC, above
CVR	crystal video receiver	DT	directional transmission (in sonar)
CVT	controlled variable time, for a fuze	DTCN	Direction Technique Construction Navale (French)
CW	continuous wave (nonpulsed); also chemical warfare	EAC	equal angle coverage
CWAT	CW acquisition and tracking	ECM	electronic countermeasures
CWI	continuous wave illuminator/injection	ECCM	electronic counter-countermeasures
CZ	convergence zone (sonar)	EDATS	extra-deep armed team sweep (British)
DARPA	Defense Advanced Research Projects Agency (U.S.)	EDM	engineering development model
DASH	drone antisubmarine helicopter (U.S. QH-50, obsolete)	EEPROM	electrically erasable programmable read-only memory (in a computer, ROM that can be electrically erased for reprogramming; it cannot be erased by the computer itself, hence is read-only)
dB	decibel, a measure of relative size; it is 10 log (base 10) of a ratio. Thus, 3 dB is a factor of about 2, and 10 dB a factor of 10; -3 dB is about a half. The reference value in the ratio is often implicit, as in radar, when it is the performance of a notional antenna radiating power equally in all directions.	EEZ	exclusive economic zone (defined by Law of the Sea Treaty)
		EFA	European fighter aircraft (multinational project)
		EHF	extremely high frequency
		ELF	extremely low frequency
		ELINT	electronic intelligence
		EMCON	emissions control (electromagnetic silence)
		EMATT	expendable mobile ASW training target (U.S.)

EMI	electromagnetic interference; also the name of a British electronics manufacturer	GFCS	gunfire-control system (U.S.)
EMSP	enhanced modular signal processor (U.S.)	GHG	Gruppen-Horch Gereat (array listening system), the wartime German low-frequency passive sonar from which several postwar systems were derived
EMP	electromagnetic pulse		
EMR	extended memory reach (in a computer)	GHz	gigahertz (thousands of MHz)
EO	electro-optical	GMFCS	guided-missile fire-control system (U.S.)
EPROM	erasable programmable read-only memory	GOPS	billion (giga) operations/sec (for computers)
ERAPS	expendable reliable-acoustic-path sonobuoy	GP	general-purpose (as in bomb)
ERDL	extended-range data link	GPS	global positioning system
ERP	effective radiated power (in jamming)	GRP	glass-reinforced plastic (construction material)
ESF	electronically set fuze, replacing mechanically set fuzes		
ESM	electronic support (surveillance) measures	HALE	high-altitude long-endurance (drone)
ESS	enhanced Sea Sparrow (U.S. missile project)	HARM	high-speed antiradar missile (U.S. AGM-88)
ESR	equivalent service rounds, measure of gun wear	HBX	high explosive (more powerful than TNT)
est	estimated	HC	high capacity (as in a shell)
ETF	electrical time fuze	HCER	high-capacity extended-range
EW	electronic warfare; also early warning	HCHE	high-capacity high-explosive (ammunition)
FA	frequency agility	HDW	Howaldt, a German shipbuilder
FAC	fast attack craft	HE	high explosive
FAE	fuel-air explosive	HEAT	high-explosive antitank (shaped charge)
FCS	fire-control system	HEER	high-explosive extended-range
FDAL	frequency domain adaptive line enhancement (sonar technique)	HEI	high-explosive incendiary
FET	field effect transistor	HEL	high-energy laser
FEWSG	Fleet Electronic Warfare Support Group (simulating enemy jamming for training) (U.S.)	HE-SD	high-explosive self-destruct (ammunition)
		HF	high frequency
FFAR	folding-fin aircraft rocket (2.75-in caliber)	HLA	horizontal line array (U.S. sonobuoy)
FFT	fast Fourier transform	HLASM	helicopter-launched air-to-surface missile
FIAR	Fabbrica Italiana Apparecchiature Radioelettroniche (Italian manufacturer)	HOTAS	hands-on throttle and stick
FIR	finite impulse response (type of radar receiver, for ECCM)	HP	horsepower (or high power or high pressure or horizontal plotter)
FLIR	forward-looking infrared	hr	hour(s)
FLOPS	floating-point instructions per second (measure of computer speed, as in 1 MFLOPS, i.e., 1 million FLOPS per second)	HS	ASW helicopter squadron (U.S. Navy)
		HSA	Hollandse Signaal Apparaten (also known as Signaal)
FLOT	forward line of own troops	HTP	high-test peroxide (concentrated hydrogen peroxide)
FM	frequency modulation (as opposed to AM)	HUD	heads-up display
FMC	U.S. defense manufacturer, formerly Food Machinery Corp.	HUMINT	human intelligence
FMCW	frequency-modulated continuous wave	HVAR	high-velocity aircraft rocket (5-in caliber)
FM/FI	fault monitoring/fault isolation	Hz	hertz (cycles per second)
FMS	foreign military sales (U.S.)		
For	field of regard (field over which a sensor can scan)	IADT	integrated automatic detection and tracking
FOV	field of view	IAI	Israel Aircraft Industry
FPB	fast patrol boat	IAM	inertially aided munitions (U.S.)
FRAM	fleet rehabilitation and modernization (U.S. program, applied to many destroyers now serving in foreign navies)	IC	internal communication (circuit) in U.S. usage; also integrated circuit
FRESCAN	frequency scanning (electronic scanning technique in radar)	ICW	interrupted continuous wave
FSD	full-scale development	IFF	identification friend or foe
FSED	full-scale engineering development	IFM	instantaneous frequency measurement (in ESM)
FSK	frequency-shift keying (symbols differentiated by different frequencies)	IIR	imaging infrared
ft	foot/feet (12 inches)	ILS	instrument landing system, often as VOR/ILS
FTC	fast time constant (radar ECCM technique)	in	inch
FY	fiscal year (U.S.: 1 October–30 September)	INF	Intermediate Nuclear Forces
FYDP	five-year defense program (U.S., compiled annually)	INS	inertial navigation system
		I/O	input/output
G	force of gravity	IOC	initial operational capability
g	gram	IR	infrared
GAO	General Accounting Office (U.S.)	IRDS	infrared detecting set
GDS	gun direction system	IRGP	infrared guided projectile
GE	General Electric Company	IRST	infrared search and track (or target designation)
GERDSM	French ASW and mine warfare development establishment	IRU	inertial reference unit
		ISAR	inverse synthetic-aperture radar
		ISUS	integrated-sensor underwater system (German)
		ITAWDS	amphibious warfare data system (U.S.)
		ITSS	integrated tactical surveillance system (U.S.)

ITT	invitation to tender (British equivalent to an RFP)	m	meter
IUSS	integrated undersea surveillance system (U.S.)	M	Mach (number), multiple of speed of sound
JCS	Joint Chiefs of Staff (U.S.)	MAD	magnetic-anomaly detector (in ASW)
JDF	jamming direction-finder	MAP	military assistance program (U.S.)
JFY	Japanese fiscal year	MARV	maneuverable reentry vehicle
JMSDF	Japan Maritime Self-Defense Force (navy)	MASC	multi-array signal conditioner (U.S., in sonar)
JSCAMPS	Joint-Service Common-Airframe Multiple-Purpose System (U.S. RPV program)	max	maximum
JTIDS	joint tactical information distribution system (U.S., NATO)	MBAT	multibeam array technology
k	kilo, thousand. In electronics, a kilobit (or -byte) equals 1024 rather than 1000 bits (bytes).	Mbit	Megabit, million bits (approximate)
K	degrees Kelvin (i.e., above absolute zero)	Mbps	Megabytes per second (measure of data rate)
kg	kilogram, 2.204 lb	Mbyte	megabytes, million bytes (approximate)
KDA	Oerlikon gun designation (Swiss). The first letter, K, indicates that the weapon is a gun (mounts are prefixed G); the second letter indicates the caliber (A for 20-mm, B for 25-mm, C for 30-mm, D for 35-mm); the third letter is a modifier (for guns, typically A, B, or C). Other typical gun designations are KAA, KBA, and KBB.	MCAR	multiple channel aural reception (sonar)
KIPS	thousands (kilo) of instructions/sec (for computers)	MCC	maintenance of close contact (sonar)
K-Kill	catastrophic kill, as opposed to mobility or firepower kill	MCM	mine countermeasures
km	kilometer	MCOPS	millions (M) of complex operations/sec (for computers)
KOPS	thousands (kilo) of operations/sec (for computers)	MCP	microchannel plate
kT	kilotons, thousands of tons (equivalent TNT)	MDC	mine-destruction charge
kt	knot(s) (nautical miles per hour)	MEKO	modular frigate (by Blohm & Voss)
kV	kilovolts	MEL	British and Canadian electronics manufacturer
kW	kilowatts	MEM	maximum energy management
kyd	kiloyards, thousands of yards	MF	medium frequency
LADAR	laser radar	MFCC	multifunction common console
LAMPS	light airborne multipurpose system (U.S. helicopter)	MFCS	missile fire-control system
LAN	local area network (for computers)	MFLOPS	millions (M) of floating-point operations/sec (for computers)
LANTIRN	low-altitude navigation-and-targeting IR system for night (U.S.)	MFR	multifunction radar
lb	pound(s)	MG	machine gun (also motor generator, to transform AC to DC current)
LCAC	landing craft air cushion (U.S.)	MGC	manual gain control (in radar)
LCS	low-cost sonobuoy (U.S.); also low-cost seeker	MHC	minehunter, coastal
LED	light-emitting diode (for electronic displays)	MHz	megahertz (millions of cycles per second)
LF	low frequency	microsec	microsecond, millionth of a second
LFDM	low-flier detection mode (in radar)	MIDAS	mine detection-and-avoidance system (U.S.)
LGB	laser-guided bomb	min	minute or minimum
LIDAR	light (i.e., laser) radar	MIPS	millions (M) of instructions/sec (for computers)
LLGB	low-level laser-guided bomb	MIR	mid-IR
LLTV	low-light-level television	MIRV	multiple independent reentry vehicles
LNFE	low-noise front end	mJ	millijoules
LOAL	lock-on after launch	Mk	mark (number, for designations)
LOBL	lock-on before launch	mm	millimeter
LOCWS	laser obstacle and cable warning system	MMW	millimeter-wave (length)
LOFAR	low-frequency analysis and recording (ASW)	MNS	mine neutralization system (U.S.)
LOVA	low-vulnerability ammunition	MoD	Ministry of Defence (e.g., British)
LPI	low probability of intercept	Mod	modification to equipment of a given Mk number, as in Mk 46 Mod 5 torpedo
LRCCM	long-range conventional cruise missile	MOP	magnetized orange pipe (U.S. mine sweep)
LRDMM	long-range dual-mode missile	MOPS	millions (M) of operations/sec (for computers)
LRU	line-replaceable unit	MOSS	mobile submarine simulator (U.S.)
LSI	large-scale (electronic) integration	MoU	memorandum of understanding
LST/SCAM	laser spot tracker/strike camera	mph	miles per hour
LTV	Ling-Temco Vought, U.S. manufacturer	MPSM	multipurpose submunition (warhead)
LWIR	long-wave infrared	mrad	milliradian (thousandth of a radian)
		MRBF	mean rounds (fired) before failure
		MR-RPV	mid-range RPV (U.S.)
		MRV	multiple reentry vehicle
		msec	millisec, thousandth of a second
		MP	medium power
		MPA	maritime-patrol aircraft
		MPC	multipurpose console
		MSB	minesweeping boat
		MSC	minesweeper, coastal
		MSD	minesweeping drone
		MSI	medium-scale integration, as opposed to LSI and VLSI; also minesweeper, inshore
		MSL	minesweeping launch
		MSO	minesweeper, ocean
		MSOW	modular standoff weapon (NATO)

MT	Megatons, millions of tons (TNT equivalent); also mechanical time, for a fuze	PK	probability of kill
MTBF	mean time between failure	POM	program objective memorandum (U.S. defense plan)
MTI	moving-target indicator (or indication)	PPI	plan-position indicator (maplike radar display)
MTT	moving-target tracker	pps	pulses per second
MTTR	mean time to repair (also multitarget tracking radar)	PRC	People's Republic of China
MW	Megawatt, million watts	PRF	pulse repetition frequency
NADGE	NATO air-defense ground environment	PRI	pulse repetition interval
NAVAIR	Naval Air Systems Command (U.S.)	PROM	programmed read-only memory
NAVSEA	Naval Sea Systems Command (U.S.)	PSP	programmable signal processor
NDB/NSB	nuclear depth bomb/nuclear strike bomb	pt	point
NEL	Naval Electronics Laboratory (U.S.)	PTA	passive-tracking algorithm; also proposed technical approach, in U.S. procurement
NFT	Norsk Forstvarsteknologi, a Norwegian defense manufacturer, formerly Kongsberg	PUFFS	passive underwater fire control (U.S.)
NIS	NATO identification system (IFF)	PWO	principal warfare officer (British equivalent to U.S. TAO)
nm	nautical mile, 6080 ft	QRC	quick-reaction contract, a U.S. procurement technique used during the Vietnam War
NMOS	n-channel metal-oxide-semiconductor (type of computer chip technology)	RAAF	Royal Australian Air Force
NMR	nuclear magnetic resonance	rad	radian, measure of angle (1 radian is about 57.3 deg)
NOSC	Naval Ocean Systems Center (U.S.)	RAF	Royal Air Force (British)
NRL	Naval Research Laboratory	RAM	random access memory (in computers); also rolling airframe missile (U.S.) and radar-absorbing material
nsec	nanosecond (billionth of a second)	RAN	Royal Australian Navy
NSR	Naval Staff Requirement (British)	RAP	rocket-assisted projectile (shell); also reliable acoustic path (ASW)
NSSMS	NATO Sea Sparrow missile system	RBOC	rapid-blooming off-board chaff (U.S.)
NSWC	Naval Surface Warfare Center (U.S.)	R&D	research and development
NST	Naval Staff Target (British)	RDF	Rapid Deployment Force (U.S.)
NTDS	naval tactical data system (U.S.)	RDT	rotationally directed transmission (sonar)
NTU	New Threat Upgrade (U.S. program)	RDT&E	research, development, testing, and engineering
NUSC	Naval Underwater Systems Center (U.S.)	RDX	high explosive (more powerful than TNT)
NVG	night-vision goggles	RF	radio frequency
ODT	omnidirectional transmission (sonar)	RF/IR	combined radio (or radar) and IR
OFD	optical fire director	RFA	Royal Fleet Auxiliary (British)
ONI	Office of Naval Intelligence (U.S.)	RFP	request for proposal
OPV	offshore patrol vessel	RGPO	range-gate pull-off (ECM technique)
OR	Operational Requirement (U.S.)	RISC	reduced-instruction-set computer
ORDALT	ordnance alteration (U.S.)	RLO	radar lock-on
ORTS	operational recording and testing system (U.S.)	RHAW	radar homing and warning
OSD	Office of the Secretary of Defense (U.S.)	RHI	range-height indicator (for radar)
OTC	officer in tactical command	rms	root-mean square
OTCIXC	OTC information exchange channel	RN	Royal Navy (British)
OTH	over the horizon (in radar); OTH-B is OTH by means of backscatter (off the ionosphere). A forward-scatter OTH system uses a beam that scatters off the target, then goes beyond to a separate receiver. OTH-B uses transmitter and receiver close together, bouncing the reflected wave back off the ionosphere between target and radar.	rnds	rounds
OTH-T	over-the-horizon targeting (U.S. term)	RNEE	Royal Navy Equipment Exhibition
PACS	plotting and combat summary display (U.S.)	RNTF	Royal Navy Torpedo Factory (now closed)
PADLOC	passive-active detection and localization (sonar, U.S.)	ROM	read-only memory (in computer)
PAIR	performance and integration refit (conversion of SQS-23 sonar to SQQ-23)	ROV	remotely operated vehicle (generally underwater)
PAL	permissive action link (in nuclear systems, to prevent unauthorized use)	RPC	reflected power canceler or remote power control (British: guns)
PD	probability of detection; also point detonating (fuze)	RPG	rocket-propelled grenade (antitank weapon)
PDD	point detonating delay (fuze)	rpm	revolutions per minute
PDF	point (instantaneous) detonating fuze	RPV	remotely piloted vehicle; see also UAV
PDMS	point-defense missile system (U.S.)	RRDT	random rippled directional transmission
PEAB	Philips Elektronikindustri AB (Swedish manufacturer)	RSLS	receiver sidelobe suppression
PFHE	prefragmented high-explosive (ammunition)	RTLOS	remote track launch on search (missile tactic)
PGM	precision guided munition ("smart weapon")	RTN	Italian (Selenia) radar designator
PI/DF	passive identification direction finding	RTV	recoverable test vehicle
		RV	reentry vehicle (for a missile)
		RVC	radar-video converter (to digital data)
		RVP	radar-video processor
		RWR	radar-warning receiver
		SACLANT	Supreme Allied Commander Atlantic
		SADARM	sense and destroy armament (submunition)

SADS	SubACS acoustic detection system (U.S.)	SSPK	single-shot kill probability
SALGP	semiactive laser-guided projectile	SSTx	solid-state transmitter
SAM	surface-to-air missile	STA	second time around, referring to radar pulses arriving back at the radar after the next pulse has been sent
SAP	semi-armor-piercing	STAE	second-time-around echo (radar)
SAR	synthetic-aperture radar; also search and rescue	STC	sensitivity time control (ECCM technique)
SCCS	submarine combat-control system	STIR	separate track and illumination radar (U.S.); also Signaal track and illumination radar (Dutch); also surveillance and target indication radar (British)
SCEPS	stored chemical energy propulsion system (for torpedoes; see U.S. Mk 50)	SURTASS	surveillance towed-array sonar system
SCI	special compartmented information (generally information outside the usual classification system; information is often "sanitized" to remove SCI so that it can more freely be used by operating forces) (U.S.)	SWCM	special warfare craft, medium (SEAL craft, U.S.)
SDC	sensor - data converter / situation - display console	SYS	sensor (radar) integration computer (U.S.)
SDI	strategic-defense initiative (U.S.): defense against ballistic-missile attack	2D	two-dimensional
SDT	steered directional transmission (sonar)	3D	three-dimensional
SEAL	Sea-Air-Land (U.S. Navy special forces)	3P-HV	programmed-proximity prefragmented high-velocity explosive (Bofors ammunition)
sec	second	TABP	towed-array broad-band processor (U.S.)
SEM	standard electronic module (U.S.)	TACAN	tactical air navigation beacon (U.S.)
SEPADS	sonar-environment prediction-and-display system	TACCO	tactical coordinating officer
SFCS	submarine fire-control system	TACSIT	tactical-situation display (in U.S. submarines)
SHAB	steerable hull array beam-former (U.S.)	TACTASS	tactical towed-array sonar system
SHF	super high frequency	TADIL	tactical digital link (U.S. and NATO)
SHINPADS	shipboard integrated processing-and-display system (Canadian)	TAO	tactical action officer
SHP	shaft horsepower	TAPS	towed-array broad-band processing system (British)
SHR	superheterodyne receiver	TARP	towed-array range processor/processing for U.S. long thin array)
SIAC	submarine integrated attack center	TAS	target acquisition system (U.S.); also tactical Arctic sonobuoy (U.S.)
SID	situation information display	TASP	towed-array signal processor
SIDS	sensor interface data system (U.S.)	TASS	towed-array sonar system
SIGINT	signals intelligence	TB	towed body (U.S. designation)
SIMAS	sonar in-situ mode assessment system	TCSS	torpedo-control system, submarine (British)
SINS	ships' inertial navigation system	TDC	torpedo-data computer
SLAM	standoff land-attack missile (modified Harpoon)	TDD	target-detection device (proximity fuze)
SLAT	supersonic low-altitude target; also surface-launched air-targeted	TDHS	tactical data-handling system (ASW)
SLB	sidelobe blanking (in radar)	TDI	target doppler or deviation indicator (sonar, for target tracking)
SLBM	sea-launched ballistic missile	TDMA	time division multiple access (type of data link)
SLC	sidelobe cancellation (in radar)	TDS	tactical data system
SLCM	sea-launched cruise missile	TDT	target designation transmitter
SLEP	service-life extension program (U.S.)	TELCOM	two-way wire guidance for Mk 48 torpedo (U.S.)
SLMM	submarine-launched mobile mine	TENCAP	tactical exploitation of national (intelligence) capabilities (U.S.)
SMA	Segnalamento Marittimo ed Aero (Italian manufacturer)	TERCOM	terrain comparison (cruise missile guidance)
SNIA	French rocket motor manufacturer	TEWA	threat evaluation and weapons assignment
SOR	specific operational requirement (U.S.)	TG	transmitter group (in sonar)
SOSUS	sound surveillance system (U.S. and NATO)	TI	target indication (British)
SPAT	self-propelled acoustic target	TICM	thermal-imaging common module
SRAM	static random-access memory	TMA	target-motion analysis (for ASW ranging and fire control)
SRARM	short-range ARM (U.S.)	TMAD	target-motion analysis display
SRBOC	super rapid-blooming off-board chaff (U.S.)	TOR	Tentative Operational Requirement (U.S.)
SRDT	steered rotationally directed transmission (sonar)	TOW	tube-launched optical wire-guided missile (U.S., antitank)
SRSSM	short-range surface-to-surface missile	TP	target practice (ammunition)
SS	submarine	TP-FP	target practice fragmentation projectile
SSB	single sideband (radio); also diesel-powered ballistic-missile submarine	TP-T	target practice tracer (ammunition)
SSBN	strategic ballistic-missile submarine (nuclear powered)	TPX	explosive (torpex, more powerful than TNT)
SSI	sector scan indicator (sonar, for target tracking)	TRAM	target recognition and attack multisensor
SSK	ASW submarine (nonnuclear)	TRDT	tribeam rotationally directed transmission (sonar)
SSLV	standard small launch vehicle		
SSM	surface-to-surface missile		
SSN	nuclear submarine		

TRF	tuned radio frequency (wide-band type of receiver)	VGPO	velocity-gate pull-off (ECM technique)
TRIASP	tri-advanced signal processor (U.S., in sonar) (three ASP packaged together, for the BQQ-5C sonar)	VHF	very high frequency
TRUMP	<i>Tribal</i> -class modernization program (Canadian)	VHSIC	very high speed integrated circuit
TSC	tactical support center (U.S., for ASW)	VIS	visual
TSS	tactical surveillance sonobuoy (U.S.)	VLA	vertical-launch ASROC (missile) (U.S.)
TT	torpedo tube	VLAD	vertical line array DIFAR (U.S. sonobuoy)
TVM	track via missile (guidance technique)	VLF	very low frequency
TWS	track-while-scan	VLS	vertical launch system
TWT	traveling wave tube (radar transmitter)	VLSI	very large scale integration (of electronic circuits)
UAV	unmanned air vehicle (this more general term is replacing RPV in many cases)	VME	versatile memory Eurobus, a current standard internal computer data bus
UDACS	Universal Display and Control System (Boeing ASW system)	VOR	VHF omni-range (for air navigation)
UEP	underwater electric potential	VP	patrol (ASW) squadron (sometimes used for patrol aircraft) (U.S. Navy)
UHF	ultrahigh frequency	VQ	ECM squadron (U.S. Navy)
ULC	up-link communications	VSTOL	vertical/short takeoff and landing
UVPROM	ultraviolet programmable read-only memory (the read-only feature is disabled when the appropriate ultraviolet light is shined on the memory)	VT	variable time (proximity), used for a fuze
VA	attack squadron (U.S. Navy) (with a number)	VTOL	vertical takeoff and landing
VAB	variable-action button (of a console)	VX	test squadron (U.S. Navy) (with a number)
VAW	AEW squadron (U.S. Navy) (with a number)	W	watts
VDS	variable-depth sonar	WAA	wide-aperture array (U.S.)
VECG	video extractor and control group (in radar)	WBL	wide-band limiting (in radar)
VERDIN	VLF emergency digital information network (secure radio for submarine broadcasts, U.S.)	WCS	weapons-control system (U.S.)
VF	fighter squadron (U.S. Navy) (with a number)	WDC	weapons-delivery computer
		WDS	weapons-direction system (U.S.)
		WP	white phosphorus (shell)
		WPB	wide pulse blanking (in radar)
		WRA	weapons replaceable assembly
		XBT	expendable bathythermograph
		yd	yard(s)
		yr	year(s)

WORLD NAVAL WEAPONS SYSTEMS

SURVEILLANCE AND CONTROL

A fleet's visible elements are its ships, submarines, and aircraft. These elements are tied together by communications links, many of them satellite-borne. Increasingly, a fleet's operations are motivated by external sources of operational intelligence data. Many of the sources and systems involved are sensitive and so cannot be described. Much of the West's knowledge of the Soviet systems, for example, has been obtained by careful sifting of intelligence obtained at great cost, and this information is by no means publicly available. Thus the systems described in this section should be considered samples of a larger whole, indications of the very important invisible elements of modern navies.

Such systems are not nearly as new as they may seem. Before World War II, for example, the U.S. Navy operated a Strategic High-Frequency Direction-Finding system around the rim of the Pacific, specifically to track the Japanese Fleet. The system fed information to naval headquarters in Washington, D.C., which in turn would have directed the CinC U.S. Fleet in Pearl Harbor into position to deal with his enemies. With the success of Allied code breaking during World War II, centralized operational intelligence became more common and more important. It remains important now, although, of course, the degree of success with which we track, say, Soviet submarines must be a matter of speculation in any unclassified discussion.

The central question in the design of all such systems has always concerned the amount of raw data a deployed commander should be provided. In World War II, it was obvious that the deployed commanders required a great deal of raw data, and great pains were taken to protect the channels by which those data were transmitted. Afterward, as the United States and its allies came to believe that a major war, if it ever occurred, would soon escalate to a nuclear exchange, the operational aspect of intelligence seemed less and less important. Systems with an operational potential, such as SOSUS (Sound Surveillance System), were valued primarily for their war-warning potential, their data prepared principally for the National Command Authority. Now it seems clearer that a war might remain non-nuclear for quite some time, perhaps throughout its course. In that case, tactical war-fighting becomes more important; and some of the same intelligence systems built up for the National Command Authority are being turned, in part, to the needs of the deployed commanders. This development explains such systems, discussed below, as JOTS (Joint Operational Tactical System) and OSIS (the Ocean Surveillance Information System).

For the United States, the investment in existing intelligence-gathering systems is so large that new tactically oriented systems cannot likely be built, at least in the short term. Instead, existing systems are being used, where they are appropriate. These systems do *not* include such classic intelligence-gatherers as photographic satellites, which cover only very limited areas at any one time, or deep-space nuclear-detonation detectors.

The other key question for the United States is to what extent fixed, as opposed to mobile (i.e., integral with tactical formations such as battle groups), intelligence systems should be supported. If the United States had to face only the Soviet Union, there would be no question: full coverage of northern waters would have the highest priority, and nowhere else would full coverage be particularly valuable. However, the single greatest asset of sea power is its mobility, its ability to deal with the unexpected—which, since 1945, has usually meant conflict in the Third World. The question of mobile surveillance has not yet really arisen, but that is only because the United States' Third World enemies have not yet had serious naval forces requiring the use of more than existing fleet assets. That may well not be the case in the future, and the United States may even have to face the Soviets outside their home waters. This issue affects systems such as SOSUS and ROTH (the Relocatable Over-the-Horizon Radar).

For the Soviets, the situation is rather different. Much of the Soviet intelligence program, including at least some (and perhaps all) space and long-range direction-finding assets, is con-

centrated in the hands of the GRU, the intelligence arm of the General Staff. It is unlikely that the GRU would ever have thought in other than operational terms; the Soviets may well rely on agents in place in other countries for such purposes as war-warning. In any case, the Soviets seem much more willing than the Americans to use intelligence data for operational purposes, whereas in the West the emphasis has been much more on protecting invaluable sources (including technical ones) to avoid losing war-warning capabilities.

On the other hand, the Soviets concentrate much more power in the hands of their central command structure, so that deployed commanders, in the Western sense, probably do not exist at all. Intelligence assets, such as most satellites, report to the central command. Deployed forces are ordered into position to attack on the basis of these reports, in some cases using satellite or other off-board data as a basis for attacking. This organization relies heavily on long-haul communications, and the Soviets are well known for their redundant command links.

From a technological point of view, perhaps the most important development has been the changing fortune of HF radio. HF communications have very long ranges because HF signals bounce off the ionosphere, but a long range subjects an HF system to intercept and to DF. HF also suffers in practice from the vagaries of the variable ionosphere.

The effect of external command/control and intelligence is to extend the horizon of an individual ship. However, most of the information so obtained is given in terms of geographical (i.e., earth-oriented) coordinates: the incoming force of bombers is in this position, flying this course, at this speed. Only if a ship at sea has reasonably accurate navigational data can it take full advantage of such information. Thus, this section includes some specialized navigational systems, such as the U.S. global positioning satellites. When these devices provide really accurate information, they can be used to guide weapons, such as cruise missiles, to specific points on the earth. The question then is whether the intelligence systems providing initial targeting data are nearly as precise as the navigational systems exploiting them. For example, it is not too useful to guide a missile to within a foot of a presumed target when the actual target is a mile away. Not knowing the target's location precisely enough is a central problem in all long-range ballistic-missile firings.

Accurate navigation is also essential to successful mine countermeasures. The minehunter or -sweeper must know precisely which channel its predecessors have cleared and precisely where it goes from there. This section, therefore, also includes accounts of the standard in-shore precision-navigation systems now in use on board Western mine-countermeasures ships. Soviet systems are presumably roughly equivalent.

The big fixed systems share and sift information so that it can be fed to ships at sea. Ships have analogous combat systems, such as the British ADAWS series, the French SENIT, and the American NTDS, whose function is to coordinate information available on board ship (including that provided by external sources) and then to present all the information in a form suitable for decision making (including weapons assignment and control).

Like the big external systems, the on-board combat system is by no means a new idea. The classic warship information center consisted of the plot, a presentation of the situation around a ship: information was provided by lookouts and signals from other ships. During World War II this idea was extended and elaborated as the British and American Navies developed the AIO/CIC. Perhaps the most important difference between a CIC and a classic plot is that the CIC must handle data that change very rapidly (such as fast air contacts); CIC must also integrate more different kinds of data (radar, visual, ESM).

The most important of CIC's functions is to filter data, deciding which information is likely to be accurate and which information is relevant. The advent of the CIC brought into question the classic way of fighting a ship. A plot, which was usually adjacent to the bridge, was a convenient source of in-

formation for the captain stationed on the bridge or in the conning tower. However, the CIC provided that captain with information on events far beyond visual range. Captains, therefore, either commanded from the bridge (and left a senior subordinate, the CIC evaluator, in CIC) or commanded from CIC. As CICs have become stations for weapons control, their importance has increased; in current U.S. practice, the TAO, who actually fights under the captain's direction, is stationed in CIC. In the future, at least in the U.S. Navy, captains will generally be expected to fight their ships from CIC.

Perhaps the single most important postwar development was the automation of CIC function, in the form of tactical data or combat-direction systems such as NTDS.

The second very important postwar development in internal ships' systems was the data bus which replaced the mass of specialized (e.g., sensor-to-display) connections.

All the data from the sensors, for example, can be fed into a common bus from which computers can strip what they need. Computers and display consoles can then be added or subtracted from a system without rewiring, since each is linked only to the common bus. Weight and space can be saved, since each console and each computer does not need a separate data cable. Instead, each is plugged into a common bus, just as each is plugged into a common electric-power grid. The success or failure of such systems depends on the carrying capacity of the bus, and it can be argued that some systems, like some in the U.S. Navy, do not use buses because the available buses have insufficient capacity.

Data busing is already quite common in Western businesses' computer systems, which link individual processors to LANs. A bus-linked combat data system is analogous to an LAN and its work stations, plus, perhaps, a powerful central computer or minicomputer. Of current interest is the extent to which systems developed for specialized naval computers should be able to interface with off-the-shelf commercial equipment.

A great deal depends on the topology of the data bus, which may be in the form of a ring or a star or may be linear. In a standard ring or linear system, the failure of any element in the system generally causes the entire system to fail; it can be resurrected only after the failed element has been disconnected or fixed. That arrangement limits the system's ability to tolerate combat damage. A star arrangement can tolerate the failure of any element except the key element at the center of the system. All of these arrangements are associated with software systems that allow the different devices on the bus to enter their data without interference. The main alternatives are to use a master scheduler, which determines which device is entering its data, or to use a "token-passing" protocol, in which a particular device transmits as long as it has priority, then passes priority to the next device. Token-passing generally requires a ring topology. The other major consideration is whether the system as a whole replicates its data base in many places, or whether the system uses a single master device for data-base storage, other devices (such as fire-control consoles) requesting data as needed.

The best-known Western data bus is MIL-STD-1553B, which was defined in 1978 (1553A dates from 1975). It is a single twisted-cable pair carrying data in 16-bit words (with a parity-checking bit and 2 synchronization pulses) at up to 50 kword/sec (800 kbit/sec) at a frequency of 1 MHz. The maximum length of the cables is 100 m, and a terminal can carry up to 32 stubs (I/O points), 1 of which is allocated to a bus controller; the bus controller keeps signals from different systems separate. It is rare for the cables to approach the maximum length or for the terminal to have all 31 stubs. The 1553B bus is standard on board many NATO aircraft, where it is used to control underwing stores.

MIL-STD-1773B is the fiber-optic version of MIL-STD-1553B.

A higher-capacity standard U.S. bus is under development; it will probably have a capacity of 20 Mbit/sec, split-channel operation (as in the French DIGIBUS), 64 remote terminals, and a maximum message length of 4000 words, compared to 32 words for MIL-STD-1553B. The impetus toward greatly increased bus

capacity is the much higher speed expected of the new VHSIC electronics. The new bus will probably be introduced in the mid-1990s.

In British service, MIL-STD-1553B is called DEF STAN 00-18.

There is also a standard commercial aircraft bus used in some aircraft tactical data systems, ARINC 429. ARINC 429 was adopted for civil aircraft (large airliners) in 1977-78; it is a screened twisted-wire pair connecting a single transmitter to up to 20 receivers, with a data rate of 100 kbit/sec or an alternative low rate of 12-14 kbit/sec, always in 32-bit words.

The standard French system is DIGIBUS (Dassault), which is related to the Bus Standard Marine of the French Navy. DIGIBUS is 2 twisted, shielded cable pairs, 1 carrying data and the other protocol messages; it can accommodate up to 32 ports, including bus-control ports. Maximum length is 100 m. However, bus repeaters are now being developed to extend this length to 300 m, plus subbus couplers for subbuses of up to 100-m length, each accommodating 31 more ports. DIGIBUS operates at 1 MHz and has a capacity of 40 kword/sec (16-bit words). DIGIBUS was originally called GINABUS (*Gestion des Informations Numériques Aéroportées*, i.e., airborne digital data management) and was developed jointly by Dassault and ESD in 1973-76; the Bus Standard Marine was developed from it in 1975-77. DIGIBUS is now standard in the French military (specification GAM-T-101) and is a proposed NATO standard.

In Germany, Blohm & Voss has specified a new bus architecture for its MEKO Mk 3 frigates, the first of which are the Portuguese MEKO 200 PN frigates of the *Vasco da Gama* class. Each weapon and electronic functional unit is fitted with a Multi-Interface Computer Unit (MICE) that connects it to the digital Data Information Link network (DAIL), an Ethernet. MICE has sufficient computing power to adapt all of the available modules (weapons, electronics, masts, pallets) to the DAIL requirements. The current DAIL is a coaxial cable; at least 2, and up to 8, can be used. The DAIL bus can also be a fiber-optic cable. In a MEKO, there are 2 separate networks, A for command/control and B for navigation and own-ship data. However, they are interconnected, and 1 can take over the other's function. In the case of the Portuguese frigates, the single DAIL bus connects the STACOS command/control system, the EW system, the NATO Sea Sparrow, the 100-mm gun, the double STIR, the weapons-control system, the radars, and the sonar. Blohm & Voss calls each system element, including its MICE interface, an Intelligent Functional Unit (IFE). MICE/DAIL has been under development since 1981. An experimental network, using 3 MICE, was tested in 1984.

MHIDAS (Multiple High Integration Distributed Architecture data-bus System) is the Selenia bus of the new SADOX/IPN systems. A single bus can be up to 300 m long, with branches up to 50 m long; it can support up to 64 bus-access modules. Each module can couple up to 4 users to the bus, for a total of 256 per bus. Data are transmitted in time-division multiplexed form, at up to 10 Mbit/sec, each word 1-4 bytes long (and each message 16-1024 bytes in length). Messages can be assigned 3 levels of priority, the bus providing priority 1 messages an average access time of 50 microsec (100 for priority 2, 200 for priority 3). Expected average throughput is 5 Mbit/sec, or 5000 messages/sec (100 bytes each, on average). MHIDAS is normally a cable bus; Selenia also offers a fiber-optic version.

Signaal has developed a 10-Mbit/sec system, which can use up to 4 triaxial cables in parallel. It is based on a commercial Ethernet LAN. Signaal has suggested that military buses may actually be less demanding than their civilian counterparts because the devices connected to military buses have much more predictable bus loadings. Perhaps many current civilian LANs can easily be militarized.

The newest British official system is DEF STAN 00-19, previously known as ASH or the ASWE (Admiralty Surface Weapons Establishment) Serial Highway. At present it is limited to British surface warships. The transfer rate is 1.5 Mbit/sec (16-bit words), using a screened single twisted-cable pair. Up to 63 computers can be accommodated in a total length of 300 m.

Racal offers a naval version of PLANET (Private Local Area Network), which can communicate both voice and digital data. The data interchange rate is 19.2 kbit/sec (normally 9.6 kbit/sec). The company, however, claims that PLANET easily carries digitized voice data at 64 kbit/sec.

The newest U.S. system is USQ-82, the Shipboard Data Multiplex System (SDMS), which can use up to 5 buses in parallel. FMC has produced UDICON, which is rated at 10 Mbit/sec using a single twisted-cable pair.

SAFENET (Survivable Adaptable Fiber-Optic Embedded Network) has been chosen as the next-generation U.S. naval LAN data bus. Work began in June 1984, and in 1987 SAFENET became part of the NGCR (next-generation computer resources) program. This token-ring bus was designed so that the same hardware could be adapted both to current software (protocols) and to evolving, more sophisticated software, which could support features such as multicast (messages transferred to several users simultaneously), and which has a higher inherent capacity: SAFENET I (IEEE 802.5 standard) is to operate at 16 Mbit/sec among 64 users, and SAFENET II (FDDI standard) at 100 Mbit/sec among up to 256 users. SAFENET can be configured to carry 2 separate data streams. For example, in the TFCC system (FDDS) one carries secret-level data (GENSER), the other specially classified (compartmented) data.

The most likely future data-bus technologies are fiber-optic cables, which are already in widespread use ashore in telephone networks, and microwave waveguides.

The systems described here are general purpose and found on board surface ships. Pure AAW combat systems and pure submarine combat systems are described, respectively, in the AAW and ASW sections.

SURVEILLANCE/CONTROL

Surveillance Systems

All navies oriented toward coast defense necessarily maintain shore-based surveillance systems as the basis of patrol boat and antiship strike operations. In many cases the shore headquarters is automated, and deployed seaborne craft and aircraft are connected to it by data link. Such linkage provides the deployed craft with the same tactical picture, and so may help prevent erroneous attacks on friendly forces. Systems of this type might be termed shore environments, just as automated air-defense information systems are commonly termed air-defense environments. Over-the-horizon surveillance, generally by aircraft (but also by land-based ESM), is an essential element of any such system.

Probably the first example of such a shore environment was the German navy's AGIS combat-direction system (described below, under shipborne systems). It seems likely that the Israeli Navy used a very similar system in the October War of 1973, although details are lacking. A shore-based environment would have provided the deployed Israeli missile boats with the locations of the Arab missile boats, and those data in turn would have permitted the Israelis to launch their long-range chaff on time and in the right place. Conventional manual messages might have sufficed but probably would not have been sufficiently timely.

The Litton system currently being manufactured for Korea also fits into this category, as does the Swedish STINA system (described below).

This list is likely to be incomplete. Reportedly, the Royal Netherlands Navy has a coastal radar net, for surveillance and EEZ control, that can pass targeting data to ships and aircraft. Many Third World countries operate small radar-equipped maritime-surveillance aircraft, often with commercial data links, but it is not clear to what extent these links are used to set up an integrated tactical picture. In at least some cases they are no more than aids to over-the-horizon targeting for individual fast attack craft. Nor is it clear to what extent Soviet coastal surveillance is integrated to the point of using automatic data links

(although it is clear that the Soviets do use data links for over-the-horizon targeting).

Almost certainly, too, more or less automatic shore environments support the fast attack boats operated by the Danish, Italian, and Norwegian navies.

FRANCE

◆ SYSCOM NG

SYSCOM NG is a shore-based naval command/control system, broadly analogous to the U.S. FCC and the British OPGON. The staff objective was written in September 1989, and the system is to become operational at the end of 1992.

SWEDEN

◆ STINA (9CSI 500)

STINA is the Swedish Navy's coast-surveillance and information system, developed by PEAB (now BEAB). STINA was designed in close cooperation with both the Navy and the Swedish Coast Guard, to provide coastal and offshore maritime-traffic control in peacetime, and combat information and communications in war. The central control panel can accept up to 13 radio, 20 telephone, and 12 radar inputs. The operator initiates automatic target tracking by placing a roller ball symbol over a radar blip, or by feeding in location, speed, and course data. Up to 200 surface targets can be automatically tracked, and low-flying air targets can be added as an option. Target positions are all stored in a disk memory, and any STINA center can transmit them automatically to another via a radio data link, or to naval or Coast Guard vessels.

The standard operator's position consists of a 41-cm color or monochrome PPI showing synthetic radar video and other processed target data, a smaller monochrome alphanumeric display, a keyboard, and a communications terminal. A typical STINA center contains 2 or 3 operators' consoles plus a commander's console (alphanumeric display and communications terminal); the commander's graphic display is a separate color, raster-scan, summary-plot unit, and a similar (slaved) unit can be provided to the operators. The operators' consoles (as a unit), the commander's console, and the 1 or 2 graphics displays are all connected to a data bus, which also carries the local main computer with disk memory. A harbor master's office can house a simpler station, consisting of 1 operator's console and 1 color graphics display, with a display generator but without any main-frame computer. In each case, the data bus includes a modem for communication with other STINA centers. An area commander has up to 3 such consoles, plus 1 or more color, raster-scan summary displays. There are 6 range scales, and particular target categories can be selectively displayed. The disk memory can play back the last 24 hr of data at 30 or 300 times real time (i.e., in about 50 or 5 min).

The major system sensor is the PEAB (BEAB) coastal radar, fixed or mobile, using an automatic plot extractor (ATD) for unattended operation; extracted plots are passed to the STINA center by narrow-band radio data link. A single STINA center can accept automatic plots from up to 6 radars.

The main computer is built around a Philips CPU 857M minicomputer; it has 2 disk drives, 1 a cold standby. The graphics processor uses a related minicomputer.

STINA entered service about 1979. By 1981 STINA had been installed in regional control centers at Stockholm, Gotland, and Malmö; the program called for 2 more. At that time PEAB hoped that the regional centers would be integrated into a national-level naval command system, 9CS600, using enhanced display facilities and a TDMA (time-division multiple access) data link to communicate with both the regional centers and deployed air and naval forces.

◆ STRIKA/SUMP

Ericsson's coastal-surveillance and weapons-control systems are for Swedish coastal artillery and (SUMP) for naval command centers. STRIKA and SUMP both use the CCIS system bus ap-

proach of the new Ericsson shipboard tactical data systems; the system computer is a Censor 900E series machine, and the terminal is the Ericsson ADT (alphanumeric display terminal). A typical 1- or 2-operator station has one 23-in vertical PPI, 1-3 ADTs, keyboards and roller balls or joysticks, and a communications terminal. STRIKA is now entering Swedish coastal-artillery service.

UNITED KINGDOM

◆ OPGON

OPGON is the British automated, national naval central-command information system, based at the naval headquarters at Northwood. OPGON supports 150 local display terminals there, as well as remote workstations aboard deployed flagships and 1 at SACLANT headquarters in Norfolk, Virginia. As of early 1989 OPGON was to have been extended to the German naval headquarters at Glücksburg, to the Allied Forces Northern Europe headquarters at Kolsås near Oslo, and to SACEUR headquarters at Brussels. An OPGON terminal was installed on board the U.S. flagship *Mount Whitney* for North Atlantic exercises. The system seems broadly comparable to the U.S. FCC, which OPGON preceded.

The initial feasibility study for OPGON was conducted in 1974, and the system became fully operational in 1985. Throughout, ICL has been the hardware and software contractor. The standard workstation consists of an Aydin color graphics display alongside a DRS 20 alphanumeric display, the latter incorporating a badge reader (to prevent low-level personnel from seeing more highly classified data); both displays have separate keyboards. The graphics display shows past, present, and predicted positions (and tracks) of all British naval vessels, together with maritime air patrols and reported contacts; coastlines and depth contours are also shown.

The central data base is held by 2 ICL 2966 mainframes, with Tandem TXP computers for input and output and for local displays. There is also an alternative naval headquarters housing a duplicate data base, periodically refreshed.

In September 1988 ICL was awarded a Dutch contract to build an OPGON headquarters for Commander, Benelux Channel Command, based at Den Helder.

Project definition of an upgraded OPGON was conducted in 1988; improvements will include the provision of intelligent workstations on board some major fleet units, presumably the light carriers. Such workstations might be analogous to the U.S. JOTS, which is currently installed on board these ships. The upgraded system is called MCCIS (Maritime Command-and-Control Information System), and as of early 1989 the British government planned to award 14-month competitive project-definition contracts. This upgrade is partly NATO funded.

USSR

◆ SOSS

Soviet Ocean Surveillance System is the generic Western name for the integrated system the Soviets use to detect, track, and target Western ships. SOSS is a natural outgrowth of the Soviet coast-defense system built up from before World War II. A combination of intelligence and passive sensors (originally, primarily HF/DF) detects ships approaching Soviet waters, and active sensors (mainly aircraft radars) are used as a follow-up for targeting. The passive sensors are supplemented by human agents (HUMINT or human intelligence), by intelligence-gathering ships (AGIs) operating near Western bases, and by warships (tattletales) that often trail Western naval formations. In recent years, SOSS has been supplemented by both passive and active satellites, but the principle of operation remains the same.

SOSS is designed to detect and target ships approaching the Soviet Union, rather than to protect a moving Soviet naval formation from the approach of hostile ships or aircraft. The system, therefore, feeds a central naval command-authority, which in turn directs Soviet ships, aircraft, and missiles to intercept the approaching enemy force. The home-defense, rather than

the formation-defense, role of SOSS is probably reflected in its criterion for target detection. Since there is considerable sea space beyond Soviet frontiers, the system can afford a low probability of detection on a day-by-day basis. In contrast, a surveillance system protecting a moving naval force cannot afford leaks.

Before the advent of satellites, SOSS's direction-finders were mainly land-based. The Soviets now operate both passive-(EORSAT, Electronic Ocean Reconnaissance Satellites) and active-radar (RORSAT, Radar Ocean Reconnaissance Satellites) satellites, which should, in theory, represent a global capability. However, the EORSATs still almost certainly report only to the central naval command in the Soviet Union. The RORSATs can link down to attacking units, but they are not the primary search sensors of the system.

For example, a carrier's transit from a U.S. base to a forward area would probably first be detected by a human source in or near the U.S. base. The carrier would be seen as it left its base by an offshore AGI and might be picked up by an offshore submarine tattletale, although the Soviets do not have enough fast submarines to use as regular tattletales. The next detection would be of the carrier's electronic emissions, picked up either by a shore-based HF/DF station or, perhaps, by an ESM satellite. This detection would necessarily be passive; any active sensor would be overloaded with data because there are just too many ships at sea at any time. However, once the passive sensors had defined the area of interest, it would be worthwhile to send out reconnaissance aircraft to confirm the carrier's position, course, and speed and, if necessary, to provide targeting data. Once the carrier was located, it could be trailed by a tattletale. The latter's mission would be not so much to confirm the carrier's movements as to confirm which ship within the battle group was the high-value target; the Soviets would view the others as missile absorbers.

Once the tattletale had joined, an attack could be mounted, using either a radar-equipped reconnaissance airplane followed by ASM-armed bombers, or a Bear-D providing OTH data to a submarine or surface ship, or a RORSAT in a similar role.

The Soviets captured the German Wullenweber HF/DF systems at the end of World War II and about 1952 began producing a Soviet version, KRUG, an array about 115 yd in diameter, consisting of 120 equally spaced monopole antennas. Direction-finding accuracy is reportedly about 1 deg, over a range of 6–20 MHz. The HF array was later supplemented by an inner concentric ring of monopoles that extended coverage into the VHF range.

The Soviets reportedly also use a somewhat less accurate land-based HF/DF antenna, Fix-24, consisting of 24 monopoles located at 15-deg intervals around a 150-m circle.

Since HF/DF is used by all the Soviet services, it is not clear from the unclassified literature to what extent, if any, particular networks are intended primarily for naval purposes. Because the Soviets take service unification seriously, through their unified General Staff (and its specialized intelligence branch, the GRU), one might speculate that there is no particular net reserved for the navy, but rather that the unified GRU net filters naval data down to naval headquarters. However, each of the four Soviet fleets reportedly has its own SIGINT (signal intelligence) collection site(s). Presumably, the GRU can also draw on HF/DF sites abroad, in Soviet client states.

UNITED STATES

◆ OSIS

Ocean Surveillance Information System (OSIS) is the combination of all the U.S. Navy's existing operational intelligence systems, joined to support tactical operations. Although tactical support might seem to be an obvious idea, in fact until the mid-1970s most intelligence was collected and disseminated for strategic purposes such as war-warning and for analysis. In the late 1970s the information began to be exploited for tactical purposes, under a program called TENCAP (Tactical Exploitation

of National [Intelligence-Gathering] Capabilities). Examples included Outlaw Hawk (1974–75) and Outlaw Shark (1975–76), which collected and collated intelligence-grade data to provide the commander of a ship (in these cases, respectively, the carrier *Kitty Hawk* and a submarine) with a reasonably complete picture of naval activity around him, beyond the immediate range of his sensors.

The object of Outlaw Shark was to provide a useful means of targeting long-range OTH antiship missiles, such as Tomahawk. The flow of operational intelligence between FOSIF Rota and the carrier *John F. Kennedy* was tapped at Naples, and edited material sent to the submarine via a special data link. Because timeliness was important, the intelligence data were sent event by event rather than by the usual scheduled broadcast, and the messages themselves were streamlined accordingly. Some arrived only 6 min later than the events they described, an important advantage for a missile, like Tomahawk, with a finite seeker-window.

OSIS represented a conscious choice to exploit existing sources of data (designed for quite different purposes) rather than to develop entirely new surveillance systems, such as the Soviet-style active-radar satellites. The choice was logical because U.S. naval requirements could not justify full and continuous surveillance of the surface of the seas, but the fleet needed information about enemy warships in its vicinity, particularly to use long-range antiship missiles effectively. The strength of OSIS is the ability to maintain large volumes of data at the analysis (data-processing) nodes and to transmit information quickly and securely. The system was initially constructed in the 1970s, and late in 1982 TRW was given a contract for an OSIS baseline upgrade.

OSIS assets include a ground HF/DF system, Bulls Eye (and a shipboard adjunct, Classic Outboard), EP-3 aircraft, and the White Cloud satellite described below, as well as SOSUS and its adjuncts (described below).

OSIS employs 6 major sites: the Naval Ocean Surveillance Information Center (NOSIC) at Suitland, Maryland; 3 Fleet Ocean Surveillance Information Centers (FOSICs) at the CINCLANTFLT, CINCPACFLT, and CINCUSNAVEUR headquarters (Norfolk, Pearl Harbor, and London); and 2 Fleet Ocean Surveillance Information Facilities (FOSIFs) at Rota, Spain, and at Kamiseye, Japan, to support the 2 forward-deployed fleets. OSIS collects surveillance data from the variety of naval and national intelligence systems and correlates these data to provide a picture of all naval movements at sea.

OSIS is being updated through an OSIS Operational Baseline Upgrade (OBU), which is being installed in the FOSICs and FOSIFs. The object of OBU is to improve OSIS's timeliness to nearly real time (to 95% accuracy) without heavy investment in new sensors, by updating the OSIS data base with each satellite pass and each new sensor reading. Given the degree of noise in existing data, this goal is probably somewhat unrealistic.

◆ FCC

Flag Command Center is the shore station of the commander of the Atlantic or Pacific Fleet. In theory, FCC is his wartime battle station. The FCC communicates directly with the TFCC on board the flagship of a deployed battle group and receives data from the national World Wide Military Command/Control System (WMCCS) and from national-level elements of the Navy Command/Control System (NCCS), such as OSIS. An FCC includes a special decision area arranged to display all-source intelligence information, with desks for intelligence and operations officers. The CNO approved development of an automated Integrated Information Display (IID) for FCCs in 1981, to replace the mass of wall charts, maps, viewgraphs, and plots currently used. In theory, the FCC performs the same role as a ship's CIC, though on a much grander scale, integrating available sensor data obtained both throughout the navy and by national means (TENCAP).

In wartime the FCCs would also control some national ASW forces via ASWOCs (ASW Operations Centers), and submarines

through the fleet SUBOPCONCENs (Submarine Operational Control Centers).

FCCs are being provided for the 2 fleet commanders, at Norfolk and at Pearl Harbor. In theory, the commander of the Atlantic Fleet has 2 operational subordinates, commanders of the Second and Sixth Fleets (the former based in Norfolk); the commander of the Pacific Fleet has the Third and Seventh Fleets. However, the situation is rather more complex. The commander of the Atlantic Fleet is also the commander of the Second Fleet, and in wartime would transform the Second Fleet into the main component of the NATO Striking Force Atlantic. Similar arrangements presumably apply in the Pacific.

In each case, the fleet commander, going from a strategic to an operational role, would have to decide whether to try to command from the shore. Opinions on this point have been mixed, individual admirals feeling very strongly either for or against command from on shore. For example, as commander, Atlantic Fleet, Admiral H. C. Mustin argued that in wartime long-haul communications (on which the FCC concept depends) would not be reliable; he expected to ride into battle on board one of the carriers of his battle force.

The issue of FCC viability is tied to the question of whether the United States will build battle force-capable flagships for the 4 numbered fleets. It might be argued, for example, that in wartime such a fleet might include up to 4 carriers, and that coordination of their hundreds of aircraft might require a substantial data-handling capacity outside the carriers themselves. The earlier flagships were retired because their cruiser hulls wore out, and there was insufficient money at the time (late 1960s and early 1970s) for replacements.

◆ NCCS

The existing Navy Command and Control System was not designed as an integrated entity. The current system still uses 1960s-era computers. They cannot support the sort of data rates required to provide the fleet with the operational information that can be distilled from the very detailed data that more recent sensors feed into the shore part of the system. For example, a submarine equipped with Tomahawk antiship missiles requires a detailed picture of the ships within 250–300 nm of her, and that data can come only from the shore NCCS. The submarine is fitted to process the data, and the satellites have the requisite capacity, but that data must still be collated, formatted, and coded ashore for onward transmission by the submarine operating authority controlling the particular submarine. A new navy front-end (communications) processor (NFEP) is, therefore, being produced to support all the NCCS ashore nodes. Work is currently proceeding on a shore targeting terminal (STT), which supports the submarines, and also on the force high-level terminal (FHLT), which supports ashore ASW sector commanders. NCCS also includes the maritime-defense-zone (MDZ) command/control system, currently being used by the Coast Guard for drug interdiction.

The NFEP system's design was completed during FY89. As of early 1990, full-scale software-engineering design was scheduled for completion during FY91, the system entering service in the fourth quarter of FY92 (July–September 1992). This schedule may well be stretched further since the planned FY90 program has already been deferred to FY91. A series of STT upgrades is now being developed.

◆ OSS

The Operational Support System is used in the FCCs to combine, display, and transmit information to deployed commanders in TFCCs. The 7 FCCs use JOTS systems, and they communicate with the deployed TFCCs via OTCIXS. OSS upgrades the current information-management system and provides modernized access to the DoD-wide WWMCCS (worldwide military command/control system). An OSS upgrade is currently under development. The first stage is to install new computers (DTC II) and large-screen displays. This baseline system employs the Fleet Command Center Battle-Management Pro-

gram (FCCBMP) and Operations Support Group Prototype (OSGP). The second stage standardizes the centers, each of which will ultimately have about 15 computer consoles, presumably DTC II. This version includes the OSIS baseline upgrade (OBU). The planned FY91 program includes development of a Capabilities Assessment Expert System (CASES).

The OSS program, which began in FY89, is being run by the Naval Ocean Systems Center (NOSC) at San Diego. The operational requirement was issued in December 1987. OSS incorporates recent DARPA work on large data-base systems.

Command Aids

Command aids as described here are primarily oriented toward external sources of data or toward data bases loaded before a ship or a force enters an operational area. They often interact with combat-direction systems (tactical data-handling systems), which, although they make use of externally provided data (via data links), are oriented primarily to a ship's own sensors and weapons.

FRANCE

◆ Aidcomer

Aidcomer is a French command-assistance system that can feed data into a tactical data system; the name means *aide du commandement à la mer*. A naval staff objective was issued in December 1987, and the system was first tested on board the carrier *Foch* off Lebanon in September 1989. Series production of a version using modified civilian equipment is to begin in 1992, based on a specification issued in December 1989.

Aidcomer uses 2–10 workstations; they are in 5 locations on board a carrier. This system is intended to be the shipboard terminal of the SYSCOM NG naval command-and-control system, and thus is broadly analogous to the U.S. TFCC/JOTS.

The Aidcomer data bank contains permanent information (entered before the ship leaves port) but can be modified when the ship is underway, either via a keyboard or via formatted messages. Subsystems: Sextant, to prepare naval operations, monitoring them in real time and analyzing them later; Disopair, to plan airborne missions and maintain operational readiness; Digiraid, to assist penetration of enemy defenses; Sachem, to receive or automatically route messages to and from the land-based SYSCOM command/control/intelligence system. Aidcomer will be linked to the SISC or SENIT of the ship carrying it, to benefit from real-time updates of the surrounding situation. Aboard a nuclear carrier, a SISC computer will be reserved to exchange information between the 2 systems. Aidcomer will be fitted to at least 1 command ship each in the Atlantic and the Mediterranean, and all large warships will have provision for its installation (components will be easy to transport).

Data bases: Digiraid (tactical air strike planning), Disopair (air operations), Sachem (communications), Sextant (naval operations).

Aidcomer is being developed by Cap Sesa Defense, Syseca Temps Reel, Graphael, and Itmi in collaboration with the French naval programming center. Software, written in Lisp, includes a relational data-base-management system and a cartographic system.

◆ CIRCE 2000

CIRCE is a French automated aircraft mission-planning system, for rapid planning of up to 5 missions simultaneously. It was conceived as a land-based system, but a variant was installed on board the carrier *Foch* in November 1988 to plan Super Étendard strikes. Maps for mission planning are digitized by a scanner, with an accuracy equivalent to 25 m; the system uses a 2-Gbyte digital optical disk (30-cm diameter) to store a map representing a surface area larger than that of the United States at a scale of 1:5 million–1:250,000. The system data base can include more detailed images, including satellite photos and 1:50,000 maps. The same disk stores terrain elevation data. The

pilot selects the area to be displayed in high resolution and can change scale, recenter, zoom, reproduce 3D terrain perspective, then use these data to plan the mission. The local library includes such relevant data as aircraft and weapons parameters, stored on a 40-Mbyte disk. CIRCE generates all flight documents, loading 2 memories for the airplane to carry, a 2-Mbyte magnetic bubble memory to store terrain data and a data-entry module (2-kbyte EPROM) containing navigation parameters such as turning points and fly-by time. For example, it calculates the amount of fuel required and maps a route to take into account enemy defense, finding an optimum route within available fuel allowances.

GERMANY

◆ TAICOS

Tactical Action Information and Command System, developed by Blohm & Voss and Philips System Technik (PST) of Kiel for the Turkish frigate *Yavuz*, the future flagship of the Turkish Navy. It stores and displays about 120 charts, enlarged sections of which can be displayed. It can also display more detailed data (e.g., concerning shorelines, depth). TAICOS also stores data on own and enemy forces. In addition, it collects, coordinates, and automatically filters track data (from links and from own-ship sensors), position data, course data, and additional information. Presumably, all these data are provided by the ship's STACOS; STACOS is presumably a subset of TAICOS. The main system components, in 2 MEKO modules, are connected by an Ethernet bus.

TAICOS might be considered the prototype of a small-ship equivalent of larger-ship command aids. The *Yavuz* installation is the prototype. The other 3 Series I Turkish MEKOs are fitted for, but not with, TAICOS, but the *Yavuz* installation can be moved rapidly to 1 of them as needed.

UNITED STATES

◆ ACS

Afloat Correlation System is an automated system that assembles off-board surveillance data for the battle group and composite warfare commanders. ACS feeds the TFCC (see entry below) and uses data from OSIS (see entry above), TADIXS B, the Tactical Signals Exploitation System (TASES), and tracks generated within the ship's combat-direction system (ACDS, see entry under tactical systems, below). ACS also sends battle-group track data back to OSIS to help ensure that the larger system carries the same tracks as the fleet at sea. That input helps solve the oceanwide gridlock problem and helps avoid wasting scarce resources. ACS is to be installed on board all TFCC ships and is to operate in conjunction with the new Electronic Warfare Coordination Module and also the Naval Intelligence-Processing System (NIPS).

The goal is to combine ACS with EWCM to form a Force Fusion System (FFS), which would both evaluate threats and handle countermeasures.

TADIXS, the tactical information-exchange data system, is a one-way satellite link transmitting ocean-surveillance information from the FCC (see entry above) to operational units at sea.

ACS might be considered the operational outgrowth of the Outlaw Shark/Outlaw Hawk programs described under the OSIS. Development is planned in 5 phases, all built around a core portion providing limited interim correlator capability. The core will initially be installed in the desktop computer-based Prototype Ocean-Surveillance Terminal (POST). In FY92 POST will be replaced by ACS Phase I, which will employ an improved version of the POST correlation algorithms running on a TFCC-compatible workstation. Phase II will use an advanced multisource, multihypothesis correlation/tracker and add interfaces with other shipboard systems. Phase III will add mainframe computers and parallel processing capabilities to meet higher throughput requirements. Phase IV will complete development of tactical analysis and threat warning capabilities and complete

the currently planned program. The advanced multisource correlator/tracker algorithm is already under development. Work on the multihypothesis correlator/tracker began under the FY88 program. The original ACS Operational Requirement was issued in May 1983.

◆ AFDS

Amphibious Flag Data System, originally developed for the two flagships *Blue Ridge* and *Mount Whitney*; the AFDS requirements were developed in 1964 by a study group convened for the purpose at San Diego.

AFDS combines an integrated operational intelligence center (NIPS, the Naval Intelligence Processing System), an amphibious command-information system (ACIS), and the ship's NTDS. NIPS matches the system on board an aircraft carrier. ACIS is built out of NTDS equipment (based on 1 USQ-20 computer) to provide an amphibious commander with force-loading data (so that plans can be changed if, for example, 1 ship is lost), with the landing plan, with the shore-bombardment and air-support plans, with a bomb-damage-assessment file, and with intelligence data.

Compared to the usual installation, the associated NTDS adds a capability to control aircraft over the amphibious objective area and to coordinate helicopter assault and resupply, close air support, and air defense.

The LHAs and LHDs have limited amphibious flagship capabilities, including austere versions of AFDS. In theory, an LCC would control a MEF-sized operation, whereas the LHA or LHD would coordinate on a lower level (MEB or MEU).

◆ APS

The Afloat Planning System is used to plan flight paths of Tomahawk land-attack missiles. Such planning requires a 3D image of the country over which the missile must fly, including likely threats to the missile, and also the necessary altitude inputs to the missile's terrain-comparison guidance system. The output is a tape whose contents are fed into the missile's guidance system. At present all such tapes are prepared ashore, on VAX 11-780 computers, and as a result ships carrying Tomahawk have little flexibility in the deployment of the missiles. APS will initially be carried on board aircraft carriers in their TFCC spaces; carrier-borne helicopters will ferry tapes to the surface ships carrying the missiles. Ultimately, the system will be aboard all Tomahawk platforms, including submarines (which cannot benefit from the carrier-based APS).

McDonnell Douglas won a competition for a seagoing ruggedized version of the ashore mission-planning system. APS uses a Rolm computer with a 1-Gbyte hard disk, full 3D graphics, and 4 independent CPUs (MIPS R3000s); it is a fully distributed parallel computer. Each CPU is equivalent to 5 UYK-43Bs in throughput. This display is a 1280 × 1024-pixel, 19-in color tube. The graphics engine can generate 100,000 polygons/sec. It can produce a mission tape in 30 sec, compared to 32 min for the VAX; and the tape is absolutely bit-compatible with that produced ashore. This situation is reminiscent of the evolution of Polaris/Poseidon, from full dependence on a computer ashore to a self-contained shipboard operation (see the Strike/Strategic Warfare section).

Total unit cost of the APS is about \$250,000. The first installation will be on board a carrier in 1990.

◆ ASWOC/ASWM

ASW Operations Center is used to support P-3 ASW aircraft. ASWM is the ASW Module on board a carrier, which has a similar function. An ASWOC plans P-3 missions, based on ocean surveillance information (such as SOSUS outputs), and also on data brought back by other P-3s and replayed for analysis. It is built around a central tactical computer, with CRT consoles and a manual plot. Console displays can be projected onto large graphic displays (LGDs) for aircrew briefing and debriefing. The ASWOC supports 4 console stations, so 4 crews can be debriefed simultaneously.

An ASWOC can communicate directly with a NAVFAC (i.e., a SOSUS node) and also (via a dedicated secure link) with the ASW force commander, with other ASWOCs, and with command sites such as FCCs. This digital link operates at 2400 bit/sec and carries both alphanumeric and graphics. The ASWOC also processes information from the merchant shipping and reporting control system. Finally, an ASWOC can also communicate with an airborne P-3C via HF and UHF, linking it to force, fleet, and group commanders and also to lateral commands for quick interchange of ASW information.

Postmission analysis is important because a crew can easily miss a target in flight. That was only a minor problem for aircraft whose crews could monitor only a very few sonobuoy channels, as printed out on their LOFARgram recorders, but a P-3C records many more channels than its crew simultaneously monitors. Hence the need for postmission playback and analysis (although it is also true that visual inspection of a spread-out LOFARgram, after flight, can sometimes reveal targets not detected in flight). The ASWOC, therefore, arose with the P-3C, and it includes a fast-time equivalent of the sonobuoy analyzer on board an ASW airplane.

The ASW Module on board a carrier performs a similar function for the carrier-based S-3; it also controls carrier-based ASW (inner zone) helicopters, and it provides the information on which the force ASW commander relies. Although P-3s or S-3s can in theory function without the support of ASWOCs/ASWMs, in practice they search relatively limited areas and, thus, have to be directed to areas of likely submarine presence. With a barrier, the ASWOC/ASWM ensures that the search pattern is efficient and that it corresponds to the tactical requirement. There are 20 ASWOCs. They are to be modernized (not least to accommodate P-3C Update IV) under a program directed by the Naval Ocean Systems Center (NOSC) at San Diego, and the new version will probably employ DTC II computers. A modernization contract with TRW was canceled in January 1990. The operational requirement for the upgrade was stated in August 1986 (but a C3 upgrade acquisition plan had already been released that May).

◆ CS@SE

The Command Support at Sea Experiment was a test of planned command-center (CIC and TFCC) upgrades (including high-resolution color graphics) by the Applied Physics Lab (of Johns Hopkins University). It is a pointer toward future systems and was probably a major driver toward the current increment 2+ version of FDDS. The displays were large-screen color (as opposed to the current large-screen monochrome) screens and operator console color screens, fed by the Aegis display system (ADS), the shipboard gridlock system with automatic correlation (SGS/AC, i.e., the NTDS picture), FDDS (see below), and the Tomahawk Engagement Planning and Exercise Evaluation (TEPEE) system, so that the experimental displays showed both own-force and OTH data.

Phase I (1987) tested the use of color and advanced graphics on board the cruisers *Ticonderoga* and *Yorktown*, which already had Aegis large-scale monochrome displays.

Phase II (1988), on board the cruiser *Leyte Gulf* and the carrier *America*, added OTH surface tracks as a new element to the display. In the cruiser, the large-screen display showed a combination of real-time (NTDS and own-ship) tracks and nonorganic tracks taken from the Tomahawk Weapons Control System, which in turn derived them from the OTCIXS net. Tomahawk engagement plans and weapons-system performance and response (SPAR) contours were overlaid on the same plot. In *America*, very similar equipment in TFCC took OTH data from the FDDS system and used SGS/AC to add real-time Link 11 data. Both systems also had a secondary small-screen color monitor, the Amplifying Local Display (ALD), at an operator console. This equipment was tested for 15 months on board the carrier and for 10 months on board the cruiser, including major fleet exercises.

The carrier version had additional features, some of them ini-

tially developed for Aegis. The display could be centered on a given latitude and longitude. Range and bearing from any hooked (designated) track to any point on the screen could be displayed. Abbreviated 3-character ship tags could be added to OTH tracks (e.g., "USA" for the carrier *America*).

The system supported Command Conferencing, a means of transmitting graphics directly from one ship to another via OTCIXS, embedded in OTH Gold messages. The receiving ship displays the data either automatically or under user control. The cruiser sent graphics produced by ADS, TEPEE, or SPAR. The carrier used FDDS, JOTS, or overlays received via OTCIXS.

Both ships found the OTH/real-time display valuable but wanted a means of distinguishing between the 2 types of track. In *America*, tracks were normally colored red for hostile and real-time air unknown, blue for OTH tracks and unknown surface, and green for real-time friendly air and other surface (the cruiser did not use track colors). Unfortunately, CS@SE did not correlate real-time tracks with OTH tracks, so some tracks were reported twice, a phenomenon called ghosting. If the OTH tracks were dimmed, ghosting was more obvious since some bright real-time tracks had dim ghosts nearby. However, that did not solve the problem.

Both ships also liked the added on-line data base (detailed maps, airways, political boundaries, cities) associated with the advanced graphics system. Because the display was in color, boundaries were filled in, for better clarity. Finally, color proved quite valuable as a means of compressing information so that it could be more easily assimilated.

The ALD proved useful. It could, for example, show a plot of altitude vs. time for a selected target (the Aegis display shows only range and bearing); such a plot would have precluded the Iranian Airbus shoot-down. The same screen could also show range vs. time, speed vs. time, bearing vs. time, speed vs. altitude, and altitude vs. range. A selected track could be tagged to show the altitude and direction of dive or climb on the main large-screen display; this, too, would have precluded the Iranian disaster. The ALD was more normally used to preview large-screen displays and run playbacks. It could display alphanumeric, and it was the operator entry screen. The ALD mimicked the function of the Aegis Baseline 4 ALD, so presumably later Aegis ships will normally enjoy these functions.

Aside from the graphics, CS@SE could store 24 hrs of tracks and play them back (at different speeds) at will, so that a staff could examine past track data in detail.

CS@SE was supported by a Sun 4/260 computer (a commercial relative of the ruggedized DTC II) with two 280-Mbyte hard disks; the large-screen display was a BarcoData 400 Graphics. The 24-hr track file consumed over 500 Mbytes. There was little space for the additional data bases tried or desired: detailed filled maps (10 Mbytes), political boundaries (5 Mbytes), cities (100 kbytes), airways (2 Mbytes), airfields (70,000 of them: 35 Mbytes), bathymetric data (over 40 Mbytes), and elevation data (over 50 Mbytes).

◆ ISPS

The Integrated Strike Planning System is a current project to develop an automated means of planning air strikes. Current planning is done with strip charts and maps. ISPS should require more massive computer resources than are currently available in any other planning system since it must take into account terrain (in 3 dimensions), enemy defenses, and aircraft and weapons characteristics. Outputs should include not only pilot instructions, but also graphics showing the strike route from the pilot's point of view for prestrike familiarization. Ultimately, such a system should be able to plan a strike route that minimizes an aircraft's exposure to defenses, or that maximizes strike effectiveness under varying conditions. The French navy already has a system of this type called *Circe 2000* (see above), but it has only a fraction of the capability required for ISPS performance.

ISPS is an umbrella program, including systems such as APS and also the intelligence-processing systems. McDonnell Doug-

las already has a TAMPS (tactical aircraft mission planning) package, which provides digital maps, threat data, and aircraft characteristics. It is not yet on board ships, but it is compatible with standard workstations. Other likely competitors include General Dynamics.

Formal adoption of ISPS would help push DTC III (or perhaps a DTC IV) toward high 3D graphic performance because so much of the route-planning function involves 3D modeling. As of the summer of 1990, it seemed likely that ISPS would be released for competition within about 6 months, and that some form of ISPS would appear within 2 yr.

◆ JOTS

The Joint Operational Tactical System will provide the commanders of virtually all ships with a summary OTH tactical picture, derived mainly from the OTCIXS satellite net. The current form uses the same computer (DTC II) as FDDS (see the separate TFCC entry below) and a subset of the FDDS software. JOTS was originally a separate system, an attempt to achieve some of the TFCC performance goals using an easily obtained non-Mil Spec computer, DTC I (an HP 9020) to run FDDS software. The DTC I version is now designated JOTS I, and it is being superseded by JOTS II. The JOTS concept, of standardizing hardware and achieving increased capability by modular additions of software in a distributed system, has now been extended, so JOTS II is a subset of the current version of TFCC. The standard JOTS workstation (the DTC II computer), software, and message format (JINTACCS, as in JTIDS/Link 16) are now used in FCCs (see separate entry) and may well become standard in the national-level worldwide military command/control system.

This development is a tribute to the very rapid advance of computer power, as the specialized central computer and simple terminals of the original TFCC (see separate entry) were superseded by very powerful machines inexpensive enough to be used in a fully distributed network. JOTS began as a poor man's TFCC, run on one powerful workstation, almost certainly as a reaction to the slow production of TFCCs. Its workstation was so powerful that it could actually outperform the specialized Mil Spec TFCC design. Its basic computer was so inexpensive that it could be planned for very widespread installation.

That is probably the first instance of a very important development. Hardware is now quite inexpensive, although software is still very costly. However, once a piece of software has been developed, it can be reproduced quite cheaply. Thus, the cost of an additional example of the hardware/software combination can be quite low, as long as it need not be modified for a particular user. With JOTS, there is little need for modification because the main input, the OTCIXS net, is standard for all users. Unlike NTDS or its successors, JOTS is not tied to any shipboard sensors (it can tap into the ship's NTDS circuit) and so need not be modified for application to a particular ship. Hence the expansion of JOTS to virtually all U.S. warships, from frigates and major amphibious ships and auxiliaries up.

JOTS has 2 functions. It maintains an OTH picture, using updates from nonorganic sensors transmitted mainly over OTCIXS. Second, it is a staff planning tool, capable of projecting ahead the consequences of various alternative decisions. Thus, its software includes both track keeping and a variety of tactical decision aids (TDAs). An incidental effect of the decision aids is greatly to reduce the amount of staff work needed to support a numbered fleet or battle-force commander. In the past the numbered fleet flagships required very large staff spaces, and much of the large staff was needed to do what amounted to supporting calculations (e.g., nuclear-strike planning). The TDAs should greatly reduce staff manning requirements, although they are available to any JOTS user.

Information used by JOTS and by TFCC/FDDS (see below) divides into organic and OTH. Organic information comes from a ship's own sensors and also from Links 11 and 14 within the ship's force. It is characterized as real-time; it is the NTDS or

CDS picture. OTH information is provided mainly by the OTCIXS satellite broadcast, and it is intelligence derived. It cannot, by definition, arrive in real time, but it is used to help build a tactical picture. Presumably, the delays inherent in obtaining such information are acceptable because it concerns objects far from the force, particularly potential Tomahawk targets, which are ships well beyond the force horizon.

JOTS maintains identical data bases (OTH tactical pictures) for all its users. As a user updates the data base, the updated data are transferred to other JOTS users. A JOTS user can, in theory, maintain a global data base. In practice, he or she will generally apply filters to limit updates to the area of interest. In addition, filters can be applied to limit access to specially classified data. Current plans are for all ships, from major amphibious units and frigates on up, to be fitted with JOTS, many in the form of a single terminal.

The standard flagship version of JOTS I is a star network of 5 standard DTC I (HP 9020) computers, 1 acting as communications manager. The DTC Is have 55-Mbyte hard disks, tape drives, one or two 19- or 25-in color monitors, digital Kurta pads for access to the JOTS data base, and 8-port multiplexers. Typically, there are 2 DTC Is in a carrier CIC. On board the carrier *Eisenhower*, for example, 1 showed worldwide ship locations, the other theaterwide data. Reportedly, in 1988 DARPA experimentally connected a similar pair of computers on board the carrier *Vinson* to an intelligence data base, probably carried on optical disks. When a ship shown on a screen was tagged, other screens showed photographs and other detailed descriptive data. The combination was called SDMS (Spatial Data Management System).

JOTS automatic contact data come from up to 3 Link 14 broadcasts, the OPINTEL broadcast (including BLUFORLOC [Blue Force Location]), OTCIXS Rainform (OTH) Gold broadcast, Link 11 (requires special link-monitor unit), "FOTC" (OTH targeting) and/or HITS (high-interest target system, via GENSER teletype), FDDS/TWCS (Tomahawk weapons-control system) broadcast via OTCIXS, TADIXS broadcast, TACINTEL (tactical intelligence, special classified information), and other 9020-based units (such as TEPEE). The system is also connected to the Prototype Ocean Surveillance Terminal (POST). For organic data, JOTS taps into own-ship NTDS and navigational data. It transmits via the OTCIXS and High-Interest Target (HIT) nets; the main JOTS net is OTCIXS.

The current TDAs are EMCON planning, C3CM satellite planning, Chainsaw (fighter tactics) planning, vector-logic-grid (fighter tactics) planning, aircraft-search planning, refueling-route planning, communications planning, ASW-search planning, barrier-search planning, area-search planning, fuel-consumption planning, surface surveillance, CAP stationing, surveillance air intercept, Tomahawk launch, multi-unit Harpoon launch, 2-track analysis, AAW surface-ship screening, ASW passive screening, sonobuoy-field management, SEATAK, intercept analysis, maneuvering board, MTST analysis, time statistics, line-of-bearing (LOB) firing, closest point of approach (CPA), and position and intended movement (PIM). JOTS produces acoustic propagation loss curves, IREPS radar-range predictions, HF-spectrum-propagation predictions, and predictions of satellite vulnerability. It also conducts contact analysis (tracking algorithms, history plots, contact predictions, constructions of containment areas, and solutions for dynamic bearings/ranges).

JOTS I software was originally derived from work done on the FDDS system, and some FDDS improvements were not implemented in JOTS. Restructuring of the program to JOTS II began in the spring of 1989; JOTS and FDDS were merged because both could use the same software and hardware. The only real difference is that FDDS is more elaborate, with more computers.

JOTS I was succeeded by 3 parallel programs: VIDS (Visually Integrated Display System), conceived as the JOTS upgrade, and TFCC installations for the cruiser *Belknap* and the carrier *Saratoga*. VIDS and the *Belknap* system used JOTS I software re-

written in UNIX and C so that they could run on the HP 835 computer, which turned out to be the unsuccessful competitor for the DTC II contract. They differed in the extent to which they could accommodate a commercial window package, X (not at all in VIDS, partly in *Belknap*, not at all in *Saratoga*).

When the ruggedized Sun-4 workstation won the contract, attention turned to a standardized system using the new DTC II workstation: JOTS II. JOTS II also introduces a standardized man-machine interface. VIDS has already been removed from the Sixth Fleet flagship *Belknap*. The first full JOTS II/TFCC increment 2+ is on board the carrier *Independence*. It fully implements the X (windows) program, and it incorporates EWCM and POST 6.0 (which is no longer a separate piece of hardware). As of the spring of 1990, the USS *Independence* installation is scheduled for operational test and evaluation at the end of June.

On board a ship the elements of JOTS II/TFCC are linked by a fiber-optic bus, initially a version of Ethernet but ultimately SAFENET II.

Current planning calls for JOTS on board all the cruisers, the destroyers, the missile destroyers, the frigates, the ocean-going amphibious ships, and major auxiliaries. The carriers and some other ships will have TFCCs. JOTS is also installed on board British flagships, including the light carriers. These units do not share the U.S. OTCIXS net directly. Instead, OTCIXS is transmitted to the naval command center at Northwood, filtered there, combined with British national intelligence, and retransmitted to the ships. Compared to the British Opcon, JOTS is superior because it provides graphics. Opcon provides only alphanumeric data, and in this case it is multiplexed with JOTS. The British installations use HP 9020 computers and are to be upgraded with HP 300s.

JOTS is unusual in that it came, not out of a stated operational requirement, but out of a felt operator need. In 1981 RADM Jerry O. Tuttle was ComCarDiv 8, on board USS *America*. He conceived JOTS as an application of the very powerful desktop computer (HP 9845, a precursor of the HP 9020 bought as DTC I), which was already available on board. Costs were held down by using some existing FDDS software. In its original form, JOTS shared data with other ship commanders via a satellite link (CUDIXS, later OTCIXS). As ComCarGroup 2 in 1983, Admiral Tuttle expanded JOTS to the command/control applications described above. The admiral brought JOTS with him when he took over the Fleet Command Center at Norfolk; it became the shore terminal of the Operational Support System (OSS). A JOTS derivative is now used by the U.S. national military command authority and by the deployed CINCs.

At each stage JOTS proved useful even though alternative programs had been proceeding for many years. The key seems to have been the flexibility inherent in the computer. JOTS changed by changing software rather than hardware. The same hardware is used both in crisis and in routine situations, although with different software. JOTS was originally developed entirely with operational (OPTAR) funds rather than through the formal programming and budgeting system. Only quite recently has it been legitimized by designation as a "rapid prototyping" system. In theory, rapid prototyping allows a user to demonstrate proof of concept without designing and developing a system based on theoretically evolved requirements. User needs are addressed in the prototype stage. Such prototyping becomes much more manageable as computer power grows to the point where software, rather than hardware, has to be prototyped.

◆ NIPS (SYQ-9)

The naval intelligence-processing system (NIPS) is the shipboard intelligence center located aboard carriers and amphibious flagships. Automatic retrieval of intelligence information becomes essential as automated planning systems (such as APS) enter service, and also as shipboard CDSs (such as ACDS Block 1) accept such data to supplement operational information. NIPS is being developed to accept data automatically from re-

connaissance and other intelligence sources, and to feed data automatically into combat-planning systems.

The current SYQ-9(V) is built around a UYK-7 computer and 7-17 UYQ-23 displays. It has a single I/O console (OA-7984), 1 or 2 disk memories (UYH-2), 2-8 teleprinters, and a digital, magnetic, recorder reproducer (RD-358/UYK). The (V)1 version has 7 computer displays and 2 teleprinters.

Full-scale engineering development of the current (V)4 version began in FY89. Work began that year on a means of transferring relevant data bases from the Tactical DoD Intelligence Information System (DODIIS) into NIPS. That year, too, an improved communications interface between the Fleet Imagery Support Terminal (FIST), a component of NIPS, and the Imagery Processing Intelligence Exchange (IPIX) began engineering development. NIPS is now being made compatible with the Tactical Aircraft Mission-Planning System (TAMPS), the Tactical EA-6B Mission-Planning System (TEAMS), the Tactical Electronic-Reconnaissance Processing Evaluation System (TERPES, a Marine Corps system), the Standoff Land-Attack Missile System (SLAM), and NCCS-A (the afloat variant of the naval command/control system, including TFCC). During FY90 work began on an interface with the Joint Services Imagery Processing System (JSIPS), the new filmless reconnaissance system (see the Strike/Surface Warfare section). The FY90 program also included initial work on NIPS interfaces to the Tomahawk cruise missile afloat-planning system (APS) and to the digital imagery workstation (DIWS).

SYQ-9(V)4 is expected to enter production in FY91.

◆ Outlaw Hunter/Outlaw Viking

These projects are intended to improve OTH targeting by, respectively, P-3 and S-3 aircraft by providing them with the wide-area tactical picture normally provided to surface ships via the OTCIXS satellite circuit, and typically displayed via JOTS. Aircraft are fitted with UHF satellite receivers for the OTCIXS circuit, as well as GPS receivers that provide them with accurate position information for use with the OTCIXS data. The aircraft terminal is the existing Advanced Tactical Workstation, a DTC computer, similar to that used in JOTS. The program appears to be an airborne equivalent of JOTS, with the same potential for quickly improving force connectivity. It is generally associated with the ongoing ISAR improvements to patrol aircraft radars.

Outlaw Hunter was a quick demonstration project; the first conversion was completed in 1989 in 9 months at a cost of only \$700,000. This figure included all development costs. Further upgrades should take 8 weeks, at a cost of \$250,000. As of early June 1990, the prototype Outlaw Hunter had already participated in several exercises, during which it provided real-time targeting data to Tomahawk and Harpoon platforms. A modified Atlantic-Area Outlaw Hunter will use a lighter-weight modem, which will reduce overall system weight from 1200 to about 150 lb, a reduction allowing the airplane to carry a full load of sonobuoys. This airplane should become operational in January 1991, for a 6-month work-up toward operational test and evaluation in the summer of 1991. Outlaw Viking is planned for FY91. Both are funded by Op-942, using OTH-T funds.

◆ SPAR

System Performance and Response is a set of computer programs running on an HP 9020C (DTC I) computer, installed on board an Aegis cruiser. It determines Aegis detection, statement doctrine, weapons control-system response, and expected missile performance against specific threats. The system takes atmospheric conditions into account.

Because SPAR is, in theory, a planning tool, it does not have to run on a Mil-Spec computer.

◆ TEPEE/TWCS

Tomahawk Engagement Planning and Exercise Evaluation is the means of planning Tomahawk (OTH missile) firings. Its OTH picture is derived from OTCIXS. TWCS is the associated

Tomahawk Weapons-Control System, which actually feeds data into the missile. In a JOTS ship, TEPEE feeds data into JOTS. Its software includes time-of-flight corrections for Tomahawk land-attack missiles, planning for coordination of tactical air strikes with Tomahawk strikes, and scenario generation for battle-group training. The system runs on an HP 9020C (DTC I) computer with a 55-Mbyte hard disk and a 67-Mbyte tape drive. Afloat installations: 4 CV, 4 CVN, 4 BB, 5 CGN, 7 CG, 15 DD, 2 LCC, a total of 41.

TWCS was introduced in 1983 on board the *Iowa* and *Spruance* classes. Initially, Tomahawk was limited to 1-on-1 engagements, partly because of the limited number of platforms, but also because of a lack of experienced battle-group staff. However, the fleet wanted more, and in 1986 the Tomahawk community introduced a Battle-Group Data-Base-Management (BGDBM) capability, initially in COMDESGRU One. Each Tomahawk platform could then perform as:

- (i) Force Over-the-Horizon Track Coordinator (FOTC), responsible for track management and dissemination of a common OTH data base.
- (ii) Participant, accepting the OTH data base from the FOTC only.
- (iii) Nonparticipant, operating as an autonomous OTH-T data-base manager, as was standard prior to the appearance of BGDBM.

In this initial version of BGDBM, all managed track data originated with the master (FOTC) ship, and ships could not use their own organic (sensor and broadcast) data. The system operated relatively slowly (the FOTC ship was in effect a bottleneck), and delays made for inaccurate shooting. This version of BGDBM was analogous to a centralized CDS. At the same time, Aegis ships had their own Aegis/Tomahawk interfaces that did not take BGDBM into account. Such ships, therefore, had to shut down their internal interfaces when accepting FOTC tracks (the communications protocols did not match).

Work on a TWCS block upgrade began in March 1986. This was a more distributed system, in which the ship knowing the most about some specific information made the correlation decision, and no system would be denied information from organic sensors. Each node (each ship) appended its own track number to a contact; the FOTC ship acted as track manager rather than as correlator and manager. FDDS and JOTS operate in much the same way. The 2 prototype platforms are the USS *David R. Ray* and *Arkansas*.

TWCS is a direct outgrowth of Outlaw Shark/Outlaw Hawk, the original attempt to provide OTH-T data for Tomahawk antiship missiles. TWCS originally used a UYK-19 computer, then a Rolm 1602, and then the current 1666B. This system also exists in TFCCs. The system accepts the same data that go into JOTS and provides high-probability classification solutions. It updates missile fire-control solutions until the moment of launch.

◆ TFCC/FDDS

Tactical Flag Command Center supports a battle-group commander and the composite warfare commanders, providing them with relevant material developed by the U.S. Navy's worldwide intelligence systems, on a timely basis. In contrast with Soviet practice, the concept is that existing sources of information, none of them intended primarily for naval surveillance, can be fused to produce a sufficiently accurate tactical picture, well beyond the horizon of the sensors within the battle group, yet still within the potential battle space. Over time the emphasis has shifted from intelligence fusion ashore (the tactical picture being transmitted to the TFCC) to a less centralized form of fusion, in which much of the picture is assembled at the TFCC. TFCC now includes the Afloat Correlation System (ACS), to correlate available off-board intelligence data with data from the force itself (i.e., to fuse it) into a consistent series of tracks. JOTS (see above) is, in effect, a less expensive and less elaborate equivalent of TFCC as originally envisaged.

The computerized FDDS (Flag Data Display System), USQ-81(V), maintains the system's OTH tactical picture, supported by the global OSIS intelligence system via the high-density (2400-baud vs. 75-baud for the normal fleet radio broadcast) OT-CIXS satellite net. It is supplemented by a second net for sensitive intelligence.

TFCC has a lengthy history. It was inspired by a Grumman study of command requirements (1968-72, for NEL [Naval Electronic Laboratory], San Diego). The then Naval Electronic Systems Command prepared RFPs in 1972-73, formulating the TFCC concept: ocean surveillance information would be provided by a fusion center ashore. An interim TFCC was demonstrated on board the carrier *John F. Kennedy* in 1975-76 (see the discussion of Outlaw Hawk and Outlaw Shark under OSIS, above). Development was slow, partly because senior officers could not agree on standardized operating facilities, partly because funds for command/control developments were limited, and partly because system requirements expanded suddenly from command team (battle-group commander) to commander plus 3 composite warfare commanders. Martin Marietta won the design competition in 1975-76 and built a prototype, but the program proved too expensive and was canceled in 1978.

In August 1979 the CNO, Admiral Hayward, broke the project into 3 increments: (1) preparation of TFCC spaces, using existing equipment; (2) installation of special command/control displays; (3) enhancements. In March 1980 a ruggedized version of the Outlaw Shark terminal was chosen as the USQ-81(V) baseline. Three interim TFCCs were temporarily installed to gain operational experience on board the carriers *Midway* (June 1980) and *America* (January 1981) and the cruiser *Josephus Daniels* (February 1981). At this stage TFCC could display an area out to 1500 nm.

In January 1981 the CNO decided to buy 6 systems, 3 for each coast, for the carriers *America* (completed 15 May 1983) *Constellation* (completed 15 July 1983), *Nimitz* (completed 15 September 1983), *Midway* (completed 15 October 1983), *Ranger* (completed 15 February 1984), and *John F. Kennedy*. A seventh TFCC was installed on board an amphibious command ship, and 2 were built ashore, 1 at the Naval Ocean Systems Center and 1 at the Unisys development center at Reston, Virginia. This version was a centralized system analogous in structure to NTDS, with a Rolm 1666B computer supporting Motorola workstations, each of which had only 64k of memory.

In 1983 TFCC was planned for 15 carriers, 4 *Belknap*-class cruisers, the *Long Beach*, and the 2 amphibious flagships. The question was whether to extend the existing installation to the rest of the ships or to redesign it to use the new UYK-43/44 computers. TFCC spaces (increment 1) were installed on board carriers during their SLEP modernizations. However, TFCC design was once again totally revised: the current increment 2+ is a fully decentralized system consisting of workstations. *Saratoga* was to have been the prototype, with Raytheon CWS workstations. However, the CWS was rejected, and *Saratoga* was fitted with DTC IIs instead. The DTC II communications module was not yet ready, so her TFCC retained the Rolm computer as a front-end communications processor.

The TFCC increment 2+ prototype is the carrier *Independence*, which is to undergo operational test and evaluation in June 1990. At this stage TFCC and JOTS have merged, with JOTS a subset of the more elaborate TFCC software; both use essentially the same hardware, except that TFCC uses 2-screen workstations with associated printers. EWCM and ACS, which had been conceived as separate hardware, will now be additional software within the standard TFCC hardware. As with JOTS, computer hardware is now so inexpensive that it is easy to extend the system to more ships. In 1990 TFCC is planned for 34 ships: the carriers, the amphibious flagships, the *Wasp* and *Tarawa* classes, the fleet flagships (*Belknap*, *Long Beach*, *Coronado*, and *La Salle*), and the 2 remaining battleships; there will also be 3 training sites ashore.

The increment 2 and 2+ TFCC is arranged around the battle-group commander's Battle Watch Station, a special T-shaped

desk with 2 chairs facing a large-screen display (LSD). The increment 2+ version of this space also contains two 2-screen and one 1-screen workstations. Additional TFCC workstations are located in spaces such as CIC, the carrier intelligence center (CVIC), and the supplementary plot (SUPPLOT); these workstations are used for track management. The system is tied together by fiber-optic LANs. Its software supports distributed processing among a communications processor (the Data Management Processor, or DMP) and the workstations.

The DMP is responsible for communications, message processing/filtering, and correlation between the inputs of the workstations, i.e., updating the system track file. Automatic track correlation is based on matching attributes in different reports and also on testing possible tracks against physical conditions, such as the maximum speed of a ship. Operators resolve ambiguities manually by forcing track updates or by creating new tracks. The correlator involved has been in use since 1980. Future versions will make better use of ELINT and maneuvering-target statistical-tracking (MTST) data.

The system data base is maintained on a distributed basis by a specially developed Database-Management System (DBMS). Each DTC II maintains a copy of the primary platform file (track file) for local reference; the copies are kept current by a broadcast initiated for each correlation or manual track update. This architecture is equivalent to that of a federated combat data system.

The current TFCC-space configuration shows the T-table for the battle-group commander, in the foreground, with the large-screen projection display above it. The tall consoles in the background are FDDS color workstations for the warfare coordinators. The flat bulkhead panels are automatic status boards. (UNISYS)

Color is used to achieve faster decisions and to present information more clearly (e.g., blue for friendly forces, red for hostile, and green for neutral); maps are filled in and tables are colored for rapid identification. The displays are windowed, and operators have trackballs.

FDDS is connected directly to OTCIXS, to Links 11 and 14, to the Fleet Broadcast, and to Flag Communications. In addition, on board a ship it is connected to POST (see below), to JOTS, to the TFCC Information Management System (TIMS), and to the Cryptologic Combat-Support Console (SSQ-93).

FDDS is one terminal in the FOTC (force OTH coordinator) broadcast. It can act as FOTC or as a participant. FOTC is a track manager; it provides consistent track data rather than individual event data (as in NTDS); ships receiving the broadcast can build up their own track files equivalent to those held by the FDDS ships, as the basis for consistent decision making throughout a force. For example, FOTC serves as a basis for Tomahawk antiship targeting.

UNISYS won a contract for up to 19 enhanced TFCCs in October 1987; the first was installed on board the carrier *Saratoga* in October 1989. The second will go on board an amphibious command ship. As of late 1989, UNISYS had received contracts for a total of 3 installations.

Software is still being developed. The current dynamic displays do not provide representative graphics and symbology; the planned upgrade will be fielded in FY91. The ELINT correlation/tracking update for FDDS will initially deploy with a reduced track-to-track correlation capability (POST 4.2); the full capability will not appear until some time in 1990 (POST release 6.2). The afloat correlation system (ACS) is to be added to TFCCs in 1992 and will be fully capable in 1994 (it was originally scheduled for 1990). The planned EWCM (electronic warfare coordination module) is to enter service in TFCCs late in

1990. As of early 1990, there were 3 alternative versions, 2 developed by naval laboratories and 1 by UNISYS. It should be emphasized that these are all software, rather than hardware, developments; TFCC will continue to be built entirely out of DTC II computers.

USSR

◆ EORSATS

EORSATS is the generic designation for the Soviets' ESM Ocean-Reconnaissance Satellites, which presumably detect radar-frequency (line-of-sight) emissions from the sidelobes of surface ships' radars. The first of these passive naval satellites was Cosmos-651, launched in May 1974. It and its successors were launched into circular orbits at 65 deg of inclination, maintaining a 93.3-min orbital period.

In 1986 the Soviets launched the first of a new generation of EOR satellites, Cosmos-1735, described at the time (by U.S. officials) as the first new design in 15 years. It works in conjunction with Cosmos-1834, launched in the spring of 1987, which has a 259×250 -mile orbit inclined at 65 deg. Both orbits are unusually low, and together the 2 satellites provide coverage of every part of the world every 3 days, compared with every 4 days by earlier systems.

EOR satellites typically provide their data, probably not precise enough for targeting, to a central naval command, which then tasks Soviet naval forces to intercept and identify the contacts.

◆ RORSATS

Radar Ocean-Reconnaissance Satellites, nuclear-powered, can supply data either to a central naval command-authority or directly to a submarine or surface ship. The submarine terminal uses the Punch Bowl antenna.

These satellites are normally launched in pairs in circular orbits 155–175 miles high (to maintain constant position relative to the targets) at an inclination of 65 deg, the pair being 6 deg apart for cooperative tracking. Each is about 14 m long and weighs about 4950 kg; power is supplied by a small 150-kW nuclear reactor (with 50 kg of U-235 fuel). Normally, the satellite is boosted into a very high orbit when its fuel has been exhausted; but in 2 cases (Cosmos-954 in 1978 and again in 1988), boosting has failed, and the satellite has crashed to earth. Useful life is reportedly 60–80 days.

Reportedly, the radar is a side-looking type that uses a slot antenna in the side of the satellite and scans a swath about 400–500 km wide. The radar probably operates at relatively high frequency since it is reportedly ineffective when the target area is obscured by bad weather.

The first operational RORSAT, Cosmos-198, was launched in December 1967, the first test vehicle having been launched in 1965. From 1967 to 1975, 10 out of the 12 Soviet naval satellites launched were RORSATs; but since 1975 passive satellites have predominated. Even among the RORSATs, orbital lifetime was quite limited until 1972—suggesting that the program was not entirely satisfactory. For example, a satellite launched in 1970 during the Jordanian crisis did not survive for a day in orbit, and another, during the Angolan War in 1975, lasted only 1 day. However, in 1972 average lifetimes as great as 4 months were observed. Both active and passive satellites supported the 1975 Soviet naval maneuvers. RORSAT launches were suspended in 1978 after the Cosmos-954 failure but resumed in April 1980.

UNITED STATES

◆ White Cloud

White Cloud is a passive ocean-surveillance satellite-system employing clusters of satellites and functioning as the overhead part of the Classic Wizard ocean-surveillance system. Each satellite is reportedly equipped with IR and mm-wave scanners and with receivers for intercepting radio transmissions. Each cluster

of 3 satellites (plus a mother) orbits at an altitude of about 700 nm and can detect emissions from ships 2000 nm away. The cluster is used so that emitters can be located by interferometry, using the distance between the satellites as a baseline.

The first cluster was launched in 1976, and the fifth cluster was placed in orbit in June 1983.

White Cloud seems to have been conceived as an intercept system to detect and catalog Soviet emitters so that units equipped with tactical ESM devices could identify those emitters. The location capability was necessary to pair the emissions with particular Soviet platforms. However, this capability could also be turned around to track known Soviet platforms, under TENCAP and related programs.

This type of system should be able to detect even line-of-sight systems such as short-wave radars by picking up their sidelobes. Interferometry is limited in its precision; in the late 1970s a program called Clipper Bow proposed to combine White Cloud with an active radar that could locate emitters more precisely. Congress killed Clipper Bow in 1980, ordering the navy to participate instead in similar air force and CIA projects (thus far unannounced).

It should be emphasized that no very limited constellation of satellites (such as White Cloud) can provide continuous coverage of the world's oceans. Instead, the partial coverage that can be obtained can be combined with other sources of information to give reasonably full information on the movements of ship-based emitters. Although the localization of targets is imprecise, the system is effective because of the limited speed of surface ships. No such system can be effective against fast-moving emitters such as aircraft. For these reasons, active radars are required to track Soviet naval bombers, and very large numbers of satellite radars would be required to provide solid coverage.

The navy is currently proposing an IR satellite for wide-area air surveillance (the air force supports an alternative radar system).

Surface Radar/ELINT (Electronics Intelligence) Systems

AUSTRALIA

◆ Jindalee

Jindalee is the Australian project, for sea and air surveillance, that consists of 3 OTH radars. Jindalee also monitors sea-state and wind direction and is currently being used to provide wind- and sea-state maps for the area north of Australia.

The name, meaning "bare bones," originally applied to an experimental OTH radar at Alice Springs. This experimental radar was conceived as the culmination of the earlier Project Geebung, which investigated HF propagation via the ionosphere, between Woomera and Broome. Since this type of propagation is the basic mechanism for OTH radar, project Geebung was, in effect, a feasibility study for such a system. In 1974 the study built Jindalee Stage A at Alice Springs; this system projected a single pencil beam toward Derby to obtain basic performance data, testing the reliability of ionospheric radar-propagation near Australia. The radar was able to detect, for example, civil aircraft at Singapore. Jindalee A became operational in 1978. Its success led to Stage B, at Alice Springs, in 1979. Two beams were steered within a quadrant looking north-westward. Stage B attained "minimum capability" (about 50%) in 1982, and this experimental program was completed at the end of 1985. Experimental targets included Mirage III, F-111, HS 748, and Pilatus Porter aircraft, as well as ships as small as patrol craft.

Target resolution is reportedly 20–40 km. Range may be as long as 4000 km. Propagation is normally off the F-layer of the ionosphere (about 350 km high), but range may be shorter when the E-layer (150 km high) is used, as is sometimes possible. Frequency is about 30 MHz, and transmitter power is about 400 kW. The frequency must be selected to avoid multipath (bouncing off more than one layer) propagation, and also to avoid in-

terference (e.g., with the Milky Way, at about 20.5 MHz). One result of the early studies was the discovery that the ionosphere, at least over Australia, is substantially more stable than had previously been thought.

The Stage B transmitter was built at Harts Range, with the receiver located about 100 km away at Mount Everard, both north of Alice Springs. The transmitter consists of a large array of log-periodic antennas, each about 30 m high, radiating over a cleared area covered with a reflecting wire-mesh mat. The receiver is 2.8 km long, consisting of 492 elements (each a twin in-line broad-band monopole). Beams are reportedly formed by a set of networks of cables cut to precise lengths. That characteristic presumably limits the extent to which the radar can shift frequencies, since the direction of a beam so formed depends on frequency (operation is equivalent to that of a frequency-scanned radar). The equipment was upgraded during 1986, and operations began in January 1987.

Jindalee reportedly incorporates special locally developed software for automatic detection and tracking. The main means of detecting aircraft is doppler; but other methods were developed for ships, and the Australians claim that the latter represent a major advance in OTH radar technology. Given Australia's reported exchanges with the United States, it may be presumed that these concepts are incorporated in the U.S. ROTHr (see below).

The three operational radars of the Jindalee Operational Radar Network (JORN) will be in central Queensland, southwest Western Australia, and southern Northern Territory. As of late 1989 the Australian government planned to award contracts immediately for 2 systems, with an option for a third. Tenders closed on 29 August; the bidders were AWA (Amalgamated Wireless of Australia)/CSA (Computer Sciences of Australia)/Transfield/GE; BHP Aerospace/Raytheon/Andrews Antenna/Logica/Computer Power; and Telecom-GEC Marconi/Lockheed Technology (Australia). AWA won early in 1990, and the first site (Queensland) is to be operational in mid-1994. The Alice Springs radar is being upgraded for further research.

In July 1988 the Australian government announced that it planned to acquire 4 AEW aircraft to fill the gaps in Jindalee's coverage. The probable implication is that Jindalee will provide early warning in a band about 3000 km distant and that the aircraft will track targets and manage the air battle at shorter ranges.

UNITED STATES

◆ ROTHr (TPS-71 [XN-1])

ROTHr is the Relocatable Over-The-Horizon Radar, a system built by Raytheon after that company defeated General Electric in a 1986 competition. ROTHr is intended primarily to provide

The ROTHr receiving array. (Raytheon)

The ROTHr transmitter array. (Raytheon)

a fleet commander with early warning of the approach of Soviet antiship bombers; ROTHrs are to be emplaced so that their beams sweep the likely paths along which the bombers may fly. It is clear that those paths may change with major shifts in the political situation. A fleet's surveillance assets should be able to shift with the fleet; ROTHr approaches that ideal by being relocatable over a period of weeks or months. ROTHr will also be able to detect ships. ROTHr was chosen as preferable to a much more expensive alternative, a system of radar satellites that would have provided continuous coverage of the entire globe.

Like other OTH radars, ROTHr operates by bouncing its HF beam off the ionosphere. Ionospheric conditions vary from place to place in the world. To be truly relocatable, therefore, ROTHr incorporates a quasi-vertical incidence (QVI) sounder and a radar-backscatter grounder for propagation management assessment (PMA), which provides automatic adjustments according to changing ionospheric conditions. Transmission is FMCW at an average power of about 200 kW, for a reported range of 1600 nm on ships and aircraft.

The system consists of 3 separate sites: a transmitter (about 1200 ft long) 50–100 nm from a receiver, and an Operations Control Center (OCC) at the receiver. The transmitter consists of a series of wires strung from short masts; the receiver is a double array of dipoles about 8500 ft long. Beams are formed digitally in the signal processor, roughly as sonar beams are formed digitally in a DIMUS sonar.

Full-scale tests began about April 1987. The receiver was located at the Naval Security Station at the North Carolina border, near the Dismal Swamp, and the transmitter was about 25 miles east of Richmond (Whitehouse, Virginia), i.e., 75–100 nm apart. About 10 ROTHrs will be built, beginning with 3 under the FY88–89 budget. The test unit is emplaced at Amchitka, in the Aleutians; of the other 3, 1 will go to Guam, 1 probably to Amchitka (each covers a 60-deg sector, so more than 1 can usefully be employed at a given site), and 1 to Virginia (for operational evaluation and training). The operational ROTHr at Amchitka entered service in 1989. Each ROTHr costs \$65–85 million.

In May 1990 it was reported that Japan plans to buy a Raytheon ROTHr radar to track Soviet Far East forces off the Siberian coast and in the Sea of Japan. The radar is to be located on Iwo Jima (no site in the Home Islands was deemed satisfactory). It is included in the FY86–90 Five Year Plan (FY90 is 1 April 1990–31 March 1991).

ROTHR coverage of 1.6 million square miles of the Caribbean, from a radar located in Virginia. (Raytheon)

Strategic Underwater Sensor Systems

UNITED STATES

◆ FDS

Fixed Distributed System is an alternative to, and possible successor of, SOSUS. The name implies the use of a large number of elementary detectors, fixed in place, as compared to the small number of big beam-formers used in SOSUS. A U.S. Navy schematic drawing released in 1989 shows lines of upward-looking point hydrophones, 5 in a line, each line about 50 nm from the next; 3 such lines form a barrier. Individual hydrophones are shown as 13 nm apart. The sensors are probably linked by a fiber-optic cable since fiber optics is necessary to carry the volume of data involved. Presumably, the individual sensors exploit reliable-acoustic-path (RAP) propagation, with an individual range on the order of 12 nm. Because each sensor is likely to be much smaller than a SOSUS array, it might be much more practicable to develop a rapidly relocatable equivalent to FDS, a successor to the failed RDSS program.

Compared to SOSUS, FDS would cover a much smaller area, but with a much higher probability of detection. FDS would, therefore, be laid in a strategic strait or choke point.

FDS was announced in 1984. In 1989 the navy issued an RFP for the FDS shore station and information processor, to be awarded on a competitive basis. As of early 1989 AT&T was prime contractor, and the full system was expected to be in service by the second quarter of FY95.

◆ SDS

Surveillance Direction System is envisaged as the integrating element of the integrated undersea-surveillance system (IUSS); the IUSS consists of SOSUS, SURTASS, FDS, and the new LFA

(low-frequency adjunct). SDS is intended to identify a contact in any one system and cue others to seek contacts representing the same object. As of early 1989 a draft RFP was expected in the late spring or early summer, with the formal RFP following in the fall, and a decision on competing contractors due in the fall of 1990 or later. This schedule parallels that of the FDS.

◆ SOSUS

This system of large fixed underwater arrays has been in service since about 1955, increasing in extent and sophistication over time. SOSUS was apparently inspired by the discoveries, just after World War II, of the deep sound channel and of the convergence-zone effect. SOSUS was originally suggested as a means of detecting submarine operating areas so that coastal convoys could be rerouted. However, it was later discovered that, with appropriate signal processing, a system of SOSUS arrays could cover much of the North Atlantic and North Pacific Oceans and thus could be used to cue patrol aircraft. Only in the late 1960s did then-Secretary of Defense Robert S. McNamara explicitly connect SOSUS with the P-3 Orion program.

The role of long-range submarine detection has changed over time. In the late 1950s SOSUS was valued as a means of detecting Soviet strategic submarines that, it was assumed, would have to approach American waters to fire. Later, it was assumed that the Soviets would surge large numbers of submarines into the North Atlantic just before attacking Western Europe: SOSUS was, then, primarily a war-warning sensor. However, it was also a means of tracking attack submarines in the open ocean and, therefore, a means of cueing patrol aircraft to deal with them. SOSUS could provide at least an approximate picture of Soviet submarines' patrol areas and could, therefore, also be used as a guide for evasion, whether by convoys or by naval forces.

The overall effectiveness of the SOSUS/P-3 combination depends upon several connected factors: first, the probability of detection by SOSUS; then, the size of the areas in which SOSUS locates a submarine; finally, the ability of the P-3 to redetect the submarine within that area. SOSUS is a passive system, but it uses several arrays whose beams should cross to locate a contact within a limited area.

In the current system, raw data are initially processed by NAVFACs (Naval Facilities), which pass their products to Regional Evaluation Centers (RECs: 1 each for Atlantic and Pacific) and then to Main Evaluation Centers (MECs), which have access to information from other sources. In 1974 it was announced officially that there were 22 SOSUS arrays; there has been some speculation that this total includes only arrays off the coasts of the continental United States.

It now appears that SOSUS was the first application of the LOFAR narrow-band signal-processing technique. The prototype array, at Eleuthera in the Bahamas, was about 1000 ft long and consisted of 40 hydrophones forming beams about 5 deg wide. When the array was first built, about 1952, each beam had to be processed separately, and detection/classification took about 5 min. The beam could then be shifted to another bearing, using delay lines. At this time the goal was to achieve detections at 50–500 miles. It is clear that these specifications no longer even vaguely apply, but they indicate the likely improvements in SOSUS: beam preforming capabilities, so that all beams can be sampled simultaneously; larger arrays at greater depths, to make better use of propagation within the deep sound channels and to achieve greater gain; and low-loss transmission lines, to send data back to the shore stations. The original installation was designed to detect snorkelers: in 1952 such submarines were quite loud by current standards.

One improvement to SOSUS has been publicly described. In common with the airborne LOFAR systems of the 1950s and 1960s, SOSUS used a time-compression (analog) method, Deltic, to build up the signatures the system recognized. That scheme was effective as long as the threat consisted of relatively noisy diesel submarines and then noisy first-generation nuclear submarines. However, the signatures of second-generation nuclear craft (Charlie, Victor, and Yankee classes) were more subtle. A Canadian company, Computing Devices of Canada (CDC), introduced digital acoustic analysis in the 1960s, applying FFTs to extract spectra from sampled inputs. When the original FQQ-1 processor was replaced by a new FFT processor, SPEAR, it was reportedly possible to recognize the new signatures by analyzing their fine structure. CDC later provided recorders to supplement SPEAR analyzers, and these systems were reportedly installed throughout the U.S. and Canadian SOSUS system.

LOFAR, i.e., detection by signature, allows different SOSUS stations to be sure that they are detecting the same submarine (so that they can cross beams to provide range as well as bearing). Moreover, given the signature of the submarine, an airplane using LOFAR buoys should have a better chance of redetection, comparing the known signature to the received signal. This combination (SOSUS plus patrol aircraft) was first extensively tested during the Cuban Missile Crisis in 1962, proving spectacularly successful.

The viability of such long-range passive detectors has been called into question as submarines have become much quieter. The usual alternative has been a low-frequency active system. One, called LORAD, was tested in the late 1950s. It would have reached out to about 5 convergence zones (about 165 nm in mid-Atlantic), and a scaled-down transducer of this type was installed in the tanker *Mission Capistrano*. LORAD would have been deployed on board special mid-ocean pickets, probably converted Victory ships. Improved SOSUS apparently solved the problem. LORAD was suggested at about the same time as the Julie active-passive sonobuoy system (see the ASW section): Julie was abandoned in favor of a better passive detector, Jezebel (airborne LOFAR).

A major SOSUS-upgrade program was reportedly ordered in

1971, including sensors moved forward into the deep ocean basins. That move seems to reflect a belief that prospective Soviet silencing would reduce effective ranges. The projected deep-ocean sensor was SASS, the Suspended Array Subsystem, a tripod, 6 miles on a side, that supported a directional array in the deep sound channel, in water 18,000 ft deep. SASS was never built (presumably, improved signal processing and delays in Soviet silencing solved the problem).

About 1971 a Computer-Assisted Array Processing project was started, to deal with the mass of raw data provided by the big LF arrays. SOSUS reportedly detected both the loss of the U.S. submarine *Scorpion* and the loss of the Soviet Golf-class submarine off Hawaii in 1968, but operators did not notice either (transient) event until the SOSUS tapes were reviewed later, after other indicators had shown that something had indeed happened. The implication is that the operators concentrated on particular spectral lines (as would be natural in a LOFAR-based system), and that transients received little attention.

More recently, SOSUS's effectiveness has been called into question as the Soviets have built quieter submarines. One solution seems to be FDS (Fixed Distributed System), which would cover a smaller area more thoroughly. It is also possible that, in analogy to the active adjuncts proposed for towed arrays, active VLF pingers could be integrated with the existing passive SOSUS arrays.

SOSUS has 2 other major drawbacks, both connected with the sheer size and sophistication of the arrays. First, although the arrays' locations are classified, they probably have not changed very much over the 3 decades of the system's existence, and the Soviets presumably know most or all of them. The arrays have to be located in relatively quiet areas, so there will not be so much local shipping noise as to overwhelm the faint sounds of distant submarines. The arrays and their shore connections may, therefore, be relatively easy to sabotage or attack early in a war. Second, because SOSUS is fixed, it cannot support U.S. ASW operations in areas other than those for which it was laid down, i.e., in areas other than (probably) the North Atlantic and North Pacific. Like other fixed sensors, then, it cannot react to political surprises, such as crises in the Indian Ocean.

The solution to both problems is a portable equivalent of SOSUS. One such is SURTASS, the towed surveillance array (see below). Another, which did not succeed, was RDSS, an air-deployed surveillance system. The requirement for a system like RDSS would seem to persist, and some form of long-range battle-group sensor, such as an air-deployed/retrieved array, may eventually enter service.

The designation SOSUS (Sound Surveillance System) has been applied both to a particular deep-water system and to the full array of fixed detectors, including several technologies, that the United States and its allies possess.

As of 1989, efforts to improve the underwater-surveillance system include development of an adaptive beam-former (ABF) and an integrated acoustic display/wide-band acoustic recall (IAD/WBAR). Here, wide band is presumably in contrast to the narrow-band operation of the past. A system so equipped could backtrack to check for transients near an assumed submarine position. See also SDS, the Surveillance Direction System.

◆ SURTASS (UQQ-2)

Surveillance Towed-Array System, using specially designed towing ships (T-AGOS) and a very long array, is a backup or gap filler for SOSUS. SURTASS replaces the 6 SQR-15 towed arrays deployed in the 1970s. Signals from the array are partially processed on board the towing ship, but most of the work is done at a shore station after the signals have been transmitted by satellite (DSCS) link. The ships are designed to steam 1500 nm to a patrol area, where they tow their arrays at 3 kt. The arrays are 8575 ft long, towed at a depth of 500–1500 ft; the tow cable is reportedly 6000 ft long.

There are 3 classes of SURTASS ships: the original monohull *Stalwarts* (T-AGOS 1-18), 4 *Victorious*-class SWATHs (T-AGOS 19 class), and 8 projected T-AGOS 23-class SWATHs (1 authorized in FY90). The latter are enlarged to incorporate new active towed arrays (ATAS) and also for better seakeeping. In addition, 5 Japanese surveillance ships (AOS, the first in the 1989 program) will tow UQQ-2 and will reportedly carry U.S. crews to operate the sensors.

The 2 main current improvements are the use of a reduced-diameter (presumably longer) array and the installation of the UYS-2 processor on board the towing ships. The latter presumably provides a degree of autonomous processing. A ship so equipped might be much better able to provide direct support for deployed fleet operations, for example, in Third World waters. Full-scale engineering development of the LF active system for the second-generation SWATHS began in 1990.

Full-scale development of SURTASS began in 1976; technical evaluation was completed in March 1978, with operational evaluation in May-June 1978. The first full system test, including the satellite acoustic data link, was conducted in July 1979. SURTASS entered service late in 1984. The first 3 contracts for SURTASS ships were let on 26 September 1980.

TACTICAL COMMUNICATIONS SYSTEMS

Radio Systems

Long-haul naval communications may be by low frequency (LF, using a ground wave, up to 300 kHz) or by medium/high frequency (MF/HF, up to 30 MHz, using a combination of ground waves and sky waves bounced off the ionosphere). Higher frequencies are inherently limited to line of sight, although most antennas are not directional. One important potential exception is bridge-to-bridge communications between 2 ships in contact. Such communications would be highly directional, and the antennas used might be the sort otherwise used for surface search or navigational purposes, outwardly indistinguishable from the radars' antennas. All navies use a combination of MF/HF and shorter-wave, higher-frequency communications, and only a few systems can be listed here. UHF is generally used for ship-to-aircraft and aircraft-to-aircraft, and for short-range ship-to-ship (line of sight). UHF and higher frequencies are generally used for satellite up-links.

Perhaps the most important recent development is the increasing interest in antijam and anti-intercept communications, focusing largely on frequency hopping. Another effort is the attempt to overcome the vagaries of the ionosphere, which is affected by, among other things, the 11-year solar cycle. For HF radio, these 2 developments are linked because the appropriate transmission frequency depends on ionospheric conditions. In the past, finding the appropriate frequency and making contact was sufficiently laborious that frequency hopping was inconceivable. Now the radio can automatically repeat the usual manual steps, and it can often achieve a connection in as little as 10 sec. The logical extension of automatic connection is automatic frequency hopping, typically 10-20 hops/sec (less than 7 millisec per hop). Hopping is unlikely to be fast enough to frustrate interception (hence, HF/DF will remain), since the existing wide-open intercept systems will probably pick up even very short snippets of message. However, hopping can frustrate jamming since it takes some time for an enemy to retune the jammer from 1 bit of message to the next.

Examples of modern HF systems are the French SPIN and the British ASSAT (Advanced Ship-to-Shore Automatic Telegraph). SPIN emphasizes ECM resistance by frequency hopping; ASSAT seems more oriented toward reliable long-haul transmissions. In ASSAT, the shore station transmits a standard message for several seconds on each available frequency, and the shipboard receiver measures the signal-to-noise ratio for each and calculates the best frequency to use; this evaluation continues throughout the transmission. ASSAT is currently being tested.

Another approach is to use the ionization from meteor bursts: meteors leave trails of ions that reflect electromagnetic energy, and there are always, it seems, enough meteors to provide sufficient (if intermittent) communications paths. Because the paths are intermittent, messages may be broken up, and they must, therefore, be quite redundant; the redundancy can be achieved by modern computer-coding techniques. The frequency band is usually 40-50 MHz, although 20-120 MHz can be used. Thus far, meteor burst has only been used for land communications, but it has obvious naval application.

DENMARK

Terma, which manufactures the current Danish naval combat-direction systems (TDS), also manufactures an associated data link, like the Swedish link, the Danish link can transmit both data and text messages. The Terma TDS is intended for use ashore, as part of a coast-defense system. Data-link messages must, therefore, be passed between coastal centers via land telephone lines; they must also be compatible with those used by other land-based command/control systems. Terma developed a Standard Communications Controller (SCC) to solve the interface problems raised by such operation.

FRANCE

◆ Link W

This proprietary data link is associated with the Vega and TAV-ITAC systems, equipment for which is manufactured by SAT.

◆ Syracuse

This system employs repeaters (7-8 GHz) in the 2 French Telecom 1 satellites reserved for military, primarily naval, use, under an agreement made in 1980. The 2 repeaters are horn antennas; the civilian antennas are dishes (14/12 GHz for French industry and for video transmission, covering France, and 6/8 GHz for telephone and television traffic between France and some overseas territories; there are also two 40-MHz repeater channels). Ground coverage extends from the West Indies to the Reunion Islands.

The associated naval system uses a pair of 1.5-m stabilized antennas in radomes, located so that 1 will always have a clear line of sight to the satellite. The antennas track either using preprogrammed satellite data or homing on the satellite's beacon. The terminals are interchangeable; about 20 ships are, or will be, fitted with terminals.

The 2 satellites will last until about 1992. The follow-on, Syracuse II, may be either another add-on to a future civilian satellite or a dedicated satellite.

INTERNATIONAL

◆ NATO Satellites

There is a family of NATO communications satellites (Phases I, II, III) covering the northern hemisphere. NATO III has a maritime role. Both the satellites and their ground stations are managed by Ford Aerospace. The program was conceived in 1965-67; and in 1988 NATO had 22 fixed ground terminals, 1 mobile terminal, and 2 active satellites in orbit. As formally proposed in 1966, the program consisted of 3 phases: I, for experiments and training; II, for reliable voice and code communications among the NATO countries' military and political headquarters; and III, for much of the capacity of the NATO Integrated Communications System (NICS), with access by mobile users. SATCOM III was 1 of the first all-digital communications satellites.

NATO IIIA, IIIB, and IIIC were placed in geostationary orbit over the North Atlantic in 1976-78; and NATO IIID was added as an in-orbit spare in November 1984, partly because the Phase IV characteristics had not yet been determined. Nine new Phase III terminals have been built, and 12 Phase II terminals modernized to Phase III standards. These satellites operate at 7-8 GHz and are compatible with the U.S. DSCS and with the Brit-

ish Skynet 4 systems. Each satellite operates 2 beams simultaneously: 1 for North America, 1 for Western Europe.

Skynet 4 has now been selected for Phase IV, with the first launch scheduled for 1990.

◆ NATO Data Links

These digital links were originally developed by the United States, but they are now used throughout NATO and thus are best listed as an international standard.

Link 1—Data link within NADGE (NATO Air Defense Ground Environment) radar chain. It is comparable to, but not compatible with, Link 11. In 1978 the U.S. Marine Corps obtained an interface, MANTA, to pass Link 1 data into its own tactical data system, which uses Link 11 formats for air information. The U.S. designation is TADIL B.

Link 4—Data link for controlling aircraft, used between airborne controllers and fighter aircraft and also between carriers and their aircraft, replacing voice radio. The current U.S. version is Link 4A, and the U.S. designation is TADIL C. This link is not encrypted, nor is it jam resistant.

Link 10—British tactical digital data system, broadly equivalent to (but not compatible with) Link 11. It was conceived by Ferranti as Link X, a less expensive alternative to Link 11, which the Royal Navy could not afford in the requisite quantities. In the 1960s, then, the British decision was to provide a few special gateways that could connect the less expensive Link 10 systems with Link 11. Data are passed without some of the command and engagement messages associated with Link 11.

The letter "X" of Link X became the numeral 10, which never had been the intended meaning. Link 10 was later sold to the Belgian, Dutch, Greek, and Turkish Navies, as well as to its primary user, the Royal Navy. As of 1978, HMS *Bristol* was probably unique among British warships in her ability to serve as a gateway between Link 10 and Link 11 units. The 3 British aircraft carriers, which are also command-and-control ships, presumably have a similar capability. Link 10 is subject to NATO STANAG 5510. Operating range is reportedly 150–180 nm.

During the Falklands War Link 10 was very successfully used to pass data from ships equipped with MTI radars (which could detect aircraft flying overland) to ships not so equipped. As a result, the Royal Navy decided to employ digital data links much more widely, but also to use Link 11 in place of the less capable Link 10.

Both Links 10 and 11 use about 3 kHz of bandwidth, and both use ground-wave propagation to avoid errors due to multipath sky-wave effects. Link 10 operates at up to 1200 bit/sec, using frequency-shift keying. The system structure as a whole is based on a series of computer-allocated time slots, and each station is allocated a number of slots based on projected needs.

Link 11—Digital encrypted HF or UHF link for the U.S. Navy Tactical Data System. This link is TADIL A (Tactical Digital Link A) in U.S. terminology. Compared to Link 10, Link 11 carries 3 times the data per target and requires about 4 times the dedicated computing power. Link 11 is subject to NATO STANAG 5511.

System architecture is based on a roll-call mode, with each station being called in turn and transmitting data into the network. One designated station controls the entire network. The Link 11/NTDS network operates with very short time delays between transmissions by different stations; the end of 1 message signals the next transmitter to start. The transmitter sends a series of synchronizing pulses, then starts sending data. One technical problem in the early versions of the system was that the receiver of the unit that had just transmitted could not start up quickly enough to receive the synchronizing pulses of the next transmission. Because time delays would be so destructive, it is not possible to transmit Link 11 data through a satellite. Even a distance such as that between Rome and Brussels is reportedly too great, in terms of the resulting time delay.

Link 11 currently operates on both HF (2–30 MHz) and UHF (225–400 MHz), the former for use at up to 300 nm, the latter for 25 nm or less. HF operation is AM; UHF is FM. Link 11 uses both upper and lower sidebands of the radio signal to achieve a degree of diversity. Messages are transmitted as 30-bit data frames, each consisting of 24 bits of encrypted message data plus 6 bits of error-detection code. The system operates at 2 alternative rates, NTDS fast (2250 bits/sec, 75 frames/sec) and NTDS slow (1364 bits/sec, 44.75 frames/sec).

The current Link Eleven Model Five (LEMF) improvement program adds new waveforms and protocols and is intended to be jam resistant in HF. A full-scale engineering-development contract for the Link 11 Improvement Program was let in 1987.

The U.S. LEMF design was completed in FY88. It is based in part on work done under the recently terminated HFAJ (high-frequency antijam) program. LEMF is part of Phase I of a longer-term Link Eleven Improvements (LEI) program, in which Phase II seeks increased capacity and quicker network access. There is also a new message standard (OPSEC 511).

Link 11 improvements include a possible change in software so that critical information is given priority (which is not possible at present). Message formats may be changed to permit the system to handle more tracks at a faster rate. The current Link 11 is limited to perhaps 200 out of a total of as many as 3000 tracks/sec that a major command might require in a major war. Track capacity would be particularly stressed in a hot air engagement, when ships would be seeing on their radars and other sensors not only friendly and enemy aircraft and antiship missiles, but also the defending anti-air missiles, their boosters, decoys, and perhaps even bursts from close-in defensive guns.

There is a current NATO Improved Link Eleven (NILE) program; the partners are Canada, France, West Germany, Italy, Netherlands, Spain, the United Kingdom, and the United States (where the team is based). The goals are better security and jam resistance, and NILE is to be ready for production by early 1991. There is some question of the extent to which NILE and Link 11 will be interchangeable.

The Royal Navy has a receive-only Link Eleven (ROLE) in some ships. As of 1987 the U.S. Navy was developing its own receive-only Link 11 to enable Aegis ships to control the firing of missiles by non-Aegis ships. Techeval/opeval was scheduled for completion in June 1988.

Besides the long-range HF, there is a line-of-sight UHF Link 11 for use between nearby ships and AEW aircraft (E-2Cs and some E-3A AWACS).

Link 11 was conceived by a CANUKUS (Canadian-U.K.-U.S.) Naval Data-Transmission Working Group (NDTWG) formed in 1954 to design a standard intership data-link format and a terminal. By 1956 the group had decided on the Kineplex modulation technique (which is still used), and the 30-bit message format consisting of data plus error detection and correction codes. The final proposal was ratified at Ottawa in late November 1957. The Royal Navy proposed a name, TIDE (Tactical International Data Exchange); the TIDE committee met at frequent intervals through 1960. The TIDE link was made the subject of a NATO standardization agreement (STANAG) in 1960–61. Four alternative links were under consideration at this time: Link 11 (a fast automatic HF link), Link 12 (fast automatic UHF), Link 13 (slower, hence cheaper, automatic HF), and Link 14 (slow semiautomatic HF/UHF). The U.S. Navy pressed for the HF links because it expected to operate its ships in dispersed (primarily antinuclear) formations, and HF (unlike UHF) could pass beyond the horizon. Hence the dominance of Link 11, with Link 14 as a backup for ships not equipped to decode and use Link 11 data.

Reportedly, the TIDE link was initially designated Link II (Roman 2), the earlier British digital link associated with the comprehensive display system (CDS) being Link I. Link III was presumably the original designation for what became Link 10. That would explain the designation of the air link as Link IV; the Roman 2 was misread as an eleven. This history would explain the absence of Links 5–9.

The name TIDE was reportedly inspired by the name of a popular U.S. laundry detergent, Tide; the data link would help clean up a messy tactical picture. Many contemporary television commercials showed Tide (or some other advertised detergent) as superior to an alternative, less expensive, "Brand X." It seems likely that the name Link X (which became Link 10) was inspired by that parallel (Link 10 is, after all, a less capable but also less expensive data link).

Link 14—Teleprinter data link between ships not equipped with NTDS.

Link 16—Link associated with JTIDS, the U.S. Joint Tactical Information Distribution System; it is also called TADIL J. This is the planned replacement for all existing U.S. airborne high-capacity data links. Since the system entails the transmission of common synchronizing pulses, and since the time of arrival of messages can be precisely measured, JTIDS is also, in effect, a tactical navigational system (pulses can be used to measure distance). In theory, JTIDS will also provide highly reliable identifications.

JTIDS operates in Lx-band (960–1215 MHz), hopping frequency randomly over a bandwidth of several hundred MHz on a pulse-to-pulse basis. A JTIDS net is defined by a particular sequence of hopped frequencies. Subscribers in the net are assigned transmission slots within the 12.8-min cycle; each slot is 7.8125 msec (1/128 second) long, so that the cycle contains 98,304 slots. One subscriber is the designated time reference, responsible for maintaining the timing of the net. Within each slot, every other message pulse is redundant, so that messages can be reconstructed even if they are badly jammed. There is also a jitter period at the beginning of each slot, so the actual beginning of the transmission of data varies. The data rate can be doubled (at a price in terms of ECCM), first by eliminating the redundant data (packed-2 structure), and then again by eliminating the jitter (packed-4 structure). This scheme is described as Time Division Multiple Access (TDMA).

Time slots are divided into 12-sec frames (1536 slots) and 64-frame epochs (12.8 min), the epoch being the system cycle. Each slot contains up to 12 Link 16 words (75 bit/word), which can be updated on every frame (the basic cycle is the epoch). The transmission waveform uses a 6.4-microsec pulse as its bit and leaves 6.6 microsec between pulses; each pulse is transmitted in sequence at one of 51 frequencies (3 MHz apart) chosen from a pseudorandomly coded list. Each pulse is subcoded (chipped) by 32 phase modulations; chipping provides additional coding so that a receiver can identify a pulse against background noise. Each net normally supports up to 32 transmitters (each can be allocated more than one slot per frame). Nets differ in their frequency-hopping sequences and time references and can run in parallel. Up to 128 can be stacked with negligible chance that 2 long words will coincide.

The navy developed a higher-capacity system, Distributed TDMA (DTDMA), which permits the operation of several concurrent independent nets (6, 8, or 16; only 1 with TDMA). The navy argued that operating multiple nets was essential because a fleet must operate simultaneously in several dimensions, and each composite warfare commander (AAW, ASW, ASUW) needs a separate net. The air force developed the single-net system because it generally operated in a more centralized way. In 1985, faced with the high cost of developing 2 parallel systems, Congress mandated the choice of a single triservice system, and the navy canceled DTDMA in favor of the existing air force–army TDMA system. This form of JTIDS is also being adopted by some NATO allies.

JTIDS line-of-sight range is about 300 nm, a figure probably limited by the time of transmission (which must be allowed for in the slot's length: 300 nm equates to about 1.6 msec); it can be extended to 500 nm. From a user's point of view, JTIDS provides all subscribers with a common tactical picture, much as NTDS does.

Link 16 is intended to replace Link 4A and to complement

(but not replace) Link 11. It is included in both the E-2C update plan and the F-14D program.

As of 1990 there was also an Interim JTIDS Messaging Standard (IHMS) already in service, which was not interoperable with either JTIDS or Link 11.

NETHERLANDS

◆ VESTA

Signaal's VHF helicopter-to-ship link is used on board current MEKO-type frigates. It consists of a transponder, which provides very accurate location data, and a short-burst (approx 1 sec) data link using voice channels (VC). The data link is intended primarily to transmit the position of a ship as seen by the helicopter's radar; digital position data are sent in FSK form (2100 Hz for a 0, 2400 Hz for a 1) and can be transmitted directly into a ship's tactical data system. Each burst consists of 50 words of 32 bits each. This is not transmission of radar video; it requires that the helicopter-borne radar do automatic target detection. Helicopter position is established by a separate VHF transponder triggered by the ship's 1–10-GHz search radar; the helicopter reply appears on the ship's radar display. The coded pulses are 2.2 microsec long, and typically there are 5 alternate codes (the system can accommodate up to 64). PRF is 20 kHz without the code. Maximum range is 64 nm.

SWEDEN

The Swedish small-craft command/control systems include a PEAB (now BEAB) specialized TDMA (time division multiple access) data link (which can transmit text messages), comparable in principle to JTIDS. All signals are encrypted. The data link is used by the STINA coastal command/control system, described above.

This data link has been exported, at least to Yugoslavia.

USSR

◆ Molniya

The Molniya satellites in high elliptical orbits cover the northern latitudes. They have been launched since 1965: Molniya 1, 33 satellites; Molniya 2, 15 satellites, from 1971; and Molniya 3, 4 satellites, from 1974. Orbital period is about 12 hr, with perigees of about 500 km in the southern hemisphere and apogees of about 40,000 km in the north. The arrangement was initially 120 deg apart (so that 3 satellites could cover the Soviet Union for 9 hr each day); but Molniya 2 and 3 were 90 deg apart, and Molniya 1 satellites were moved to positions between the

The Don-class submarine tender (floating base, in Soviet parlance) *Viktor Kotel'nikov* shows her 2 Big Ball satellite communications antennas, a type of equipment formerly carried by now-defunct *Sverdlov*-class command cruisers. The lattice mainmast carries the Slim Net air-search radar and 2 Square Head IFF interrogators.

The Don-class submarine tender *Dmitriy Galkin* shows the standard Soviet Vee Cone long-range HF antenna on her lattice mainmast. The angle between the cones can be varied, and the sides of the cones are solid in some ships. The weapons and sensors date from the 1950s and 1960s—100-mm guns in open mounts, a Wasp Head main-battery director with a Sun Visor radar, and 2 Hawk Screech secondary fire-control radars.

Molniya 2 and 3 satellites in 1976. Molniya 1 is UHF; Molniya 3 and later satellites operate in the SHF range.

The first synchronous satellite, Cosmos-637, was launched in 1974, and Molniya 1S was placed in synchronous equatorial orbit that year. It was followed by a series of about 11 Raduga/Gorizont satellites, operating in SHF. In 1980 the Soviets launched the first of their Volna geostationary communications satellites.

The Soviet Union evidently employs numerous data links, e.g., that connecting a Bear-D with the submarine or surface ship for which the aircraft furnishes targeting data. However, apart from some identifications of the antennas involved, details have not been made public.

UNITED KINGDOM

◆ Links X and Y

These are Ferranti proprietary data links. Link X came first; it became NATO Link 10 (see above). In the early 1970s Ferranti wanted to sell digital data links to non-NATO navies. Link Y was a version of Link X sufficiently altered (e.g., in message categories) to avoid duplicating the NATO link. Sales included the Argentine, Brazilian, Egyptian, and Thai Navies, and surface-to-air and air-to-air versions have been sold for use aboard Third World maritime-patrol aircraft and missile-firing aircraft (Beechcraft, Boeing, and Fokker). Different users all have their own versions, indicated by suffixes, e.g., Link YB for Brazil, YE for Egypt.

Link Y operates in a time-slot mode, allowing for up to 24 units/cycle, or for more slots for a smaller number of subscribers. The standard message format is two 24-bit words; standard transmission speed is 300–1200 bit/sec (2400–4800 bit/sec optional). The current Ferranti Link Y processor is based on the company's Argus minicomputer. It maintains a track data base of up to 120 tracks, comprising both tracks passed by link and own-ship tracks. This figure is presumably typical of the capacity of a Link Y system. The current version uses a color display and can accommodate data points up to 2000 miles from own-ship position.

Link Y equipment is now also manufactured by Signaal.

◆ Link Z

Ferranti's non-NATO version of Link 14.

◆ Skynet

Skynet is the British military/naval communications satellite system, begun in 1967 with the trials of the NEST ship terminal. Skynet 1 and 2 cover longitudes east from Britain to Australia. Skynet 2B was launched in 1974. The program's sponsor is the RAF, but the Royal Navy is the chief user.

The current version, Skynet 4, was first launched in 1988. It has 300 times the power of its predecessor and provides 2 UHF and 4 SHF channels, and beamwidths down to 3 deg. There is also a single experimental EHF up-link.

The associated ship's terminal is SCOT, operating in the 7–8-GHz (SHF) band (chosen to avoid radar and cosmic interference). Frigates and destroyers use a SCOT 1 (1.1-m dish); larger ships use SCOT 2 (1.8-m dish). An enhanced SCOT 1A was ordered in 1984 for delivery beginning in 1986: it provides a 1.2-m dish for both classes of ships and the equivalent of 4 secure-voice communications channels. Bandwidth is 500 MHz, compared to 50 MHz for SCOT 1; the 1A terminal can be tuned to any 50-MHz channel. All 17 remaining units of the original 21 SCOT 1 terminals are being brought up to SCOT 1A standards. The larger SCOT 2 terminals are also being modified for greater bandwidths. As of 1985 the Royal Netherlands Navy planned to buy SCOT terminals, and the U.S. Navy wanted 8 of them as an alternative to its more expensive WSC-6. For example, the USS *Enterprise* had SCOT antennas in 1986. The German Navy was also considering SCOT.

SCOT is not far from the X-band missile-seeker and fire-control-radar frequencies, so that it may be necessary to shut down nearby ESM equipment when SCOT is in use. Reportedly, that interference contributed to the loss of HMS *Sheffield* in the Falklands. In the future these systems will move into the EHF band.

UNITED STATES

WSC-3 is the U.S. Navy's standard satellite-communications terminal. It is also the standard line-of-sight radio transmitter/receiver, in part because its modular design made modifications simpler. V(2) and V(3) were the original FLTSATCOM terminals. V(6) and V(7), the next to be produced in quantity, were line-of-sight radio terminals. V(8) was a coast guard radio, remotely controlled. V(9) was compatible with AFSATCOM's 5-kHz-channel spacing. V(10) and V(11) are Have-Quick upgrades of V(6) and V(7). V(12) is a V(2) adapted for Trident submarine use. V(13) operates from a 400-cycle power supply, and V(14) has an interface compatible with MIL-STD-1553. RT 1217 is a line-of-sight WSC-3 for the Danish and Norwegian Navies. RT 1217-2 is the relevant Have-Quick version. RT 1244 adds a fast frequency-hopping synthesizer to the WSC-3 used by the Australian and New Zealand Navies.

◆ DSCS

RCA's Defense Satellite Communications System is the main high-volume system for the Defense Department and for diplomatic communications. DSCS serves users such as the fleet commanders, the National Command Authority, and the major U.S. defense agencies. MILSTAR should take over the strategic circuits, with DSCS remaining as the link between fixed tactical users.

Phase II, the current system, consists of 4 satellites in geostationary orbits plus 2 in-orbit spares, all built by TRW. Each has 4 transponder channels, and most of the terminals are fixed on land. Seven DSCS II satellites had been launched as of 1985; estimated service life was 5 yr. All DSCS satellites have a small propulsion plant on board so that they can be repositioned to meet contingencies.

DSCS III (General Electric) will consist of 4 active SHF (7–8 GHz) satellites and 2 in-orbit spares, each carrying a 6-channel transponder (compared to 1 channel in AFSATCOM). There are 4 Earth-coverage horns (2 transmitting, 2 receiving); a 61-beam waveguide lens receiving antenna; two 19-beam waveguide lens

AS-3018A/WSC-1, the standard U.S. UHF satellite communications antenna. It is also used for a directional line-of-sight ship-to-air and ship-to-ship link, and many NATO navies use the antenna for that purpose. This one was photographed in 1988 on board HMS *Bristol*. The antenna is 54 inches in diameter. (H. Lime)

transmitting antennas; a gimballed dish transmitter for selecting the area of coverage; and UHF transmit-and-receive antennas. These satellites should have higher power and, thanks to their movable beams, should be more difficult to jam. As of 1985 the planned total procurement was 14, with 7 having been included in the Defense Department's explicit plans.

One DSCS satellite was procured in FY88, and 2 were scheduled for FY89.

◆ FLTSATCOM

FLTSATCOM is a UHF (244–400 MHz) fleet-communications system that provides worldwide high-priority communications between aircraft, ships, submarines, ground stations, the Strategic Air Command, and the National Command Authority. The system, managed by the Air Force System Command (Space Division), uses 3-axis body-stabilized satellites in geosynchronous orbit. Each satellite has an 8-ft hexagonal body (50 in high), with an 18-turn-helical UHF receive-antenna and a 16-ft-parabolic UHF transmitter antenna. The satellites are powered by two 7×13 -ft solar panels, and they weigh 4250 lb (5100 lb for satellites 7 and 8). Each supports more than 30 voice and 12 teletype channels or, alternatively, 23 high-capacity channels [1 for fleet broadcast; 9 [7 low- and 2 high-power] for navy relay; 12 [all low power] for air force narrow-band; and 1 for DoD wide-band]. Hydrazine engines are used to maintain stability and also to relocate the satellites as required.

The contract for the system's development was awarded to TRW in November 1972, and the first launch was made on 9 February 1978. As of 1988 the 4 oldest (of a total of 7 launched) have already exceeded their 5-yr design lives. Satellite 5 was damaged during launch (6 August 1981) and thus could not perform satisfactorily. Satellite 7 was launched on 4 December 1986 (actually the sixth launch), but Satellite 6 (seventh flight) had to be destroyed soon after launch on 26 March 1987. An eighth satellite has not yet been launched, and satellites 7 and 8 incorporate an experimental EHF package as a prototype for future systems. Thus, in 1988, 5 were operational, with 4 in use and a fifth designated as an in-orbit spare.

The navy issued an RFP for a UHF follow-on satellite in November 1987, and the contract was to be awarded in July 1988. The RFP called for a 39-channel capacity using demand-assigned-multiple-access (DAMA) technology; the satellites are to be fully compatible with FLTSAT and LEASAT, and they will use existing ground terminals (and hence will require 1 SHF up-link to supplement their UHF capability). As an example of this type of system, TRW's proposal called for 3 times the capacity (28 low- and 10 high-power navy relay, 40 high-power air force narrow-band, but no DoD wide-band and no fleet broadcast channels) and twice the lifetime of the existing FLTSAT-COM. It is presumed that this program is affected by the loss of launch capacity as a result of problems with the space shuttle and with the major launch boosters.

The Hughes HS-601 satellite was selected at the end of July 1988, 6 weeks after Australia had chosen that same design. The contract called for 1 satellite plus options on 9 more; these satellites will replace both FLTSAT and LEASAT. The first should be launched in mid-1992, the second late in 1993, 2 in 1994, 3 in 1995, and 3 in 1996, either by shuttle or by expendable launcher. Each satellite will weigh about 2300 lb (FLTSAT weighs about 2200) and will have double the capacity of the earlier vehicle: 21 narrow-band channels (5-kHz bandwidth), 17 relay channels (25-kHz bandwidth), and 1 fleet broadcast channel (25-kHz bandwidth). All but the fleet broadcast channel use UHF up- and down-links (the fleet channel uses SHF, 7–8 GHz).

◆ Have Quick

Have Quick was originally the air force's program, now adopted by the navy, for providing antijam communications, primarily by frequency hopping across the radio net. The primary piece of hardware is the Have Quick A20 control module, which contains the processor, memory, signal interface, and controls. The air force's version applied to airborne ARC-164 UHF radios. The navy's contracts, awarded in 1981, applied to airborne ARC-182 radios and shipboard WSC-3s.

Under this program, the navy has adopted the ARC-182 combination radio (low- and high-power VHF/FM, VHF/AM, UHF/FM, and UHF/AM) with frequency-hopping filters and broadband antennas. The army's Single-Channel Ground and Airborne Radio System (SINCGARS) will be adopted for shipboard use, with airborne UHF relay pods and VHF relay pallets ("poor man's satellites") for communications within the battle group (to limit intercept range). The pod uses 4 ARC-182s, 2 of them modified to carry Link 11. Development of the pod was completed during FY87.

In a typical battle group, a carrier and a cruiser might communicate over a Have Quick link; other users would be the E-2C and the F-14D and the air force AWACS.

As of 1989 there is a new Combination Radio (ARC-210 and Shipboard SINCGARS) program, for airborne/shipboard tactical antijam radio systems, that is interoperable with the other services and with NATO. ARC-210 is a small, secure, jam-resistant UHF/VHF radio using Have Quick I/II and SINCGARS waveforms. Shipboard SINCGARS will provide VHF (FM) jam-resistant communications, a digital communications terminal (DCT), and a VHF relay pallet aboard naval gunfire support and amphibious ships. The radio itself will be an existing type, but the necessary filters and multicouplers are new. ARC-210 is

already being developed for the F/A-18; under the FY88 program, work began on the Shipboard SINCGARS program, with an RFP expected in FY90.

◆ LAMPS Data Link

LAMPS I helicopters communicate sonobuoy data to their ships via an AKT-22 FM transmitter, the simplex analog data link that can carry 2 DIFAR or 2 DICASS channels, as well as a voice channel. Originally the link could also transmit up to 8 channels of LOFAR data. Of the channels, 7 had 10–2000 Hz bandwidth, and 1 had 10–2800 Hz bandwidth. The dynamic range of each channel was 0.16–16 volts (a range of 20 dB). Alternatively, the link could transmit 4 omnidirectional sonar channels (for active buoys, at 26–38 kHz). The 4- and 8-buoy modes were abandoned when the U.S. Navy decided to concentrate entirely on directional buoys. The helicopter antenna (AS-3033) has 2 sections, 1 to receive sonobuoy data, the other to transmit to the ship.

Because AKT-22 operates in S-band (2200–2290 MHz, on 1 of 20 channels), it is limited to line-of-sight range, and thus a LAMPS I helicopter cannot prosecute a target beyond the ship's radar horizon: LAMPS I was intended to operate within 50 nm of the parent ship.

The LAMPS I data link is primarily acoustic. It does not carry radar video from the helicopter's LN-66 radar.

LAMPS III uses a C-band (4435–4535 MHz) duplex digital link (SRQ-4), for sonobuoy data plus radar and ESM data. It cannot transmit radar and sonobuoy data simultaneously. However, the system does carry a full duplex command/control channel parallel with the data channel. Typically, helicopter sensors (ESM and radar) are operated remotely, from the parent ship, and their outputs are presented primarily on board the parent ship. The main data link is line-of-sight, but LAMPS III also has an HF-voice radio link, for distances beyond the horizon. It is intended to operate 100 nm from the parent ship.

◆ Leasat

The U.S. Navy leases some commercial satellites to fill gaps in national systems, e.g., to support operations in the Indian Ocean. Examples are the Comsat General Gap-filler (now obsolete), which provided limited UHF cover of much of the eastern hemisphere from 1976 on, and the Hughes Leasat, a 4-satellite system (orbited 1984–85). Unlike military satellites, these commercial types almost certainly are not hardened against attack (e.g., against EMP). However, their use indicates the number of U.S. communications satellites that can be turned to military use in an emergency.

Leasat is to be replaced by Hughes's UHF Follow-On Satellite (see FLTSATCOM).

◆ Link 11 Data Terminal Sets

The data terminal set (DTS) is the interface between a ship's NTDS system and other ships or aircraft in the same NTDS net. The DTS accepts digital data (which the KG-40 key generator has already encrypted) and converts them into a series of tones for radio transmission. It also detects and corrects errors, controls link protocol, and controls the NTDS interface. Normally, it operates in half-duplex mode, sending or receiving data, but not both (it operates in full duplex mode only when being tested).

Subscribers to the Link 11 net operate either as net control station (NCS) or in picket (PKT) mode, and each unit is assigned its own picket or participating unit (PU) number. The system generally operates in roll-call mode, the NCS polling each PU in its net in turn, then reporting its own message. The NCS terminal must enter each of the PUs. Alternative modes are broadcast (BC), short broadcast (SBC), net sync (NS), net test (NT), and radio silence. In broadcast mode, a station continuously broadcasts to all net participants and must coordinate with the NCS to avoid jamming (except in the case of USQ-79 users). SBC is a single broadcast. NS is an initializing transmis-

sion by the NCS to synchronize the pickets. NT is a test pattern broadcast by the NCS.

This official table of data terminals in service as of 1990 gives numbers active (dates are dates of entry into service):

USQ-36(20)	1964–66	49	CG, CGN, CV, CVN, DDG (DDGs 37–41, 43, 45), FF, LCC
USQ-59(15)	1971–72	9	DDG (JPTDS ships), LHA
USQ-63(15)	1973–74	35	DD (<i>Spruance</i> class), DDG (<i>Kidd</i> class)
USQ-74(61)	1981–87	85	BB*, CG (<i>Ticonderoga</i> class, CG 30), CGN (<i>Truxtun</i>), CV (CV 62), CVN (CVNs 71 and 72), DDG (DDGs 42, 44, and 46 and NTDS <i>Adams</i> class), FFG (<i>Perry</i> class), LHD, AGF*
USQ-76(4)	1983	31	SSN, ASWOC (this is the (V)4 version)
USQ-79(15)	1979	17	NTISA, TACC, TAOC
USQ-83(APE)(61)	1986–89	2	TechEval FF, AGF
USQ-92(20)	1984	2	MULTOTS Detachments 1, 2
MX-512P(80)	1990	—	PHMs, Coast Guard

*Receive Only

In each case, the number in parentheses is the number of PUs the device can support.

AEW and ASW aircraft use versions of USQ-79. USQ-59, -63, and -79 are all based on the same equipment (CV2969). The reference to FF TechEval is *not* to the original ASW tactical data system on board the *Koelsch* and *Voge*, which is much older. MULTOTS is the Multiple Units Link-11 Test and Operational Training System; NTISA is the Navy Tactical Interoperability Support Activity, which tests NTDS programs before they become operational. The reference to a high-capacity DTS for the PHMs and to the Coast Guard suggests an effort to provide all units enforcing the antidrug blockade in the Caribbean with a common tactical picture; the blockade is being run as a maritime-defense zone (MARDIZ).

Los Angeles-class submarines can now share the NTDS net. FFGs 36–61 were all completed with Link 11 (2 way). Earlier *Perry*-class frigates were completed with provision for later installation of Link 11, and this is now being accomplished. The frigates (FF) fitted with an experimental tactical data system are the *Koelsch* (1049) and *Voge* (1047), which had an experimental ASW tactical data system. The *Koelsch* has been transferred to Pakistan, and the *Voge* is in reserve.

The limited PU numbers available explain why NTDS cannot be used directly to control tactical aircraft.

The DTSs should be distinguished from the data-link terminal, USQ-69, which is an operator interface with the DTS and related components.

◆ Milstar

Milstar is the all-service U.S. military communications satellite system, to enter service in the 1990s. It is the first U.S. mm-wave (EHF) communications satellite system (44-GHz up-link, 20-GHz down-link), and the system is to have a minimum of 7 operational satellites at any time (at first there will be 4 synchronous satellites, 1 of them an in-orbit spare, with all 4 in inclined polar orbits). Milstar was considered important enough to receive overriding (Brick Bat) priority. The advantages of going to EHF include escape from the crowded lower-frequency bands, better resistance to ECM (because there are more frequencies and because beamwidths are very narrow), and reduced

terminal size (or, for a given size, a narrower, and hence less easily intercepted, beam).

Lockheed was awarded the prime satellite contract in 1983.

◆ Spinsat

The Office of Naval Research Special-Purpose Inexpensive Satellite is to provide battle-group commanders with their own expendable satellite, the "Commander Class" bus with a 50–75 kg payload and with an on-board rocket motor allowing it to maneuver in space. Spinsat is conceived as an alternative to current practice, which makes satellites too valuable (and too capable) for brief tactical use. Yet a satellite would provide a battle-group commander with the best communications over an extended battle space, and quite possibly with the best hope of detecting an enemy force at the edge of that space. The satellite is made by the Intraspace Corp. of Utah, based on the company's T-Sat design, and the prototype flew on board the Pegasus rocket, carried aloft by a B-52 bomber. ONR's goal is to hold cost to the level of a tank, an airplane, or a small ship. The satellite launcher would presumably be carried on board a ship of the battle group.

◆ Satellite Information Exchange System

The U.S. Navy communications satellites carry a combination of fleet broadcast and other nets. The naval communications system as a whole employs a combination of HF radio and UHF/SHF satellite broadcast, plus automated facilities that assemble and retransmit the broadcasts. The chief nets supported by the satellite information exchange system are:

CUDIXS, the Common User Digital Information Exchange System, carrying general service (GENSER) messages to and from ships.

SSIXS, the Submarine Satellite Information Exchange System, carrying the submarine broadcast messages in unformatted text, plus targeting information in formatted computer-readable standard message formats (RAINFORM formats).

OTCIXS, the Officer-in-Tactical-Command Information Exchange System, the battle group's command/control channel, carrying RAINFORM messages (at 2400 baud), teletype (75 baud), and narrow-band secure voice (2400 baud).

TACINTEL, the Tactical Intelligence Network, exchanging special intelligence data, using the USQ-64(V)5, and carrying both RAINFORM and unformatted messages.

TADIXS, the Tactical Digital Information Exchange System, a 1-way satellite link, carrying ocean-surveillance data from the FCC to deployed forces.

Narrow-band secure-voice channel supporting the High Command Net, linking fleet commanders with battle-group commanders. There is also a Fleet Tactical Net.

Submarine Communications Systems

A submarine's radio communications with surface ships and aircraft are inherently limited because seawater is a barrier to most signals. The primary communications choices for submarines are currently surface radio (HF and above), periscope-depth radio (LF and VLF), and ELF (extremely low frequency) radio. Conventional antennas can transmit signals down to VLF, although VLF antennas can be quite large. For example, the airborne VLF antennas used as backups for communicating with strategic submarines are several thousand feet long and must be trailed from a considerable altitude. The sheer sizes of LF and VLF antennas make it impossible for submarines to transmit at these frequencies; LF and VLF are usable only for communication to submarines.

Only ELF penetrates to great depths, but it requires very large land-based transmitters (which in turn require favorable geological conditions) and has a limited capacity for carrying information. Moreover, because ELF has so great a range, it is subject to jamming, intentional or otherwise, by other nations'

Standard U.S. Navy submarine communications buoys. (Spears Associates)

ELF systems. The U.S. ELF system was originally conceived as a means of alerting strategic submarines, using transmitters so large and so redundant that they might well survive an initial nuclear attack. A test installation opened at Clam Lake, Wisconsin, in 1969; it was given a message-handling capability in 1976 and functioned successfully through 1978. The project was opposed on political (nominally environmental) grounds, and it was canceled by President Carter in 1978. It was revived, in limited (and vulnerable) form, by the Reagan Administration and is now in service. ELF has been extended to all U.S. submarines. The operating frequency is 76 Hz; wavelength is then about 2500 miles. The antenna at Clam Lake, Wisconsin, is 28 miles long, and the one on the upper peninsula of Michigan is 56 miles long. The current system became operational in 1987.

Submarines monitoring ELF broadcasts must trail a long neutrally buoyant wire antenna, but the submarine need not approach the surface. The first major submarine-ELF-receiver contract (with GTE) was announced in 1988, the receiver having been tested successfully in the Pacific Fleet in May 1985. A total of 137 (to equip attack as well as strategic submarines) are to be delivered in 1989–92.

In mid-1987 the British announced that they were building an ELF site in Scotland (Glen Gally Forest, near Fort William). A French ELF system, Astarte (with a transmitter at Rosnay), was to enter service in 1988–89.

The Soviet Union has the type of geology needed for ELF transmission; the basic idea is very well known, and the technology involved is not very complicated. In 1987 it was reported that the Soviets were building an ELF station.

Deeply penetrating land and waters, ELF is always receivable. It acts as a bell-ringer, informing a submarine commander that the sub must come near the surface to receive a more conventional message, e.g., by HF or satellite link.

Although an ELF transmitter, with its very long buried antenna, could in theory be hardened against nuclear attack, existing ELF systems are generally not so protected. For example, the U.S. system was initially conceived as a hard communications device, but only the soft demonstrators were actually built.

A submarine must put an antenna either through or very near the surface to receive all of the usual long-haul naval signals (HF or satellite-transmitted SHF, UHF, or EHF). For example, many submarines are equipped with buoys containing wrapped-wire HF antennas. Higher line-of-sight frequencies are useful either for air-to-submarine communications or for submarine-to-satellite communications. One advantage of very short wavelengths (such as SHF or EHF) is that the antennas can be so small that they can be housed atop periscopes.

At lower frequencies (VLF), radio waves can penetrate the water's surface down to 10–30 ft. Typically, reception requires

either a wire loop (which may be in a towed buoy) or a towed linear floating antenna. Using a towed wire limits the submarine's depth, speed, and course. Moreover, any method of communicating requires the submarine to place an object near the surface, where the antenna is more visible and marks the submarine's position.

GTE, the supplier of current U.S. submarine strategic-communications equipment, has proposed a compromise radio system, SubTACS (Submarine Tactical Communications System), operating at low frequency (but not quite ELF frequency), with a higher data rate (about 15 words/min, 300 times that of ELF). Like ELF, SubTACS employs a trailing-wire (rather than a floating-wire) antenna, and the existing standard ELF receiver can be modified to accept SubTACS's signals. Effective range is 1000+ nm, and a submarine can listen at any speed and at keel depths of about 250 ft. These range and penetration figures are far beyond those of a conventional VLF (periscope-depth) system. Compared to ELF, SubTACS is a transportable system, requiring no special geological conditions; its antenna is an insulated 12-km-long antenna cable laid on the surface of the earth. That characteristic makes the system a candidate for the U.S. requirements for reconstitutable strategic communications (i.e., for systems that can be reassembled in the event of a nuclear attack). Alternatively, the transmitter and antenna can be adapted to installation on surface ships. Signals can penetrate seawater, ice, and also the earth itself.

SubTACS is a GTE private-venture (IR&D) program, begun late in 1987, with some U.S. Navy support. As of March 1989, the company hoped to conduct a demonstration experiment late in 1989 or early in 1990.

One alternative that has been proposed in recent years is the use of blue-green lasers. Such lasers penetrate to substantial depths (they were once proposed as antisubmarine sensors, but did not penetrate quite well enough for 2-way use), and they can carry considerable amounts of information. Effective information transmission is limited, however, because the laser must scan its relatively narrow beam over the wide area in which a submarine may be located, repeating the message frequently enough for any submarine touched by the beam to receive all of the information. No operational blue-green-laser communications system currently exists, but the U.S. Navy and the U.S. DARPA have been developing a suitable space-based laser, which was tested (in airborne-form) in 1987.

This test, called "Project Y," showed that clouds did not prevent transmission to a submarine at operational depth. The navy is also conducting "Project Lambda" (i.e., upside-down Y) to investigate laser-communications up-links from submarines, although it is difficult to imagine that such up-links could not be intercepted easily.

Plans for the U.S. Navy's laser-communications satellite, SLCSAT, were reportedly abandoned because of cuts in the FY89 budget. However, navy-funded SLCSAT studies have continued.

In September 1989 it was reported that under its FY89/90 program DARPA was running a major 2-way laser submarine-communications study, between submarines and high-altitude long-endurance unmanned aircraft (HALEs), as an outgrowth of the agency's Tactical Air-Launched Communications (TALC) program. DARPA was working on an HALE transmitter/receiver, as well as a transmitter/receiver for the submarine, concept exploration of an LPI uplink, and modification/integration of an HALE. There was some fear that TALC was drawing funds that might otherwise have gone into a laser satellite program.

CANADA

◆ WQC-501

This new underwater telephone was first fitted in the modernized *Oberon* class (SOUP program). WQC-501 is manufactured by Safare-Crouzet, which makes the French TUUM-2. Transmission is omnidirectional, with a rated range of 20 km. This range can be reduced, for greater security, by reducing the power

output. Operating modes are voice, key, transponder, and automatic transmission. The standard submarine outfit includes both an omnidirectional transducer and 4 directional transducers, plus a transducer-switching unit and a power amplifier. The frequency used is the NATO standard, 8.0875 kHz, carrying both voice and Morse signals (the latter at 712 Hz). Signals are single-sideband modulated, with a maximum power level of 94 dB.

FRANCE

◆ TUUM-2

The standard underwater telephone, made by Safare-Crouzet, has a range of 10 km (20 km with a 1-kW amplifier). The basic design operates at standard NATO frequency, but the unit can be modified to operate at alternative frequencies. Characteristics are similar to those of the WQC-501 (see above), but there is no transducer-switching unit. The customer decides whether to install directional or omnidirectional transducers.

Strategic Communications The current command link for SSBNs uses the VLF (20-kHz) transmitters at Kerlouan and Rosnay, which were built specifically for the strategic submarine program. An airborne VLF system, Astarte (*Avion station relais de transmissions exceptionnelles*), analogous to the U.S. TA-CAMO, is based on 4 Transall aircraft. Astarte is being developed and was scheduled to enter service in 1988-89. It will be hardened against EMP.

ITALY

◆ TS-200/TS-510

These underwater telephones operate at NATO standard frequency (8.3-11.1 kHz), with a single sideband and CW transmission. TS-200 has 2 modes: omnidirectional (vertical beamwidth of 90 deg), and directional (about 28 deg of vertical beamwidth).

TS-510 is a smaller omnidirectional unit with a smaller transducer.

USSR

◆ Whale Tongue

Whale Tongue is the standard Soviet acoustic-communications device, used for submarine-submarine and submarine-surface ship communications. Whale Tongue is fitted to all destroyers and larger surface combatants and to all Soviet submarines.

For many years, the Soviets have been credited with superior, and probably covert, means of coordinating their submarines and surface ships. The Soviet style of naval command/control requires considerable direction from above and would demand an effective system for communicating with submarines. At the same time, because the Soviets tend to use stereotyped tactics, they might be able to tolerate a very low information rate, or a very limited repertoire of messages, so that developing a satis-

A Victor-I class submarine displays her Park Lamp antenna (open loops on the aftermost mast). Although possibly usable for direction-finding, Park Lamp is almost certainly primarily a VLF receiver, usable at periscope depth, analogous to the U.S. Navy's loop antennas (originally radio direction-finders) of World War II. (U.S. Naval Institute)

A Golf-II-class ballistic-missile submarine shows her communications-buoy housing, abaft her sail. The tall sonar dome forward is an underwater telephone. (U.S. Navy)

factory secure and covert underwater communications system would be easier. The U.S. Navy appears to have been far less successful in this endeavor, perhaps because the more flexible U.S. tactics require much greater information exchange.

Radio Links Submarines currently rely on VLF. The standard mast-mounted VLF/LF receiving antenna is Park Lamp (which is often described as an ECM or navigational antenna). In addition, strategic and some tactical missile submarines (Charlie-II, Oscar) tow buoys, which are often carried in prominent housings. Of the new classes of attack submarines, Akula seems to be unique in towing a communications buoy. Many submarines (including all strategic submarines) also have satellite antennas (Pert Spring). Submarines operating the SS-N-12 and SS-N-19 missiles have been equipped with a radar satellite down-link antenna (Punch Bowl).

Bear-J aircraft function as strategic communications links analogous to the U.S. TACAMO. These aircraft entered service in 1985.

UNITED KINGDOM

Underwater telephones are listed under sonars.

UNITED STATES

◆ BRC-6 (XSTAT)

The Expendable Submarine Tactical Transceiver, a 2-way expendable buoy for UHF communication between a submarine and an airplane, is produced by Sippican. XSTAT is launched from a submarine signal ejector. After launching, a lifting body separates from the buoy, remaining attached to the submarine (and, therefore, to the terminal) by a 40-ft tether cable. Very fine wire (0.008-in diameter, up to 10,000 ft long) unreels from the flying body, maintaining a connection to the rising buoy. When the buoy reaches the surface, it deploys an antenna for 2-way radio voice communication. The buoy normally receives; it is placed in a transmit mode by keying the microphone on the submarine. The antenna itself is a quarter-wave ground-plane with 4 radials. It feeds from a battery useful for 45 min, but the life of the system is really controlled by the length of fine wire, which unreels as the submarine steams away from the nearly stationary buoy. Typically, the wire lasts for 8 min at 10 kt, or for 20 min at 4 kt.

This form of operation contrasts with that of the air-launched communications buoys described below, which are essentially

transponders, converting a submarine's acoustic signals into radio signals for air transmission, and vice versa.

◆ SLOT (AN/BRT-1)

Sippican's submarine-launched 1-way transmitter, a buoy launched through the submarine's signal ejector, carries a 4-min tape-recorded message (either voice or CW) and a radio transmitter. The message is recorded using a BRM-2 test set and can be checked by playing back through the buoy transmitter. SLOT can be set to delay transmission either by 5 min or by 1 hr, giving the launching submarine time to clear the datum created by the buoy. The buoy can function in sea-states up to 5, and it rises at 2 m/sec. Transmission is by VHF (on a sonobuoy frequency), and an aircraft or surface ship can command the buoy to turn off by using a UHF signal. The buoy then floats until sunk by its scuttle timing unit; selectable lifetime is 1, 3, or 8 hr. Dimensions are 3×39.12 in, and weight is 7.25 lb.

BRT-2 is a SLOT buoy manufactured by Electrospace.

◆ BRT-3 through -5

BRT-3, -4, and -5 are submarine-launched expendable buoys to provide improved bad-weather submarine identification and position. They operate for 30 min; each buoy transmits a characteristic tone: 300 Hz for BRT-3, 2700 Hz for BRT-4, and 900 Hz (pulsed, amplitude-modulated) for BRT-5. These devices date from 1974. All are launched from submarine signal-ejector tubes, which limit overall dimensions to 3×11.5 in (weight 1.4 lb).

◆ BRT-6

Hazeltine's 1-way UHF satellite communications system for submarines, consisting of a buoy launched from a standard 3-in signal ejector, carries a tape-recorded message and is usable up through sea-state 5. The satellite channel can be preselected (290–315 MHz). Data are transmitted digitally into the SSIXS system, and 1–15 transmissions can be made. The buoy is normally preset for 2400 bits/sec; alternatively, 75, 300, 600, 1200, 4800, or 9600 bits/sec can be selected. As with BRT-1, a message transmission delay can be selected (in this case in 5-min increments), with output selectable between 25 and 100 W. The buoy scuttles within 30 min after its final transmission. Dimensions are 7.6×103.1 cm, and weight is 4.4 kg.

This device was technically evaluated on board USS *Baltimore* and operationally evaluated on board USS *Sea Horse*; approval for full production (AFP) was granted in 1983.

There is also a Hazeltine submarine-launched 1-way satellite relay UHFSATCOM buoy (BRT-6). Work on a tethered 2-way UHFSATCOM buoy, comparable in concept to XSTAT (BRC-6), began under the FY89 program.

◆ Probe Alert

See SQS-26/53 sonar.

◆ OUTPOST

This Sippican-developed 2-way communications buoy uses a 20-km fiber-optic link in place of the fine wire of BRT-1. OUTPOST is now in advanced development at NUSC New London.

◆ SLATE

This submarine-launched UHF expendable transceiver buoy is launched through a 3-in signal ejector and connected to the submarine by a fine wire. SLATE is presumably an earlier alternative to BRC-6.

◆ SSQ-71

The air-dropped 2-way air-submarine acoustic-communications buoy (ATAC) can be tuned to 1 of 3 radio channels. It is in current production. This A-size buoy weighs 25 lb.

◆ SSQ-86

This A-size communications buoy (25 lb) is tunable to 1 of 99 RF channels.

◆ SUS

Sound Underwater Signal is a small device dropped by an airplane to send signals to a submarine. For example, SUS can indicate an emergency, telling the submarine to stay down; ask an unknown submarine to surface for visual identification; or act as a bell-ringer, asking the submarine to establish radio communications. The current version is the Sippican Mk 84 Mod 1, replacing the earlier Mk 64. An earlier version of SUS was the sound source in the Julie explosive echo-ranging system (see the ASW section).

Mk 84 can be launched at 100–10,000 ft, at speeds of 30–380 kt. It sinks at 14.5 ft/sec, spin-stabilized by its canted tail fins. The signal, which lasts 45–128 sec, consists of 2 tones (2.95 and 3.5 kHz), coded by pulsing for either 0.5 or 1.5 sec. The tones may alternate at 2 different pulse lengths, for 4 signals, or the SUS can transmit steadily at 3.5 kHz, for a fifth signal. The signal's source level is 160 dB. The desired signal is selected before launch by using a switch on the side of the SUS. Dimensions: 3 in × 15 in (6.5 lb).

◆ TACAMO

The national command link to strategic submarines is currently operating on board the EC-130G/Q aircraft, but the TACAMO's electronics are being transferred to the E-6As because they are hardened against EMP. The communications suite is designated USC-13; it receives over the VLF-to-UHF range and transmits in VLF, using a dual (long and short) trailing antenna. Messages are received from the navy's shore bases and from airborne national command posts (ABNCPs), via satellite and other emergency radio links.

The long trailing antenna is half the wavelength of the transmission; the short antenna, which is active, is trailed at a length tuned to that of the long reflector. About 35,000 ft of long and 5,000 ft of short antenna are available, but typically the long antenna is unreeled to a length of 16,000–20,000 ft. The signal is vertically polarized and can penetrate the sea's surface. Transmitting frequencies are 14–30 kHz.

The current upgrade program has 2 phases. Block I provides a high-power transmitter to ensure that the TACAMO aircraft can communicate with U.S. Air Force airborne national command posts over the central United States. It also adds a VLF/LF high-power transmitter and dual trailing-wire antennas to replace the current obsolete system. Block II improvements include provision for the E-6A to use the Milstar communications and GPS navigation satellites. The existing Verdin (VLF submarine communications) communications system (processor and modulator/demodulator) will be replaced in 2 phases. Phase I is a replacement to host the Phase II Enhanced Verdin System (EVS), which should improve communications performance. A new Compact VLF (CVLF) system will ultimately replace the current receiver/demodulator and transmitter/modulator (except for its high-powered elements) and the Verdin and EVS processors. A new high-power solid-state transmitter system (HPTS) will replace earlier 200-kW vacuum-tube equipment; HPTS is being developed for both the E-6A and the air force command posts. Block II also includes the TACAMO Message Processing System (TMPS). Full-scale development of these improvements was originally scheduled for FY90, with techeval/opeval in FY91. However, a cut in the FY88/89 budget pushed Block II into FY93, with the exception of the provision for Milstar.

The term TACAMO derives from the order to a submarine commander to "Take charge and move out." Work on the system began in 1962, and the 2 TACAMO squadrons became operational in 1968. The decision to upgrade to the E-6A was taken in 1977. Although escalating costs prompted some considera-

tion of cancellation, the contract for 15 new E-6A aircraft was awarded in 1986, and the first E-6A flew in February 1987.

◆ Towed Devices

U.S. submarines employ towed buoyant cables and towed buoys, both manufactured by Spears Associates. These devices grew in importance during the late 1970s and early 1980s because they appeared to be the best way to provide submarines with the sort of UHF receiving capability needed for full battle-group integration, i.e., the ability to receive Link 11 on at least an intermittent basis (the *Los Angeles*-class submarines, then being built, had been bought as battle-group escorts). UHF also became more important at that time because it was the frequency of the fleet satellite; by 1975 a program was underway to provide all submarines with WSC-3 UHF satellite receivers. The satellite system was so arranged that a submarine could request stored tactical messages at a convenient time, rather than having to put up an antenna for regular fleet transmissions as in the past). UHF does have 1 major drawback: it requires that the receiver be at or very near the surface. This consideration led to renewed interest in both cables and towed buoys.

The standard buoyant cable antenna (BCA) is 2000 ft long (1900 ft of it deploying cable), with a diameter of 0.65 in, allowing for reception at 10 kHz–30 MHz or at 10 kHz–200 MHz, depending on the version. The submarine can also transmit HF signals from the portion of the antenna near the surface. The antenna can be deployed either by an electric winch outside the pressure hull (the "Bustle" device demonstrated on board a U.S. nuclear attack submarine in the 1970s) or by a hydraulic unit inside the pressure hull (which is standard). The cable includes an in-line amplifier, which can operate over the 2–400 or 2–30 MHz range.

The main disadvantage of the towed buoyant antenna is that, as the submarine increases speed, the cable tends to stream directly astern. Since the antenna must lie at or very near the surface to be effective at high frequencies, it is usable (at those frequencies) only at relatively low speed. However, because it is a very broad band device, it can receive VLF signals at higher submarine speeds, when it is well below the surface.

The cables listed above are presumably outgrowths of the new antenna program of the early 1970s, which produced the BRC-2 in-line transceiver, $\frac{5}{8}$ in (0.675 in) in diameter. BRC-2 used twin hydrofoils and a stabilizing counterweight to keep itself at the surface; by 1975 it had demonstrated 2-way communication with an airplane at a range of over 100 nm while the submarine was running at 300 ft at 13 kt. In this case the antenna was a whip extended up from the cable; the antennas described above do not have any such elaborate fittings.

There are 3 standard towed buoys:

OE-305/BRR 97.5 × 30 × 24.38 in (height less fin); 41 in high including the fin; air weight 900 lb (buoyancy 750 lb); payload volume 2 ft³ (95 lb)

BRR-6 90 × 36 × 24.38 in; height 35.38 in including fin; 900/750 lb; 2 ft³ (95 lb)

BSQ-6 72 × 26 × 19.5 in; height 31.25 in including fin; 650/300 lb; payload 3 ft³ (200 lb)

All 3 are proof against 650 lb/in² of sea pressure. They are made of fiberglass-reinforced plastic, and their shape causes them to follow the contour of the sea surface at a shallow depth, to avoid broaching and thus revealing the submarine's presence. Buoys are typically towed at up to 15 kt, and they can contain both receivers and transmitters. BSQ-6 is presumably a descendant of the BSQ-5 buoy designed in the early 1970s as the Buoy Integrated Antenna System (BIAS), suitable for receiving VLF through UHF signals and transmitting HF through VHF. It was designed specially for towing just under the surface and, like its predecessors, was limited to 15 kt. Its new feature was that its body contained part of the transceiver electronics, thus minimizing significant line losses experienced at UHF frequencies

(the line from the submarine to the buoy operates at a lower frequency).

COMPUTERS

Modern digital computers have 4 basic elements: a processor, fast read/write data storage, program storage, and some means of input/output. In civilian machines, the contents of fast read/write storage is volatile, i.e., is generally lost when the machine loses power, but many military machines have nonvolatile running memories. Input/output generally includes a connection to some form of mass memory, in nonvolatile form. All of these elements are familiar to users of personal computers: the processor is the basic chip (e.g., an 8088); the fast storage is the RAM (random access memory); the programs actually being executed are stored with the data in the RAM; and the input/output channels are, typically, the computer screen, a printer, and the disk drives.

The computer memory is typically organized in words of fixed length (in bits, the binary digits whose value is either 0 or 1). Each word has its own address, and a program refers to the addresses of the data on which it operates. In theory, then, the maximum size of the memory (in words) is fixed by the largest address that can be written in the form of a single word. For example, the largest 8-bit word is 256; the largest 10-bit word is 1024 (1k). The largest 16-bit word is 64k. Some systems get around this limit, either by using longer address words or by dividing memory into pages, within each of which items of data can be separately addressed.

These limits do not apply directly to mass storage, in which data are organized in files (whose names, however, must generally be entered in a file directory). For example, a typical word-processing program, written for 8-bit computers, can accommodate up to 256 files in its mass storage. The length of each file is limited by the overall size of the mass storage.

Because address capacity is necessarily a power of 2, it is generally given in terms of k (units of 2 to the 10th power, 1024). It may be given as a number of words, bytes (units of 8 bits each), or bits. The standard NTDS word length is 30 bits, and some early computers were similarly organized. More recently the standard length has been an even number of bytes or half bytes ("nibbles"). The current standard is 32 bits.

In many cases a single word does not provide sufficient precision for calculation. Therefore, many machines have a provision for double-precision arithmetic, in which numbers are represented as pairs of words. In the past, the distinction between "scientific" and "business" computers was generally a distinction between machines that could or could not execute double-precision arithmetic. This distinction carries over to the math coprocessors, which generally calculate in terms of longer (multiple-precision) words.

Most of the machines described here employ bit-slice processors, capable of handling data in slices shorter than entire words. Typically, there are separate 2-, 4-, and 8-bit processors, so that the processor as a whole can handle anything between 4 and 32 bits. Bit slicing makes for higher speed when less than full precision is needed, but it also makes for complicated programming.

Computer hardware has developed through 4 fairly well defined generations. First, in the early 1950s, came vacuum-tube machines, which required considerable volume for their processing elements. Many machines of this generation had magnetic-drum storage, in which data were stored as magnetized spots on the surface of a revolving drum. Typically, the drum might rotate at 3600 rpm, so that the average bit could be read at an interval of 17 msec. Drum memory was compact and rugged (if slow), and it persisted into the 1960s in military applications, such as the computer of the A-6 Intruder. By the late 1950s drums were being replaced by magnetic (ferrite) core memories, in which each bit of data was stored in terms of the direction in which a small ferrite ring was magnetized. Core memory was much faster than drum memory and was also

much more flexible (since each core could be addressed independently and randomly), but it also required considerable volume, since (at least at first) each core was about $\frac{1}{16}$ in in diameter. Moreover, each little ring had to be wired by hand. Total memory size was quite limited. Typically, a magnetic core took 1 microsec to read, a considerable improvement over the more compact magnetic drum. A typical vacuum-tube computing speed was 40,000 operations/sec (0.04 Mops), i.e., a typical operation would require 25 microsec.

By the late 1950s it was clear that transistors offered a much more compact and much more reliable alternative, a second generation. The earliest solid-state computers appeared in 1959, using magnetic-core memory. These machines use *discrete devices*: individual transistors and other electronic components are separately wired into the machine. A typical large transistor machine might be capable of 200,000 operations/sec (0.2 Mops), i.e., a typical operation would require 5 microsec.

Transistors and their associated devices could be combined into compact integrated circuits, manufactured as units. The integrated circuit was invented in 1958. The results of this small- or medium-scale integration could be wired into compact (third-generation) processors. A typical large machine might be capable of 1 million operations/sec (1 Mop), i.e., about 1 microsec/operation. The U.S. UYK-7 fits into this category.

Integration made possible the production of memory units far more compact (as well as faster than) magnetic cores. Semiconductor memories first appeared in the late 1960s. In 1970 Fairchild introduced a single chip, the size of a core, that could hold 256 bits of memory, each readable in only 7% of the time it took to read a magnetic core (i.e., 70 nanosec). Four years later the cost per bit of such memory fell below the cost of magnetic cores. Single memory chips can now accommodate as much as 1 Mbit of random access memory.

Core did have one advantage. It held its magnetization even when power was lost, whereas the successor semiconductor memory is volatile (memory vanishes when power is lost, as many users have found to their dismay). For that reason the use of core is often equated to military suitability. In machines that have to be too fast to afford core memories, some form of reliable fast mass memory is needed, so that the contents of the read/write memory can be saved periodically. Military computers commonly also incorporate backup battery power supplies, so that main (read/write) memory can be saved in the event of power failure. Even so, in some cases any power interruption makes it impossible for the associated combat-direction system to keep track of the tactical situation. Moreover, it takes some time to restart the system, during which the tactical situation may have changed too much for much correlation between the saved tactical picture and the real one.

Mass memory is nonvolatile, but it is also much slower than fast internal memory. The classic forms of mass memory are tapes and magnetic disks, but both are sensitive: at one time it was notorious that the shock of catapult firing would often disable the tape cartridge of the AYK-10 mission computer of the S-3A. A current solution to the problem is magnetic bubble memory, which is reasonably fast, is nonvolatile, and has no moving parts vulnerable to shock.

An integrated processor is much smaller than one built of discrete devices. One consequence of integration, then, was the development of a class of small desktop machines, minicomputers, with performance similar to that of the large second-generation machines. The first such machine was the Digital Equipment Corporation PDP-8, first delivered in 1968. The U.S. naval example of this technology was the UYK-20 of 1974.

The next development was large-scale integration (LSI), which made it possible to produce an entire computer (a central processor) on a single solid-state chip, a microprocessor. Typically, LSI is defined by the ability to place 1000 components on a single chip. The next step, VLSI (very large scale integration), is an order of magnitude more compact (10,000 components/chip), and 100,000 devices/chip are not unusual in current ma-

chines. Such processing chips made modern microcomputers (such as personal computers) possible. The first integrated-chip computer, the Intel 4004, appeared in 1971. The first general-purpose microprocessor, the Intel 8080, appeared in 1974, and it in turn powered the first generation of personal computers (microcomputers). Many single-chip processors (8086, 80386, and 68000 series) are employed in current naval devices, and they are described in the U.S. section below.

The processor generally runs much faster than the main memory. From the early 1970s on, a solution to this mismatch was to provide a *cache* of very fast memory at the main processor, to store the next few instructions as well as a limited amount of data. In a typical large commercial computer, an IBM 3090 (1985), the processor cycle time is 18 nanosec (0.018 microsec), but the main-memory cycle time is 200 nanosec; the machine has a cache with an 18-nanosec cycle time. Main memory in this particular machine is 64–128 Mbytes; the cache is 128–256 Kbytes.

Speed *within* the chip depends on the size of the chip (smaller size means shorter electrical connections) and also on the type of device employed. Much current work is going into a combination of VLSI and increased computing speed, VHSIC (very high speed integrated circuits).

Evolution has been very rapid, one rule of thumb being that the number of devices on a chip doubled annually in the 1960s. The rate declined in the 1970s, but it still quadrupled every 3 years. For all of this period, the price per chip remained virtually constant because the process of chip production is akin to printing. It may be expensive to produce a master, but the unit cost of reproductions is low. The most expensive part of computer production, then, is the physical assembly of the chips. The greater the power per chip, the less the work of assembly and the less expensive the machine, as numerous private users well know.

The balance between hardware and software costs has shifted dramatically in recent years. In the 1960s about 75% of total U.S. Defense Department computer spending went to hardware. By the mid-1980s the proportion had more than reversed: 80–85% went to software. As long as most of the cost of a system was spent on hardware, the cost of additional units was basically a multiple of the cost of any single unit. Software, however, is very easy to reproduce (as many software manufacturers have discovered, to their cost). Total software cost is, therefore, virtually the same whether the software is used for 1 unit or 1 million. If software development is the bulk of total system cost, then, it is inexpensive to increase numbers. This change should begin to affect overall policy as very inexpensive hardware enters service in increasing quantities. It seems likely that the mass retirement of earlier-generation ships and aircraft, due to the defense cuts of the early 1990s, will make the new trend apparent in the major Western navies. Until now the presence of large numbers of earlier-generation machines has obscured the economics of the newer machines.

Numerous examples of early solid-state computer technology remain in service, even though much less expensive alternatives exist (or have existed for many years). Perhaps the main reason is that navies still treat computers as major capital items, as indeed they certainly were during the analog and early digital eras. Existing machines represent sunk costs, and they are adequate to their roles. Replacement would require considerable new expenditure, particularly in the case of very widely used machines. A second, and quite important, factor is the high cost of rewriting software for newly acquired machines. In some cases the newer machines are designed specifically to run software developed (and tested) for their predecessors. This is called upward compatibility.

Much depends on the logical organization of data flow within the computer. The central processor itself handles only 1 instruction at a time. If it must also handle input and output, then it must pause to execute those commands as well. In a fast machine, therefore, the central processor may feed its data into an intermediate device. With the data will come an output com-

mand that the device can execute to shunt the data into the appropriate channel. The greater the decentralization of the system, the faster it can run.

A single fast central processor, then, can share its time among numerous output channels. Each channel can be assigned its own series of program commands, the central processor executing a slice of the program associated with 1 channel before shifting to the next. In the early 1970s this time-sharing operation was sometimes called parallel computing (later it was called multitasking). Such an organization made it possible for a single computer to execute numerous relatively simple programs; each user would see its channel as a separate computer. However, time-sharing is inherently inefficient, in that time is lost each time the central processor shifts programs (and saves the last program's data until the next time they become relevant). In many tactical applications the results of 1 calculation may be relevant to another. Other applications may require so much sheer power, expended in repetitive calculation, that any form of time-sharing is unacceptable. As machines have become much more powerful, time-sharing has returned in a slightly different form as the creation of "virtual machines."

In theory, the different virtual machines (run by the same software) can reside in 1 or in several processors. The failure of any one processor will not bring down the system since the program normally run by that processor can be run instead on a virtual machine hived off from another, at a sacrifice in overall speed. Ultimately one processor can, in theory, carry the system load. The Ferranti System 500 command/control system exemplifies this approach.

Whether time-shared or not, the central processor follows a single path through its program. It is a *serial* processor, in that each program step must await the execution of the step before. Overall computing performance, then, depends on how quickly each of those steps can be executed. However, there are computing problems in which some of the steps do not depend upon previous ones; they must be executed whatever the result of the other steps, or the other series of steps. An example would be the addition of a pair of vectors, in which each element of the resulting vector (represented as a series of numbers) is the sum of the corresponding pairs of numbers from the 2 original vectors. Each pair must be added, whatever the result of adding any other pair. Many kinds of signal processing can be represented by such repetitive, parallel arithmetic. Another parallel process is scanning a data base for matching data.

Some machines are pipelined. A pipeline is analogous to a production line, in which different stages of production can be conducted simultaneously, the products going from 1 to the next. Pipelining can, for example, be used by a time-shared (multitasking) computer to prepare for the next set of tasks while 1 set is being executed, the data for the next set being extracted from main memory while the processor is otherwise occupied. The Signaal SMR-4 exemplifies this approach. A simpler form of pipelining is to fetch and set up the next instruction while the last is being executed, on the theory that fetching and preparation take less time than actually executing.

The next step in parallelism is to provide multiple central processors, each computing independently. Current examples are the Loral Aspro and the British Inmos Transputer chip.

In many cases, elements of the computer are connected by data bus rather than by hard (direct) wiring. Just as in other applications, the bus carries all the data produced by and for the elements it connects; the elements strip messages they need out of the stream based on addressing information. Such stripping action becomes more practical as individual computer elements become less expensive and more compact.

A modern computer will use data busing on 3 distinct levels. The highest, involving the fastest flow of data, will connect the processor and the fast memory. In a personal computer, for example, this kind of bus or connection will exist within 1 circuit board. Each board will use this very dense stream of data to produce output at a slower rate. The boards in turn will be connected by a bus within the computer. In a minicomputer

cabinet, this board is the *backplane bus*, so called because it often runs up the back of a cabinet, in which cards are inserted horizontally. It is exemplified by the VME bus in many 68000-series machines. Finally, the computer itself may feed into a large-scale bus. This organization mimics that in some combat systems, in which the tactical data-handling computers are connected by a local-area-network bus, which itself feeds into a weapon/sensor bus.

The program is stored in memory as a series of numbers, indistinguishable from data. Individual instructions consist of a numerical code (which the processor interprets from a special read-only dictionary), and the addresses of the 1 or 2 pieces of data being processed. The richer the repertoire of machine-language instructions, the easier it is to program the computer to carry out a given task. On the other hand, the richer that repertoire, the longer it takes the processor to look up the particular instruction it is to execute. A paucity of machine-language instructions can always be made up for by more elaborate programming. There are 2 current alternatives: machines using increasingly elaborate instruction sets made practicable by larger-scale integration and machines with drastically simplified instruction sets. The latter are called RISCs (reduced-instruction-set computers); they are typified by the 88000-series RISC chips described in the U.S. section below.

An alphanumeric form of machine language, directly translatable into numerical form (but much easier for a programmer to read), is called assembler language, the assembler being the translating program that translates between alphanumeric and numerical form. For example, the machine may read 4B (B is a hexadecimal number equivalent to 12) as the command to add; the programmer finds it much easier to read ADD. In many cases, a processor may be *microprogrammed* to emulate some other machine, so that existing software need not be rewritten. Each instruction is read, interpreted into the machine's own language, and then executed.

Major programs are not written in machine or assembler language, but rather in a higher-order language, more akin to English or to mathematical notation. The U.S. Navy standard is CMS-2. Such programs are translated into machine language by intermediate programs called compilers. The high-order version of a program is written in relative terms; it does not refer directly to the addresses in memory to which the machine-language program must assign particular pieces of data. At compilation time, all such assignments are made automatically. Revision to the program generally requires recompilation because revision will generally involve reassignment of addresses. Compilation is generally inefficient; a compiled program can often be edited to fit limited space and time. Such editing causes problems when the basic program is modified since memory allocations will have to change. As a consequence, although large programs are generally written in terms of independent modules, the machine-language versions of such programs lose their modularity, and hence are difficult to modify piecemeal.

As machines become faster, inefficiency in programming becomes less significant, so postcompilation editing becomes less important. It becomes possible to envisage the use of a single universal high-level language, and thus the development of a series of standardized building-block programs. A system written in such a high-level language should be transferable between different computers. This is not a new idea, but it has become much more practicable with current computer performance. The U.S. Department of Defense has adopted such a language, ADA (named after the Countess of Lovelace, the first programmer, who worked with Charles Babbage in the nineteenth century). ADA is based on a standard commercial language, Pascal.

ADA was conceived by a Department of Defense working group formed in January 1975; a series of alternative languages was tested in 1975-78 under the code names Strawman, Woodman, Tinman, Ironman, and Steelman. The Steelman language, based on a French language developed by CII-Honeywell-Bull, was chosen; and the basic U.S. reference document on ADA was released in July 1980. ADA is also currently the standard

language of new British and Swedish defense software. It is supported by compiler projects in Denmark, Israel, Spain, and West Germany. Much recent effort has gone into developing and testing (verifying) efficient ADA compilers; advertising for particular machines often mentions that verified ADA compilers exist for them.

The promise of ADA has not always been fulfilled; its compiled programs are still somewhat inefficient (editing would negate the central feature of ADA, the transportability of its software). In one case, a program written in ADA produced 4.5 times as much code (when it was compiled) as a comparable program written and edited in assembly language. The new computer, for which the program had been rewritten in ADA, was not fast enough to make up the difference (it was only 3 times as fast as its predecessor). In this case, 2 computers had to be bought to replace a single older, slower one. The moral is that raw computer speed is not in itself a sufficient measure of overall system performance. On the other hand, once the program had been written in ADA, it could still be used when a much faster machine became available. The adoption of ADA is an expression of faith that brute computing power will ultimately solve the inefficiency problem, and that the important efficiency is transportability of software, i.e., that software is the current and future bottleneck.

Like their civilian counterparts, naval computers fall into 4 basic families: supercomputers, mainframes, minicomputers, and microcomputers. The naval equivalent of a supercomputer is a specialized signal processor, usually for sonar; such machines are described in the ASW section. The mainframes are the central computers of command/control systems, and sometimes they are used in other systems as well. Typically, minicomputer equivalents are used for local processing, although distributed command/control systems are sometimes built up entirely from them. Microcomputers comparable to civilian personal computers are found in many "intelligent" displays, and many current computers are built up from standard microcomputer processor chips.

There are also naval equivalents of civilian workstations. A workstation is a much more powerful alternative to a microcomputer, equivalent in power to a minicomputer. A workstation tends to be oriented more toward graphics; a typical civilian application is to computer-aided design or manufacturing. In a naval system, the workstation or microcomputer will often function as a terminal (console) within a larger system. Given the processing power required to support the newer displays, it is sometimes difficult to distinguish between a "smart" display (which may be equivalent to a civilian workstation) and a dedicated computer. In this book, workstations are described under tactical data-handling systems or, in some specialized cases, ASW. In some cases of distributed processing, such as the U.S. JOTS and TFCC, the workstations are the main computing elements; there is no central computer at all.

Moreover, newer mini- and even microcomputers may greatly exceed the performance of older mainframe units still in service, even still in production (because of the high expected cost of replacing the relevant software). One important distinction, which is apparent in the characteristics listed here, is the number of input/output channels. The main computer of a combat-direction system must accept inputs from several different devices, and it must interact with several consoles. A civilian minicomputer or a microcomputer will generally have only a very few input/output channels.

In the computer descriptions below, machines are generally credited with 16-, 24-, 30-, or 32-bit words. In many cases the actual stored word is 2 (for 16-bit machines) or 4 bits (for 24- and 32-bit machines) longer, the extra bits being used to check against transmission errors within the computer. In one case (UYK-43 with HBM), 7 extra bits are used (4 for parity, 3 for scheduler and block selection). The parity check bits have no computational significance, so they are normally not counted in calculations of memory capacity. The 30-bit standard was chosen to match the Link 11 message format, the 24-bit format

to match the alternative Link 10 or Link X. More modern machines have adopted the commercial standards of 16 and 32 bits (2 or 4 bytes) and of hexadecimal (base 16) internal organization.

Current naval minicomputers and workstations are generally built around a standard data bus (backplane bus), VME (originally versatile memory Eurocard, IEEE 1014), 32 bits wide, with a capacity of 40 Mbytes/sec. The U.S. Navy has adopted the Futurebus (IEEE 896) as its next-generation standard. Bus width is 32–256 bits, and capacity is 100–800 Mbytes/sec with the current (1990) protocol. By 2000 capacity should be 200–2000 Mbytes/sec, using a new packet protocol, in which data are sent in blocks (packets) for faster reading by devices on the bus. Futurebus has so much more capacity than is currently needed that one manufacturer, Ferranti, calls it the first bus architecture designed to support multiple generations of technology.

Finally, a note on high-level computer languages. The principal ones mentioned below are ADA (see above), Algol, Fortran, JOVIAL, and Pascal.

Algol (Algorithmic Language) was developed in the late 1950s (formally defined in 1960) specifically to express algorithms (series of operations) rather than single formulas; compared to the earlier Fortran, it has more compact ways of specifying paths through a program (e.g., loops and decision points). Algol was also designed for a more modular form of programming than Fortran.

Fortran was the first high-level calculating language; the name means Formula Translation. It first appeared in 1954 and is similar to the Basic language, which many machines now use.

JOVIAL (often JOVIAL 73) is a U.S. Air Force language, originally Jules' Own Version of the International Algebraic Language (Algol). Jules was Jules Schwartz of the System Development Corporation.

Pascal is an Algol-related language developed in the early 1970s. It was conceived for teaching purposes, as a demonstration that programming could be made systematic, and is specifically designed to detect programming (coding) errors. The original Algol is a subset of Pascal.

The computers described in this section are characterized by their word length, their memory capacity (generally, but not always, in terms of words), their speed, the size of their instruction set, and the number of their I/O channels. Speed is somewhat difficult to characterize in comparable terms. Ideally, computers could be compared in terms of some standard complex operation, such as compilation of a number of on-board and off-board tracks, but in fact command/control systems differ radically in the demands they place on their embedded computers. The speeds listed *are not* the clock rates so often listed for personal computers. A computer clock provides timing impulses, but instructions often require several ticks of the computer's clock. Similarly, the significance of the number of individual instructions in the computer's set is somewhat ambiguous since much depends on the details of the instructions. The number is a measure of the flexibility of the processor and, therefore, of the complexity of programs using it. Instruction sets have become considerably more complex as solid-state components have become smaller and less expensive; quite standard machines of the 1960s and 1970s often had fewer instructions than machines now characterized as special RISC types.

CANADA

The software of the pre-SHINPADS Canadian combat systems is written in NELIAC, a language developed by the U.S. Naval Electronics Laboratory at San Diego in the early 1960s.

◆ AYK-502

The AYK-502 is the tactical computer of the CP-140 Aurora maritime-patrol aircraft and is the Canadian version of the U.S. AYK-10.

◆ USQ-501

Word Length: 32 bits

Memory Capacity: 40 kwords, expandable to 80k

This is the Litton L-304F computer of the Canadian CCS-280 command/control system; the same computer is used in the U.S. E-2C.

◆ UYK-501

Word Length: 25 bits

Memory Capacity: 4 kwords, expandable to 32k in 4k modules

Speed: memory cycle time, 2 microsec; add/subtract time, 8 microsec; multiply time, 110 microsec; divide time, 118 microsec

Instructions: 110 **I/O Channels:** 64

A CDC minicomputer, UYK-501 is used by the Canadian Navy for fire control and tracking and also by the U.S. Navy. UYK-501 entered service about 1967 and is presumably the basis of the Canadian ASROC fire-control system.

◆ UYK-502/UYQ-503/UYQ-504

UYK-502 is a less militarized version of UYK-505 (see below) with a fast semiconductor memory in place of the slower core memory, used primarily to drive displays. Memory capacity is 16–256k in 16/64 kword (16-bit words) increments. The machine can accommodate 4 types of memory: dynamic NMOS RAM (65k modules), core (64k module, can be combined with NMOS RAM in 192k modules), CMOS static RAM (16k modules), and RAM/PROM (4k/12k combinations, 16k total). Typical operating rate is 240 KOPS. There are up to 64 I/O channels. A circuit card can accommodate 1 full duplex fast NTDS channel, 1 full duplex ANEW channel, 1 full duplex slow NTDS channel, 1 full duplex NATO serial, 4 full duplex 188C serials, or 4 full duplex RS-232 serial channels. UYK-502 began as an internal Sperry (UNISYS) Canada program for a low cost processor (LCP) compatible with UYK-20 for noncritical tasks. It was selected by the Canadian government as a primary computer for many Canadian systems, including the SHINPADS combat-direction system.

UYQ-504 is a UYK-502 with a SHINPADS embedded node, so it can be integrated into a SHINPADS system. UYQ-503 combines the SHINPADS nodes and the UYK-502 processor in a single unit. It is a joint project with UNISYS (U.S.) and began late in 1988.

◆ UYK-505

UYK-505 is a Canadian UNISYS-manufactured version of the U.S. UYK-20A, which has memory expanded over that of UYK-20 (160 kwords, expandable to 256k). It is the main computer of the SHINPADS combat-direction system of the Canadian "City"-class and "Tribal Update" (TRUMP) frigates and is the basis of the ADLIPS 90 CDS. The UYK-20A design dates from about 1980 and was roughly simultaneous with that of UYK-502 (above).

◆ UYK-507/UYQ-505

Word Length: 32 bits

Memory Capacity: up to 4 Gwords, see below

Speed: 5 MIPS **Instructions:** 516

I/O Capacity: 16 modules (see below)

UYK-507, introduced in 1990, is intended to supersede the UYK-502/505 series in such naval systems as SHINPADS. It uses some UYK-44 technology but is a separate development. Existing UYK-502/UYQ-504 computers will be upgraded since their cabinets can accommodate the new cards. UYK-505s will be replaced since their UYK-20 cabinets are not compatible. A UYK-507 can emulate a UYK-44 or -502. It is a hybrid, combining new electronics with an old existing cabinet. Consequently, it is much less expensive than a new UYK-44 (but also less rugged, particularly against threats such as EMP and TEMPEST).

Versions: (V)1 is a newly built computer, (V)2 a refurbished UYK-502 or UYQ-504 with fewer slots. As of 1990, the first 6

"City"-class frigates are to receive (V)2s (they have already had their SHINPADS installed), but the last 6 will be fitted with newly built machines. Other possible applications include the data loader/dumper for the new Canadian naval helicopter.

UYQ-505 is a SHINPADS node embedded in a UYK-507, analogous to UYQ-504.

The computer consists of a series of circuit boards connected by buses. The central processor lies on a 32-bit common bus, which also carries the memory interface and the I/O processor, and which can accommodate a coprocessor (for future growth). The I/O processor feeds a separate RMF (reconfigurable modular family, for SHINPADS cards) bus connected to a series of interfaces and to an embedded SHINPADS node set (UYQ-505). Thirteen different types of I/Os can be accommodated, including NTDS fast and slow, NTDS serial, NATO serial, and A-NEW. I/O is in modules; the computer can accommodate up to 16 modules and up to 64 channels.

The processor can directly address 4 Gbytes of memory. It includes an Expanded Memory Reach (EMR) set of registers, to address further memory (up to 16 Gwords) by paging, with 256 groups of 64-page registers for code and 256 groups of 64-page registers for data. The processor uses a 64-kbyte cache memory.

The minimum configuration is 256 kwords of semiconductor RAM plus 2 kwords of bootstrap EEPROM (for start-up). It can be expanded by another 256 kwords of semiconductor RAM or EEPROM, plus 512k-8M words of RAM in 512-kword increments. The much larger number of directly addressable words refers to mass memory. The processor is pipelined. The instruction set is described as ADA-friendly; it includes instructions beyond those in UYK-44, specifically designed for easy compilation of ADA programs.

Cabinet dimensions are 17.5 × 19.0 × 18.5 in (total weight 116 lb).

FRANCE

The standard military programming language is LTR (Pascal derivative).

◆ IRIS 35M

Word Length: 16 bits

Memory Capacity: 16-256k bytes (ferrite cores); increments are 16-64k bytes (each of 3)

Speed: memory cycle time, 1.6 microsec; add/subtract time, 5.4 microsec; multiply time, 14.1 microsec

Instructions: 58 **I/O Channels:** 34-36

This was the smallest of the IRIS computer family, made by CII (Compagnie Internationale pour l'Information, now part of the Thomson group); it was proposed for the small-ship version of SENIT about 1969. It was used in the Pluton tactical-nuclear-missile system; in a land-based command system, ATAC; and in the DLT 4 submarine FCS. IRIS 35M is software-compatible with other IRIS-series computers, such as IRIS 55M (described below). IRIS 35M could be equipped with up to six 1-Mbyte magnetic-disk mass memories. MTBF was 4000 hr.

◆ IRIS 55M

Word Length: 16 bits

Memory Capacity: 512 kbytes, in 32-kbyte increments

Speed: memory cycle time, 1.2 microsec; add/subtract time, 2.5 microsec; multiply time, 5.3-7.7 microsec

Instructions: 80 **I/O Channels:** 24

Made by CII (now part of Thomson-CSF), IRIS 55M was the first French SENIT computer, all previous versions having used U.S. computers. Input/output channels include an NTDS channel (1300 bytes/sec) and a multiplexing channel (which can accommodate 8 external connections) with a rate of 400 bytes/sec. Direct input/output is in 16-bit words, and there are 4 independent memory accesses.

◆ MLX Series

These are new (1989) military (including naval) computers produced by the CIMSA Sintra Division of Thomson-CSF. They

are built around the standard Motorola 68020 microprocessor (future ones will use the 68030, and others planned will incorporate the 88000 RISC chip). The internal bus is the VME, and the operating system is the Unix Series V. MLX 32/20 is based on the 68020 chip (3 MIPS); MLX 32/30, with the 68030, will run at 4 MIPS (clock rate will be 25 MHz).

◆ 15M/05

Word Length: 16 bits

Memory Capacity: 32 kwords, expandable to 64k

Speed: typical instruction time, 1.2-1.8 microsec

Instructions: 98

CIMSA's minicomputer is typically used for signal processing. It is supplied in board as well as chassis form.

◆ 15M/125

Word Length: 16 bits

Memory Capacity: 128 kwords, expandable to 512k

Instructions: 128

These are CIMSA minicomputers. The 15M/125F version has a fast arithmetic processor. The 15M/125S version is used for space applications and has a 64k-memory capacity; it has 135 instructions. The 15M/125X version is the main computer of the Atlantique 2 patrol aircraft. Unlike the earlier machines, it uses 32-bit words. Memory capacity is 1 Mbyte (much the same as in the /125), and throughput is 1 MOPS. The first airworthy prototype was delivered in 1986.

The 125 and 125S versions are made in both full- and half-chassis versions; 125X is made only in a full-chassis version. The 15M/125X version is the one used in the new missile destroyer *Cassard*.

ISRAEL

The 32-bit Elta EL/S-9000 is the standard naval mainframe computer. Throughput is 8.4 MOPS.

◆ EL/S-8600 Series

Word Length: 16 bits

Memory Capacity: 64 kbytes, expandable to 2 Mbytes

Speed: load, 1.34 microsec; add/subtract, 0.66 microsec; multiply, 6.56 microsec; divide, 9.26 microsec

Instructions: 90

These are standard Elbit 16-bit computers for air, land, and sea applications. Data apply to EL/S-8610, which has 15 modules. Another member of the family, EL/S-8611, has only 4.

ITALY

◆ CDG-3032

Word Length: 32 bits

Memory Capacity: 128 kwords (4 memory modules)

Speed: memory cycle, 0.7 microsec; half-word memory cycle, 0.15 microsec

Instructions: 112 **I/O:** 4 modules, 250 kwords/sec/channel

This Selenia machine is the main computer of the IPN series. It was introduced about 1973. Memory is semiconductor (MOS), and operation can be in full- or half-words (16 and 8 bits). The memory can be addressed simultaneously by the main processor and by the I/O channels.

◆ MARA series

Word Length: 16 bits

Memory Capacity: up to 16 Mbytes

Speed: 0.8 MIPS

The acronym of these Selenia computers stands for Modular Architecture for Real-Time Applications. The main naval version is MARA 286, i.e., MARA using an 80286 microprocessor. Data above apply to the version using a single such processor; there are also MARAs with 2 or 3, with maximum memory capacities of 24 and 32 Mbytes and with throughputs of 1.6 and 2.4 MIPS.

MARA can be fitted with circuit boards for a RISC unit, for a bubble memory, and for either a multiprocessor or a mono-

processor application. Other boards can connect it to either an Ethernet or a Selenia MHIDAS bus.

The airborne version of this machine is SL/AYK-204/1; 204/2 and /3 are the multiprocessor versions. SL/AYK-203 is a slower version (0.3 MIPS), using an 8086 processor, with a maximum memory capacity of 1 Mbyte.

◆ NDC-160/E

Word Length: 16 bits

Memory Capacity: 64 kwords (core or semiconductor)

NDC-160/E is the standard computer of the Italian SADO and related systems; it is being superseded by the MARA series described above. There are 2 operating systems, a Disk Operating System and a Time-Sharing Executive.

NETHERLANDS

JOVIAL is the high-level language for the SEWACO systems.

◆ SMR

Word Length: 24 bits

Memory Capacity: 8 kwords (0.5-mm ferrite cores); maximum 64k

Speed: load or store word, 2 microsec; memory cycle time, 1 microsec; add/subtract time, 2 microsec; multiply time, 12 microsec; divide time, 22 microsec

Instructions: 60

I/O: autonomous control; maximum transfer rate, 168 kwords/sec

SMR is the main computer of Signaal SEWACO/DAISY systems. The first unit was delivered in 1970 to a program generation center. The SEWACO I unit, for the *Tromp* class, was first delivered in 1973; it is the 64k version. A 24k version was offered in 1975 for a weapons system including a twin Bofors 12-cm gun, Exocet missiles, NATO Sea Sparrow, and a WM25 fire-control system. The 32k version was delivered to Canada in 1970 for ASWDS (together with two 24k units, presumably for training). The Belgian frigates' SEWACO IV system (1974) uses the 64k version.

SMR (and the later Signaal computers) uses bit-slice arithmetic, in which the 24-bit word is broken down into six 4-bit subwords that are processed in parallel.

In 1971 Signaal estimated MTBF as 4000+ hrs. In a typical 24k configuration, SMR weighs 310 kg; dimensions are 53.5 (wide) × 62 (deep) × 169.7 cm (high). SMR means Signaal Micromin Reckoner (computer).

◆ SMR-4

Word Length: 24 bits

Memory Capacity: 1 Mword internal, 1 Mword external

Speed: memory cycle time, 0.416 microsec; effective cycle time with pipelining and interleaving, 0.250 microsec (can be as little as 0.166 microsec) **Instructions:** 273

I/O: up to 256 peripheral devices; maximum rate 230 kwords/sec; up to 1 Mword/sec with DMA

SMR-4 is the latest Signaal mainframe computer, the basis of the current versions of the SEWACO or STACOS combat-direction systems, e.g., in the Turkish MEKO frigates. It is a development of SMR-MU; the -4 indicates fourth generation in the Signaal series (SMR/SMR-S, SMR-S1, SMR-MU, SMR-4).

The main processor is designed for multiprocessing (time-sharing). There are 16 levels of process priorities, and for each level there is a 256-entry register. Each process (i.e., each time-shared program) is defined by hardware context (the contents of 11 process registers), software context (e.g., 2 process stacks), and the setting of the memory-management unit (MMU). The contexts and the MMU settings are saved when the processor switches to the next process. SMR-4 incorporates memory pipelining to reduce the waiting time involved in reading memory during the shifts from process to process. Memory is organized into 16 logical pages/process, each of 4k, 16k, 18k, 32k, or 64k words.

The memory bus, which connects the central processor to the main memory, can also be connected directly to an Ethernet LAN (in a combat-direction system) and to direct memory ac-

cess (DMA) controllers; external devices can also be coupled directly to the memory bus. There is a separate input/output processor that transfers data to and from the main memory without direct reference to the main processor. Memory access by the application software is controlled by the MMU, which also prevents illegal access to specified parts of the memory (e.g., to provide special protection to specially classified data).

Signaal estimates the MTBF as 2653 hrs; MTTR is 5 min, using line-replaceable units. Weight is about 23 kg; dimensions are 176 (width) × 536 (height) × 672 (depth) mm. SMR-4 was announced in 1987.

◆ SMR-MU

Word Length: 24 bits **Memory Capacity:** 16–64 kwords

Speed: memory load time, 2.25 microsec (12 microsec for double precision); add/subtract time, 2.25 microsec (16.125 and 16.875 microsec in double precision); multiply time, 11.25 microsec (19.875 microsec in double precision); divide time, 10.875 microsec (19.5 microsec in double precision)

Instructions: 146

I/O: up to 62 devices can be connected; maximum I/O rate 120,000 words/sec; maximum DMA rate 400,000 words/sec

Announced in 1978, SMR-MU is a minicomputer superseding SMR-S and is upwardly compatible with the earlier machine (i.e., it can run programs written for SMR-S, but SMR-S cannot run some SMR-MU programs). DMA is optional; it allows a high-data-rate device to be connected directly to the memory. The higher-memory version can have 48 kwords in either 16k modules of read/write memory or in 4 kword modules of PROM (i.e., permanently programmed read-only memory). An earlier version had a basic 4 kword configuration, expandable to 64k, with the 60k in 4k read/write memory modules or else in 4k PROM modules. This version was credited with 151 instructions. In the latest version (1984) the basic configuration is 64 kwords, and the maximum is 2 Mwords, addressable in 8k pages. In 1979 Signaal estimated MTBF as 21,000 hr for the 16k version.

◆ SMR-S

Word Length: 24 bits

Memory Capacity: 4k, expandable to 64k in 4k modules (RAM or ROM)

Speed: load or store word, 4 microsec; add full word, 4 microsec; multiply, 16 microsec; divide, 28 microsec; sin/cos (optional), 8 microsec

Instructions: 56

I/O: 6 channels (up to 64 peripheral devices); data transfer rate 100 kwords/sec

SMR-S is a minicomputer derived from the SMR, using the same word structure, the same instruction set, and the same flexible I/O system. The memory is solid-state MOS (Intel 1k chips) rather than ferrite cores. SMR-S was introduced in 1973. At that time Signaal estimated MTBF as 13,000 hrs. SMR-S weighs 20 kg, and its power supply adds another 20 kg.

◆ SMR-S1

Word Length: 24 bits

Memory Capacity: 4 kwords, extendable to 64k in 4k modules

Speed: load or store, 2.7 microsec; add, 2.7 microsec; multiply, 10.7 microsec; divide, 18.7 microsec; trigonometrical functions, 8.0 microsec (optional)

Instructions: 56

I/O: autonomous I/O control; maximum transfer rate, 150 kwords/sec; HSDC rate, 700 kwords/sec

Introduced in 1975, SMR-S1 is a faster replacement for SMR-S. An optional High-Speed Data Channel (HSDC) allows direct connection of a device with a high-data rate to the memory. Memory is solid-state. Signaal estimated MTBF at 13,000 hr. The mainframe, including 32 kwords of memory and 6 I/O channels, weighs 20 kg. Dimensions are 170 (wide) × 600 (deep) × 540 (high) mm, matching those of the earlier SMR-S.

NORWAY

The current standard high-level language is Mary:

◆ KS500

Word Length: 16 bits

Memory Capacity: 64 kwords, expandable in modules of up to 32 kwords each

Speed: 164 KIPS (Wheatstone test) **Instructions:** 130

KS500 is the standard computer of NFT command/control systems (such as NAVKIS and MSI-3100); it is being superseded by KS900, but as of 1990 it is still in production. Because it is used to integrate a very wide variety of weapons and sensors, many of them designed in the 1950s, it can be connected to an unusually large variety of interface modules.

◆ KS900

Word Length: 16 bits

Memory Capacity: up to 4 Mbytes per board, total of up to 128 Mbytes, plus up to 256 kbytes of EPROM for processor programs

Speed: clock frequency, 15 MHz; typical memory access time, 0.270 microsec

I/O: see below

KS900 is the main computer of the current NFT command/control systems. It is conceived as a process control computer for use in particularly difficult conditions, e.g., in North Sea oil rigs, as well as for military applications. Therefore, application programs are described as processes rather than in more conventional language. The first user was the MSI-90U submarine command/control system.

The main processor is a Motorola 68020, with a 68881 math coprocessor. The computer uses separate microprocessors to control its I/O functions, and its operating system kernel combines the power of the central processor and the subprocessors. KS900 is built around a 32-bit bus with a secondary 180-kbaud serial bus for built-in testing. The bus (backplane) carries a processor card (characteristics above), a Budos interface to the external system bus, a console interface, a mass memory module, an interface to instruments, a serial interface, a graphics interface, and an interface to the built-in test equipment. Each I/O board has its own local microcomputer (68000-series) for local control. Because the modules are all united by a bus, individual microprocessors controlling input/output can load their own programs directly from the mass memory, without intervention by the main processor. Module functions are largely controlled by EPROM software. All of the modules are in extended euroboard module format, 233.4 × 220 mm.

The memory listed above is accessed as local memory by the main processor and as system global memory (via the bus) by the I/O boards. This type of direct access is not too different from the access that allows modular operation in the Hughes Modular Combat System; see the description of that system.

KS900 can accommodate up to 63 user processes and 1 system process, expandable to 255 user processes with additional memory. Each process consists of up to 16 segments, each of up to 512 kbytes.

The system uses Intel i8751 processors for built-in test, communicating with one another via a separate serial bus. These devices operate at a clock rate of 11.53 MHz. This device also acts as the main processor for the console interface module, and also for the raster-scan converter module.

The bus controller itself provides a 65,536-Hz time reference. Although the system as a whole has a bus width of 32 bits, the processor operates on a normal word of 16-bit length, counting 32 bits as a long or double word.

Mass memory is up to 28 Mbytes of magnetic bubble memory, in 512-kbyte capsules (8 to a board). Data transfer rates are 100 kbytes/sec (average) or 400 kbytes/sec (maximum), and data are stored as pages of 128, 256, or 512 kbytes.

◆ SM-3

Word Length: 16 bits **Memory Capacity:** 64 kwords

Instructions: 32 **Speed:** memory cycle time, 0.8 microsec

Kongsberg (now NFT) computer, used in the Penguin system and then in the NATO Sea Sparrow; the U.S. designation (see below under U.S. NavOrd computers) is Mk 157.

SWEDEN

As of 1988, ADA was the standard language of all future defense projects.

◆ Censor 908

Word Length: 4 bytes (32 bits)

Memory Capacity: 16 kbytes (ferrite cores), expandable in 16k increments to 128k

Speed: memory cycle time, 1.0 microsec

Censor 908 is a Standard Radio & Telefon (now Ericsson) minicomputer, part of the Censor 900 series (ca. 1971). It was designed to operate either as a central computer or as a satellite to a Censor 932; the main memory can be accessed independently by the main computer. Up to four 908s can be connected to 1 932. In such a system, a common main memory can serve both the 908s and the 932 master.

◆ Censor 932

Word Length: 4 bytes (32 bits)

Memory Capacity: 4–128 kwords (16–512 kbytes), in 4-kbyte increments up to 128k

Speed: memory cycle time, 1.0 microsec **Instructions:** 80

Censor 932 is a Standard Radio (now Ericsson) main computer, originally designed for use in air-defense centers, and then used in shipboard command/control systems. Its architecture allows for 64 priority interrupts, compared to 32 in the Censor 908 minicomputer. Memory can be supplemented by up to 2 Mwords of ferrite core mass storage.

◆ Censor 932E

Word Length: 32 bits **Memory Capacity:** 512 kwords

Speed: memory cycle time, 0.525 microsec; add word, 2.4 microsec; multiply/divide time, 16 microsec

Censor 932E is the current standard Swedish Navy tactical computer, in the Maril combat-direction system. Operations can be conducted with half- or double-length words. Typical dimensions are 500 (high) × 530 (wide) × 230 (deep) mm; weight is 35 kg.

◆ 9LV System Computer

Word Length: 32 bits

Memory Capacity: 64–256 kwords

Speed: typical execution speed, 0.5–2 microsec

This is the current standard distributed minicomputer of the 9LV Mk 2 system. In the Mk 3 system, it is replaced by a single-board CPU using a 68020 microprocessor, with up to 4 Mbytes of on-board memory (and 256 kbytes of EPROM-carrying programs).

UNITED KINGDOM

The standard high-level language is Coral 66, structured similarly to Algol, with some features taken from JOVIAL and Fortran. Coral 66 is now being superseded by ADA (which became mandatory in British defense projects on 1 July 1987). Fixpac is the assembly language of the Ferranti FM 1600 series computers.

The current standard minicomputer is the Argus F700, and the standard microcomputer of the 1980s was the F100.

◆ Argus M700

Word Length: 16 bits **Memory Capacity:** up to 256 kwords

Speed: 250 KIPS (M700/40: 1.6 MIPS) **Instructions:** over 120

These Ferranti minicomputers are typically used in combination with FM 1600-series main computers. In the basic version, 64 kwords are directly accessible, and total memory (including bus memory) is 256 kwords. M700/20 incorporates a memory-management card and can access all 256 kwords directly. M700/40 is an LSI version, with a 4k cache memory.

M700/42 incorporates up to 256 hardware-implemented sub-routines, such as conversion between fixed- and floating-point formats, square root, and trigonometric functions.

Argus 700 supersedes the earlier Argus 400, introduced in 1966, with 4–12 kwords of memory in ferrite core. Word length is 24 bits, as in the larger Ferranti computers; there are 38 instructions. Speed: add/subtract, 12 microsec; multiply, 18–162 microsec; divide, 162 microsec.

◆ F100-L/F200-L

Word Length: 16 bits **Memory Capacity:** 32 kwords (see below)
Speed: clock rate, 8.5 MHz (13.5 MHz in commercial version); multiply time, 9–13.5 microsec; divide time, 12–16.2 microsec
Instruction Set: 153

F100-L is a standard Ferranti microprocessor, developed for the British Ministry of Defence. It can address up to 32 kwords. The microprocessor, clock-generator, multiply/divide unit, and 2 bus buffers are available as a single hybrid chip (FBH 5092).

F200-L is an improved version, which can address 64K–1M words, on-chip multiply/divide, and higher speed (rated at 300 KIPS).

◆ Poseidon

Word Length: 24 bits **Memory Capacity:** 8 kwords (ferrite cores)
Speed: memory cycle time, 6 microsec; instruction read time, 2 microsec
Instructions: 32

This Ferranti machine was the basis of the earliest Royal Navy automated tactical data systems that were on board HMS *Eagle* (1964) and some "County"-class destroyers (beginning in 1966). As such it may still exist in Chilean service. Poseidon was developed by Ferranti and ASWE (Admiralty Surface Weapons Establishment) in 1959–60, and the first production machines appeared in 1963.

◆ FM 1600

Word Length: 24 bits
Memory Capacity: 16 kwords, expandable to 256k (ferrite cores) (speed roughly halved above 128k)
Speed: memory cycle time, 1.0 microsec; add/subtract time, 1.3 microsec
I/O Channels: 64

FM 1600, which was introduced in 1968, replaced the earlier F 1600. FM 1600 replaced the discrete technology of the earlier machine with small-scale integrated circuits. FM 1600 was the most powerful of the original FM 1600 series. Dimensions: 23 × 21 × 58 in.

◆ FM 1600B

Word Length: 24 bits
Memory Capacity: 4 kwords, expandable to 64k in 4k increments
Speed: memory cycle time, 1 microsec; add/subtract time, 2.7–4.3 microsec (fixed point), 6.3–7.0 microsec (floating point); multiply time, 11.3–13.3 microsec (fixed point), 14.0 microsec (floating point); divide time, 13.0–16.0 microsec; clock rate, 3 MHz
I/O Channels: 20 (maximum)

FM 1600B was introduced in 1968 as a lower-powered alternative to FM 1600 (which was not used in any shipboard systems), with half the computing power in one-fifth of the volume; dimensions are 19 × 16 × 7 in. It was used in CAAIS tactical data systems as well as in submarine tactical systems; some were exported for use by the Royal Netherlands Navy. The original version used 1-microsec memory, but in 1969 a 600-nanosec (0.6-microsec) memory was introduced. When this machine appeared, Ferranti claimed that it was the only available small computer designed for floating-point operation in its central processor; other computers required additional programming (which carried a speed penalty) for such operation. Modules for automatic radar-data extraction and for analog-to-digital conversion for synchros were designed for FM 1600B.

◆ FM 1600D

Word Length: 24 bits

Memory Capacity: 4 kwords, expandable to 64k in 4k or 8k increments

Speed: memory access time, 1 microsec; add/subtract time, 4.7–14.0 microsec; multiply time, 0.9–137.0 microsec; divide time, 68.0–98.0 microsec; typical throughput, 350 KIPS

Instructions: 325 **I/O Channels:** up to 16

This version of FM 1600 appeared about 1972. It uses an 8-bit processor, handling its 24-bit words in slices. It is also capable of double-precision arithmetic. Capacity is equivalent to that of FM 1600B. FM 1600D is a standard airborne computer, in the Searchwater radar processors of the Nimrod and the Sea King early-warning helicopter.

FM 1600C had no naval applications.

◆ FM 1600E

Word Length: 24 bits
Memory Capacity: 32–256 kwords
Speed: clock rate, 12 MHz; floating point divide, 9.6 microsec (from main store); conditional jump, 2.1 microsec; read or write to memory, 0.75 microsec
I/O Channels: 28 (4 high priority)

FM 1600E is the most powerful of the FM 1600 series, the larger equivalent to FM 1600D; both embody medium-scale integration technology. Both are, therefore, small enough to be integrated into the display consoles themselves, so that there is no need for a separate computer room. FM 1600E uses a cache (kernel) plus main storage, and there is provision for program protection through memory partitioning. Of the input/output channels, the 4 high-priority ones have their own buffers and can transfer a word in 6.5 microsec. The other 24 channels are multiplexed in 2 groups; transfer rate is 1 word in 9.0 microsec. The semiconductor memory is in modules of up to 128 kwords each. This computer dates from about 1977.

◆ F2420

Word Length: 24 bits **Memory Capacity:** 3 Mbytes (1 Mword)
Speed: 3.8 MIPS

F2420 is the successor to the FM 1600 series, with 4 times the computing speed and much more memory. The 3-Mbyte memory can be extended to 24 Mbytes using external addressing. As in the U.S. UYK-20/44, the faster and more powerful machine can run programs originally written for the smaller and slower one but can also do much more. F2420 is used in the enhanced version of the Ferranti CAAIS/WSA 400 series, and it replaces FM 1600s in the CACS tactical data system. F2420 is sometimes described as enjoying 6 times the computing power of its predecessors.

This computer was originally named FM 1600F but was renumbered because it embodied major architectural changes.

◆ GEC-Marconi 920ATC

Word Length: 16 bits
Memory Capacity: 64 kwords, plus up to 192 kwords externally (ferrite cores)
Speed: internal memory access time, 0.42 microsec; cycle time, 1.0 microsec
I/O: up to 16 peripherals, including magnetic tape and bootstrap loader; nominal data-transfer rate, 1 MHz (64 and 500 kHz rates are also available)

This is the central tactical computer of the Nimrod MR.2, replacing the 920B of the MR.1 version. 920ATC is also the computer of the AQS-901 acoustic system on board the MR.2. The main computer is housed in a single ATR Short case; maximum weight is 37 lbs. Word length does not include 2 parity bits; 920ATC is sometimes described as an 18-bit computer. The manufacturer describes its floating-point operation in terms of a 16-bit exponent and an 18-bit mantissa, so under some circumstances it would seem that all 18 bits are used.

◆ Transputer

Inmos' Transputer is a single-chip 32-bit processor specially designed for parallel computing; it can communicate both with the unusual I/O channels and also with other Transputer chips.

Transputers are used in the British next-generation surface-ship and submarine command systems (SSCS and SMCS). Reportedly, a single Inmos T800-20 has about 5 times the performance of a 68020 combined with a 68881 floating-point processor. In a typical application, T800 is credited with a speed of 1.75 Mflops, or 12 MIPS of scalar (single-number) processing power.

UNITED STATES

The current standard large computer is UYK-7, and the corresponding minicomputer is UYK-20. They are being replaced by, respectively, UYK-43 and UYK-44. In a few cases, UYK-19 is used instead of UYK-20. The new standard airborne computer is AYK-14. Some special output channels are NTDS slow (41,667 words/sec), NTDS fast (125 kwords/sec), and A-NEW (125 kwords/sec); the last refers to the A-NEW ASW system introduced in the P-3C airplane. AYK-14 has an additional high-capacity digital channel, Proteus (10 Mbit/sec), for communication with a separate on-board acoustic-signal processor.

The current minicomputers are available as SEM (standard electronic module) boards, suitable for embedding in other devices.

The current standard naval programming language is CMS-2 (second generation Compiler Monitor System programming language, adopted in the mid-1960s). This language exists in several versions (dialects), -2M, -2Q, and -2Y. ADA is being introduced for new systems. There is also a special signal processing language, SPL/1, which is also suitable for graphics display processing. Like ADA, SPL/1 is related to the Pascal civilian language.

In recent years the standard Mil-Spec computers have increasingly been supplemented by very powerful commercial machines (DTC I and II) for semitactical applications such as JOTS and FDDS. These machines are generally programmed in the C and UNIX commercial languages.

◆ ASN-91

Word Length: 16 bits

Memory Capacity: 16 kwords (12 kwords protected)

Speed: cycle time, 2.5 microsec; average speed, 125 KOPS

Instructions: 37

I/O Channels: 5 output, 8 input; 67 discrete inputs, 32 discrete outputs

ASN-91 is the IBM tactical (weapons-delivery) computer of the air force A-7D and the navy A-7E. In the A-7E, ASN-91 computes a navigation solution in 0.20 sec and a weapons-delivery solution in 0.03 sec. The computer portion of ASN-91 is designated CP-952; it is the IBM System/4 Pi model TC-2. See also the separate entries for the IBM System/4 Pi series and for the A-7E tactical data system.

ASN-91A(V) (IBM TC-2A) of 1974 had pluggable memory expansion units (total memory could be 16k, 24k, 32k, and 40k words) and a signal converter modified so that it could be installed on a common backplane with the computer.

◆ ASQ-114

See CP-901/ASQ-114, below.

◆ ASQ-155

The IBM central computer of the A-6E, ASQ-155 is an upgraded version of the earlier ASQ-133 (IBM Series/4 Pi Model TC-3), introduced onto the A-6E production line in April 1976. There are up to 60 I/Os, including displays and air-data information, many of them converted from analog form by a Fairchild A/D converter. ASQ-133 is a 32-bit computer (with 4 additional bits/word for parity and storage protection) and 36 instructions; storage is 32k 18-bit words. Speed: 0.9 microsec maximum access time; 2.5 microsec memory cycle; fast conversion speed, 35 microsec digital to analog and 105 microsec analog to digital. ASQ-133A added an expandable memory and a core memory unit for the addition of logic tables. ASQ-155A is similar, but capacity is doubled to 32k 36-bit words. ASQ-133 replaced the Litton ASQ-61 of the original A-6A and -6C, part of the DIANE

(Digital Inertial Aircraft Navigation Equipment) system. ASQ-61 was a 20-bit computer with 22 instructions.

Grumman proposed replacement of the ASQ-61 by a solid-state computer as early as 1967, and the navy funded development work at that time. However, the computer was not replaced until the shift to the A-6E. ASQ-61 used a rotating-magnetic-drum memory; Grumman proposed that the drum be replaced by an IBM solid-state core unit, and this interim improvement was made on aircraft reaching the fleet from June 1970 on.

◆ AYA-6

The tactical computer of the EA-6B is being replaced by AYK-14 in the ICAP-2 version. Memory is 1k of 70-bit ROM words and 8k (expandable to 16k) of RAM (32-bit words): 2700 words of navigation data, 3746 reserved for countermeasures data, and 1264 words for built-in test. AYA-6 is the computer and associated display electronics group produced by AIL, containing the IBM System/4 Pi computer.

◆ AYK-10 (Univac 1832)

Word Length: 32 bits

Memory Capacity: 64 kwords (expandable to 96k)

Speed: memory cycle, 0.75 microsec

Instruction Set: 133 I/O Channels: 18

The Sperry (UNISYS) AYK-10 is the central tactical computer of the S-3A, analogous to the ASQ-114 of the P-3C; it is also the central tactical computer of the Canadian CP-140. There are 2 independent central processors, 2 I/O controllers, and 2 I/O interfaces, all of them cross connected. Both processors have access to the entire memory, which is in 32k units (normally 2, with a growth option to 3). Each 32k unit contains two 16k memory banks. In addition, there is a magnetic drum for mass memory, separated into 2 halves (1 fed by each I/O interface). Each of the 2 I/O interfaces has 6 Type I channels, 4 Type II, 1 Type III, and 1 spare. Type I channels are multiplexed (up to 7 devices/channel). Devices include the sensor operator inputs, the FLIR, ESM data, and navigational data. Type II channels communicate with the tactical display system (4/interface, or 8/computer). Type III channels communicate with the mass (drum) memory. One of the Type I channels is reserved for growth; the spare is presumably also a Type I channel. Another Type I channel is reserved for test purposes. The 18 channels listed above presumably omit these and the drum memory channels.

The drum memory functions both as auxiliary storage for the computer and as the memory of the S-3A's acoustic-data processor. A portion of this memory stores most of the operational subprograms used by the AYK-10. An S-3A also has a 7-track digital magnetic tape recorder, connected to a Type I channel. The computer runs 21 concurrent programs, as well as 4 displays; it uses a 1553B data bus.

Total weight is 410 lb, with a power consumption of 2.3 kW.

In the S-3A, the tactical system includes an OL-82 acoustic processor. An AYK-10A version was developed for the S-3B, which uses the UYS-1 acoustic processor in place of the earlier OL-82 integrated with the AYK-10 in the S-3A. A proposed AYK-10B would have had 256k of main memory and a magnetic bubble mass memory.

AYK-10 is the Univac 1832. The prototype was delivered in 1971. It was the first Univac computer to use medium-scale integration; it was also the first large-scale use of a patented Univac mated film memory, intended to replace the earlier ferrite cores. The metal of the memory was deposited on glass substrates, and UNISYS (then Sperry) claimed that it permitted extremely fast operation (over 2 MIPS); when AYK-10 was announced, it was described as twice as fast as existing machines.

◆ AYK-14

Word Length: 16 bits (can operate on 4-, 8-, 16-, 32-bit data)

Memory Capacity: 4 Mwords in 32-kword (semiconductor) or 64-kword (core) modules

Speed: typically, 300 KIPS–2.3 MIPS; add/subtract time, 0.6 microsec; multiply time, 1.9 microsec; divide time, 3.9 microsec; clock rate, 1 MHz

Instructions: 307 I/O: up to 16 modules (see below)

AYK-14 is the current standard aircraft computer (in the AV-8B, F/A-18, E-2C, EA-6B, P-3C, and SH-6B); about 5000 are in the fleet. Versions are also used in weapons such as the Mk 50 torpedo. Control Data was the original manufacturer (AYK-14 was developed from that company's 480 microcomputer). It entered series production in 1980. Reliability has improved from an MTBF of about 200 hr in 1981 to above 1500 in 1989, and cost has fallen about 8.2%/year, from \$185,000 in 1981 to \$80,000 in 1989. UNISYS is now the second-source producer.

The AYK-14 was designed to be functionally and physically partitioned into replaceable modules so that it could be upgraded. In 1987 Control Data received a contract for a pre-planned product-improved (P3I) version, and deliveries began that year. In this version 3 of the cardlike processor modules are replaced by a single module with twice the processing power and 8 times the memory (using 0.5M- and 4M-memory modules). The single-card processor incorporates both a 16-bit central processor and a 32-bit math coprocessor, the EAU (extended arithmetic unit). There is also a cache memory, and the card has an extended instruction set. This version is used in the F-14D, V-22, Mk 50 torpedo, and new-production F/A-18, EA-6B, and SH-60B aircraft.

Data above refer to this P3I version. The P3I version is the one currently manufactured by UNISYS.

Control Data has also been developing a VHSIC processor module (VPM) for the AYK-14 since 1986. This plug-in module quadruples the processing power of the P3I version and also substantially increases memory. It incorporates a 64k cache memory. Reliability should also be greatly improved; expected MTBF is about 9000 hr. The first experimental VPM was delivered in September 1989, and production deliveries are to begin in 1991. Ultimately, VPM will be inserted in most fleet P3I AYK-14s.

AYK-14 addresses its 4 Mwords by paging, using 16-bit addresses on pages to refer to 19- or 22-bit physical addresses in memory, the choice depending on the chassis type. Physically, the computer uses 2 memory buses, even (EMEMBUS) and odd (OMEMBUS), for efficient overlapping memory access; they are controlled by a memory-control module interface.

A standard AYK-14 can accommodate up to 16 I/O modules, up to 5 of them smart modules incorporating their own on-board controllers, to execute chain programs and initiate data transfers using DMA. The other (standard) modules require the central processor to intervene to move data in and out. An AYK-14 expansion chassis can provide additional I/O bus ports.

The Computing Devices Co., Ltd., of England produces an AYK-14 derivative designated ACCS 2000 (airborne computing-and-communications system), which is the mission computer of the RAF Harrier GR 5. Deliveries of an enhanced version, ACCS 2500, began in 1989.

AYK-14 was the first truly standardized U.S. Navy airborne computer, all previous machines having been purchased as part of a total aircraft systems package. Development began in 1976, initially for the F/A-18 and LAMPS programs; the specification required that AYK-14 be able to emulate the UYK-20 instruction set, so that programs written for the latter could be used by the former. The AYK-14 instruction set includes that of the earlier machine.

◆ CP-642B

Word Length: 30 bits (can operate in 15-bit half words)

Memory Capacity: 32 kwords (ferrite cores)

Speed: memory cycle time, 4 microsec; typical execution time, 8–12 microsec; time to add and store (fixed point), 24 microsec; time to multiply and store (fixed point), 56–72 microsec; time to divide and store (fixed point), 80 microsec

Instructions: 62

I/O Channels: 4, 8, 12, or 16 rapid channels; can have NTDS interface

CP-642B was the central computer used in the original NTDS installations, part of the larger USQ-20 system. The initial version, CP-642A, had a memory cycle time of 8 microsec, and a typical instruction-execution time was 13 microsec. There were 12 input and 12 output channels for external equipment, plus 2 input and 2 output channels for intercomputer communication. In addition to the main memory, there was an auxiliary 16-word memory to store critical instructions and constants for automatic recovery in the event of program failure (crash). CP-642B (1962) introduced the use of control memory (32-word read-only magnetic thin film with a faster cycle time, 2 or 3 microsec), and a –3-volt I/O interface. These features increased data transfer rates to 125 kwords/sec/channel.

Dimensions were 72 in high × 38 in wide × 37 in deep (2400 lb). The components were mounted on 13 roll-out chassis (the more massive predecessors of circuit boards): 8 for logic I/O and arithmetic, 5 for memory.

Design work on the original CP-642 began in 1958, and it entered service in 1961.

NTDS programs for CP-642 were written on an earlier machine, USQ-17 (1955), a 32-kword (30-bit word, 20 microsec average execution time) machine that was probably the first U.S. Navy solid-state computer. Six were built (at least 1 is still in service).

◆ CP-789 (Univac 1218)

Word Length: 18 bits

Memory Capacity: 4, 8, 16, or 32 kwords (2 bay for 16k, 3 bay for 32k)

Speed: cycle time, 4 microsec

Instructions: 96 I/O: 4 or 8 channels

CP-789 is a component of some cruiser NTDS systems, including those upgraded via the New Threat Upgrade (NTU) program. It has 32 words of ROM for starting (bootstrap memory). Clock rate is 1024 Hz.

This computer was designed in 1962 as a military version of the 18-bit Control Unit Tester (CUT). It was an 18-bit spin-off of the CP-642B and was the predecessor of the 16-bit machines. CP-642B could compute in 6-bit slices, which were, in effect, its bytes; in these terms CP-789 was a 3-byte machine (the computer industry had not yet standardized on an 8-bit byte). Univac 1219B was the next-generation 18-bit computer (see Mk 152, below).

U.S. Minuteman missile sites used a double-word version of this computer (1218) as a weapons-system controller about 1969. At that time the specified MTBF was 10,000 hr, but this has been exceeded by several orders of magnitude.

◆ Mk 152 and CP-848/UYK (Univac 1219B)

Word Length: 18 bits

Memory Capacity: 8, 16, 32, or 64 kwords

Speed: 1.8 microsec typical execution time; clock rate, 1024 Hz

I/O: 4, 8, 12, or 16 channels

CP-848 is a second-generation 18-bit computer. Compared to CP-789, CP-848 has faster memory and a core buffer (500 nanosec) to speed I/O. Circuitry is more compact, so memory capacity increases within a 26-in cabinet (2 bays), and I/O capacity within a 3-bay cabinet (38 in wide). I/O modes are (Univac) 1218 normal, 1218 NTDS, and 1219B. This computer was an early application of preassembled circuit boards, what might be called very small scale integration (the individual devices are quite visible).

Mk 152 was the U.S. naval ordnance designation for this machine; it was the first U.S. standardized digital fire-control computer. In this form it has 16 I/O channels plus a slow interface. Memory capacity is 32 kwords, plus a separate 256-word control memory. Mod 0 (1966) weighed 1370 lb (dimensions: 72 in high × 38 in wide × 30.5 in deep). It was used in a digital Talos fire control system (Mk 77 Mod 3). Mod 1 (1966) had 8 I/O channels (1070 lb). Mod 2 (1400 lb, 1968) was similar to Mod 0 but had 8 fast and 8 slow I/O channels, with 2 paper tapes bootstrapped to channel 13, and modified input on channels 11 and 17. Mem

memory access time was 2 microsec. It was part of Fire-Control System Mk 86. Mod 3 (1370 lb, 1969) for the cruiser *Long Beach* (Talos fire-control system Mk 77 Mod 4) had a 40k memory. It was otherwise similar to Mod 0. Mod 5, for digital Tartar (fire-control system Mk 74 Mod 8, 1100 lb, 1972) had a 48k memory and was otherwise similar to Mod 1. Mod 6, for later versions of the Tartar (Mk 74) system and for shore sites, was a Mod 5 with 16 I/O channels (1460 lb). Mod 7 was a modified Mod 5 with a 64k memory for fire-control system Mk 74 Mod 8 (1050 lb, 1980). It added 4 memory stacks and the associated printed cards. In several cases, more capable versions of systems employing Mk 152 computers have UYK-20s instead.

◆ CP-855/UYK (Univac 1230)

Word Length: 30 bits **Memory Capacity:** 32 kwords (ferrite cores)
Speed: memory cycle time, 2.0 microsec; add/subtract time, 2–4 microsec; multiply time, 8 microsec; divide time, 14 microsec; clock rate, 1024 Hz
Instructions: 78 **I/O Channels:** 16

CP-855 was designed as a successor to the CP-642 series, as a second-generation 30-bit computer. Originally designed for NASA (for the Apollo program), CP-855 was not used in the U.S. NTDS system, but it was used in the French equivalent, *Senit III* (on board the frigate *Aconit*).

The 32k memory operates as 2 parallel 16k memories, and there is a separate 128-word control memory (expandable to 256 words). There is also 80k of mass storage. Two memory banks, operating in parallel, allow 2 simultaneous references for I/O, instruction extraction, or operand processing during 1 cycle. This architecture later appeared in UYK-7 and its successor, UYK-43. Special registers permit expansion of memory to 128 kwords, for use with the Univac 1503 expanded memory unit (EMU) and the hardware floating-point option. Typically, an EMU would be connected to a pair of 1230 computers, providing each with 2 or 3 banks of additional memory (16k per bank) and up to 4 I/O channels.

Compared to CP-642B, CP-855 has a larger instruction set, including 15 logical instructions and a hardware square-root instruction. The control memory includes seven 15-bit (17-bit in expanded mode) index registers (CP-642B had seven 15-bit registers). There is a 64-word ROM plus a 128-word fast (0.4 microsec magnetic thin film) control memory. Dimensions: 72 in high × 38 in wide × 37 in deep, 2200 lb).

◆ CP-890/UYK

Word Length: 32 bits (30 data, 2 parity)
Memory Capacity: 32 kwords in 2 banks (cores) expandable to 262 kwords using external chassis (18-bit rather than 15-bit addresses)
Speed: memory cycle, 1.8 microsec; clock rate, 1024 Hz
Instructions: 105, including 27 executive
I/O: 12 or 16 (half fast, half slow)

CP-890 was built specifically for the navigational system (which feeds the strategic-missile fire-control system) of Polaris and then Poseidon submarines. It has also been adopted for British Polaris submarines. The main design limitation was that it had to be able to pass through a 25-in hatch; it was, therefore, built in 3 hinged sections. Aside from high precision (for very accurate navigation), it had to be extremely reliable and was probably the most reliable U.S. Navy computer until quite recently.

CP-890 was the last of the Univac 30-bit computers, ending the series begun with USQ-17 and CP-642. It immediately preceded UYK-7. Architecturally it was almost identical to UYK-7 but was designed for slower speed. However, in practice it was faster, since memory cycle was actually 1.6 microsec, and UYK-7 cycle time was not faster than 1.7 microsec (vs. 1.5 designed). CP-890 used the earliest 3-wire ferrite cores, which are now standard. CP-890 was also the first militarized floating-point computer, the first with I/O memory (64 bits, in the form of chips, in 4 × 16-bit cells). The project began about May 1966, and the first was delivered in 1968; CP-890 remained in production until 1983 or 1984.

Trident submarines use a new 32-bit memory processor with a CP-890 instruction-set architecture. In these ships, much pre-processing was moved back from distributed system elements to the central navigational computer because the latter proved the most reliable element of the overall system. The current standard U.S. air-traffic-control computer (ARTS III) is a modified CP-890 and is still in production.

◆ CP-901/ASQ-114 (Univac 1830A)/Univac 1830B

Word Length: 30 bits
Memory Capacity: up to 64 kwords in 16-kword banks; can address up to 128 kwords; 512-word bootstrap (start-up) memory
Speed: 2-microsec cycle time without overlap; 1-microsec memory cycle with overlap; clock rate, 1024 Hz; typical performance, about 275–300 KOPS
Instructions: 70 basic **I/O:** 4, 8, 12, or 16 channels

The UNISYS tactical computer for the P-3C has been in service since 1968. It performs a function analogous to that of the central computer in a shipboard NTDS system. CP-901 is not the aircraft sonar-signal processor but maintains the current tactical picture, integrating data from the various sensor stations.

The mass memory media are a magnetic drum and a digital magnetic tape set, the latter to retain data for postmission analysis. ASQ-114 is connected to the aircraft sensors by the GE AYA-8 data-analysis programming group.

CP-901(V)6 is a modernized CP-901 developed in 1988, with an extended memory unit (64k increased to 4 Mwords of CMOS and bubble memory) and 16 I/O channels. I/O address capability is increased from 32 to 128 kwords.

The UNISYS designation for CP-901 is Univac 1830A. Univac 1830B (1970) is the main computer of the German AGIS fast attack boat command/control system. Compared to CP-901, 1830B can accommodate up to 8 memory modules (total 128 kwords). It has increased power-supply capability, optional I/O control memory (48 words), and nonbussed output channels. There are 76 basic instructions, and the clock rate is 102.4 kHz. Addresses beyond 32k are written in page mode. This computer was adopted by the U.S. Navy for the hydrofoil *Pegasus* since the ship was intended as the first of a NATO series using the German command/control system. Reportedly, it is designated CP-901B in U.S. service (although CP-901A, described below, is a very different and much later computer). The other 5 *Pegasus*-class ships have UYK-44s.

CP-901 was developed in parallel with CP-890 and can be considered an avionics version of the -890 architecture without the floating-point feature. It has a very similar memory but a less extensive instruction set. Performance is broadly equivalent to that of the Univac 1230 (CP-855) adopted by the French Navy. This and the other 30-bit computers were abandoned in favor of 16/32-bit machines because 32 bits became the commercial standard.

◆ CP-901A

Word Length: 32 bits **Memory Capacity:** 1 Mword (see below)
Speed: 9 MIPS throughput **Instructions:** 68030 set
I/O Channels: 34 (see below)

In October 1989 UNISYS received a contract to design and produce a new version of the CP-901 computer, with improved throughput but with greatly reduced overall size, weight, and power requirements, for P-3C aircraft. A contract for a memory upgrade had already been awarded. The new version will use ADA software, but it also has a CMS-2 compiler for compatibility with existing software. Presumably, CP-901A is part of the planned modernization of existing P-3s (not Update IV).

The new version is an entirely new machine within the same space, weight, and power requirements of the earlier CP-901. -901A uses a dual memory bus like that of other current UNISYS naval computers. Instead of a single central processor, it has 3 Motorola 68030 microprocessors (with card slots for 4 more). Throughput can be increased to 12 MIPS by using the 4 additional microprocessors.

Each of the 3 microprocessors has a local memory of 256 kwords, which can be increased to 1 Mword/processor. The 1 Mword listed above is the global memory available to all 3 processors. All of these are volatile memories (CMOS); there is also a 3-Mword bubble memory for fast mass storage. In addition, each microprocessor has 32 kbytes of bootstrap and diagnostic memory (EEPROM); UNISYS has proposed replacement of this memory by 32 kwords (128 kbytes) of UVPRM. The total global memory (1 Mword CMOS and 3 Mwords of bubble mass memory) can be doubled within the cabinet dimensions.

The I/O channels are two 1553B buses, 4 ARINC 575 serial channels, 10 synchro-to-digital channels, 4 digital-to-synchro channels, 10 A-NEW channels (MIL-STD-1397C), and 4 stroke-display (i.e., cursive video) channels; there are also 3 manual-entry-system (keyboard) interface cards. Growth options are 1 video input channel and 4 color, raster, display channels.

CP-901A incorporates the functions of the AYA-8 logic units and the CV-216 signal data converter, previously separate equipment, in its cabinet. The cabinet is 52 × 13.5 × 17.7 in and weighs about 380 lb; it uses 6 × 9-in printed circuit cards.

◆ CP-1469 (ASPRO)

This Goodyear (now Loral) Associative Parallel Processor was designed for the Grumman E-2C. Production began in 1980, the first prototype was delivered to Grumman in mid-1982, and as of 1989 a total of 46 had been manufactured. In June 1989 Loral was awarded a contract for 10 to support OTH-T by nuclear attack submarines. ASPRO achieves a throughput of 110 MOPS in the space occupied by a 1-MOPS UYK-44.

ASPRO was derived from a series of Goodyear computers embodying a patented multidimensional access memory. Development led to the announcement in 1972 of STARAN, the first commercially available parallel-processing computer. This work derived from a series of studies requiring high-speed searches of existing data files. Goodyear's approach was to associate incoming data with data already on file, and this association or correlation could be done most rapidly using a parallel processor. In 1979 a later version of STARAN was demonstrated as the most efficient means of upgrading the E-2C tactical data system.

ASPRO is designed to handle more than 4000 computations simultaneously, for functions such as track-to-track correlations. It can perform arithmetic operations, such as coordinate transformations or dead reckoning, on numerous tracks simultaneously.

ASPRO is conceived as an add-on to a larger host computer. In a volume of 0.44 ft³ (8 × 10 × 9.5 in, 37 lb), ASPRO contains 1792 processors with 896 kwords of associative storage. Program memory is 32 kwords (32-bit words) with a read/write rate of 5 Mbytes/sec. No net processing rate is available, but the associative processor multiplies two 16-bit words in 108.5 nanosec (0.1085 microsec; 194.5 nanosec for the 1792 items in parallel). The power requirement is 200 W.

◆ MIL-STD-1750

MIL-STD-1750 is a standardized requirement for future air force 16-bit microcomputers; presumably, it will become a triservice standard. Some 1750A computers are to be incorporated in the new A-12 attack bomber (see separate entry on A-12 computer). The standard defines an instruction-set architecture with about 100 instructions, suitable for single-, double-, and triple-precision calculation. The standard machine has 64 kwords of memory. A revised MIL-STD-1750A, defined in 1982, envisages a standard triplex bus (backplane), 1 of whose lines is used for built-in test. The other 2 are a Pi-Bus and an IEEE 488 bus. A typical computer would employ a standard processor, a volatile bulk-memory module, a nonvolatile (mass storage) bulk-memory module, an interface module for a 1553B data bus, a fast data (50 Mbit/sec) dual-redundant bus module (to connect to a fiber-optic bus), and a timing and discrete-switch module. Typical processor performance is 3 MIPS, with 512 kwords of local memory. The volatile memory module has expandable storage

of up to 5 mwords per module; nonvolatile storage (EEPROM) is in modules of 1.5 Mwords. Each bus interface module has its own microprocessor plus 256k of buffer memory.

As in the case of the navy NGCR, the objective is to be able to buy any of a wide variety of commercial machines. Development began in 1976, on the basis of Strawman, an early approach to what became the ADA computer language. The MIL-STD-1750 standard was released to industry on 21 February 1979; the figures above apply to current UNISYS machines intended to meet MIL-STD-1750A. No single manufacturer dominates the 1750A market (UNISYS has about 3% of it); at one time Delco made 21 different 1750A processors. Commonality is limited to dimensions and to the instruction-set architecture.

An attempt to define a 32-bit MIL-STD-1750B failed because the main chip manufacturers, Intel and Motorola, saw little point in encouraging competition. 1750B was, therefore, 1750A with minor changes.

◆ OL-77/ASQ

OL-77 is the central tactical computer of the E-2C, a double version of the Litton L-304 (see below). It is to be replaced by a new high-speed processor, but no choice had been made as of early 1990, and the replacement program had not yet been funded. See also the discussion of the E-2C tactical data system (ATDS) later in this chapter.

◆ USQ-20

USQ-20 was the computer system of the early version of NTDS, including the CP-642 computer described above, plus a separate control console (C-3413) and mass storage in the form of tape drives. System software, the Dynamic Module Replacement (DMR) program, allows the system operator to insert or delete particular program modules into the running operational program. For example, an ECM module can be inserted when needed, then deleted to leave more memory space, without stopping the system. USQ-20 is a modular system in which individual CP-642s can be run in parallel for increased total processing power.

◆ USQ-69B

This UNISYS device is an intelligent version of the USQ-69 data-link terminal, incorporating an 80386 chip with an 80387 coprocessor; it can accommodate up to 40 Mbytes of DRAM memory and a 3.5-in high-density disk. USQ-69B uses the MS-DOS language and can function as a stand-alone computer. Alternatively, it can be installed as a modification to an existing USQ-69, fitting into the latter's logic drawer. The marines plan to connect 12 on an LAN on board an LHD for troop-location planning. Preproduction deliveries began in June 1990, and production deliveries are scheduled for March 1991.

◆ UYK-7

Word Length: 32 bits (can do double-precision arithmetic)

Memory Capacity: 262 kwords (ferrite cores)

Speed: memory cycle, 1.5 microsec; add/subtract time, 1.5 microsec; multiply time, 10.0 microsec; divide time, 17.0 microsec; clock rate, 1024 Hz

Instructions: 130

This UNISYS computer replaced USQ-20B in the NTDS system. UYK-7 was originally conceived for 3 programs: Aegis, the *Spruance*-class destroyer, and the *Los Angeles*-class submarine. The current standard U.S. Navy central computer, UYK-7 is being replaced by UYK-43. UYK-7 can operate either as a single or as a multiple processor. The single-cabinet version has a capacity of 48 kwords of memory and up to 16 I/O channels. Up to thirteen 16-kword modules can be added. Such additions are described as multibay configurations (1-, 2-, 3-, or 4-bay) UYK-7(V) is an upgraded version.

UYK-7 has two unusual features. The main memory can be read as several parallel memories, for faster processing (speed is increased by a factor of 2 in the single-processor version, and by a factor of up to 8 when several processors are used together).

UYK-7 has a bus connecting the memory modules, and up to 3 central processors can be connected to the same bus.

The standard UYK-7 cabinet is 40.88 in high $\times$ 19.80 in wide $\times$ 22.34 in deep (excluding handles); total weight is 527 lb, including the cooling blower.

UYK-7 was developed in 1969.

◆ UYK-15 (Univac 1616)

Word Length: 16 bits

Memory Capacity: 8–64 kwords in 8k increments

Speed: add, 0.750 microsec; multiply, 3.75 microsec; divide, 3.75 microsec

Instructions: 64

I/O: 16 parallel channels; or 8 parallel and 8 serial; or 4 parallel and 16 serial channels

This is the UNISYS computer of the SPS-52 through -52B radars; SPS-52C has a UYK-20 instead. The memory banks (increments) are independently addressable. Dimensions: 14.4 in high $\times$ 20.75 in wide $\times$ 25.75 in deep (approx 170 lbs). UYK-15 appeared about 1970. UYK-15 was unusual in using a very large number of registers (256) but a small number of separate instructions (as in the later RISC computers). There was no separate accumulator for arithmetic results; instead, all computation was conducted from register to register, and the large number of registers could accommodate numerous parameters.

UYK-15 is a ruggedized version of the Univac 1616. Customers included air force intelligence programs. Performance (about 500 KOPS) was roughly equivalent to that of the contemporary VAX 11/780 (which never ran at its rated speed of 3 MIPS). This computer was totally interrupt-driven to cue its program, and was also adapted to a high I/O rate (it was conceived as a front end for mainframes such as the UYK-7). Work on this machine led directly to the development of UYK-20. The architecture is different: UYK-15 has an independent I/O controller and a time-sliced memory, whereas UYK-20 uses an emulator in its processor for handling I/O. Hence, to maintain the same throughput, 2 UYK-20s are equivalent to 1 UYK-15.

UYK-15M was conceived for the integrated radio room of Trident submarines. Because of the I/O limitation, the 2 UYK-15s originally planned were replaced by 4 UYK-20s.

◆ UYK-19

Word Length: 16 bits

Memory Capacity: up to 128 kwords (32k modules); 512-kbyte read-only memory

Speed: clock rate, 20 MHz; memory cycle time, 2 microsec; add time, 1 microsec; floating-point add time, 4.6–10.1 microsec; floating-point divide time, 20.95–29.95 microsec

Instructions: 101

I/O: up to 7; transfer rate, up to 1.32 Mbytes/sec

This Rolm computer competes with UYK-20. UYK-19 is used mainly in electronic-warfare systems; it beat out the UYK-20 for application to both the SLQ-32 ESM system and also the Tomahawk missile targeting system. UYK-19 is also the standard computer of the Hughes Modular Combat System (H930) and drives displays of the Tactical Flag Command Center. The processor of the USQ-81 display (which was part of the Outlaw Shark and Outlaw Hawk predecessors of TFCC) is an enlarged UYK-19.

UYK-19 is a militarized version of the Data General NOVA computer and first appeared about 1974. There are 5 versions, which Rolm designates 5605, 1603A, 1650, 1602B, and 1666B; the last is also designated UYK-64 and uses an expanded instruction set. Data above refer to Model 1602B. Hughes is currently testing a Model 1666 as an upgrade to its Modular Combat System; details of this computer are given below. See also UYK-64 (Rolm 1666B), which is intended as the UYK-19 successor, in analogy to UYK-44, the UYK-20 successor.

See UYK-64, below.

◆ UYK-20

Word Length: 16-bit words (can operate on 4- and 8-bit subwords)

Memory Capacity: UYK-20: 8–64 kwords; UYK-20A: 32–262 kwords (32k increments) (ferrite cores)

Speed: memory cycle time, 0.75 microsec; add time, 0.84 microsec; multiply time, 3.6 microsec; divide time, 6.6 microsec

Instructions: 283 I/O Channels: 16

UNISYS introduced this minicomputer in 1974; the development contract was awarded in March 1973. As built, UYK-20 outperformed the original version of UYK-7. The processor was of MSI (medium-scale integration) design. UYK-20A is a more powerful version, capable of addressing a larger memory. Typical dimensions are 20 in high $\times$ 19 in wide $\times$ 24 in deep (230 lb). UYK-20 is also supplied as a set of 6 $\times$ 2-in SEM-B cards, which can be embedded in another system.

In 1984 MTBF was reported as 2000 hr.

UYK-20 was the first of the series of 16-bit standard naval computers, which now includes UYK-44 and AYK-14.

◆ UYK-43

Word Length: 32 bits (can do half word and double-precision arithmetic)

Memory Capacity: 4 Gwords (see below)

Speed: throughput, 2.25 MIPS; cycle time, 150 nanosec; add time, 150 nanosec

Instructions: 258 I/O Channels: 64

The UNISYS UYK-43 replaces UYK-7 as the standard U.S. Navy shipboard mainframe computer. UYK-43 was designed to be compatible with the earlier machine, so that programs written for UYK-7s could be run on -43s with minimal modification. However, because UYK-43 is so much more powerful, programs written for it can add capability not practicable with the earlier machine. Applications include the Advanced Combat-Direction System (ACDS), which is replacing NTDS. UYK-43 uses VLSI technology. The German navy now uses the UYK-43 (in the new Type 123 frigate), and Taiwan will use it in the new *Perry*-class frigates.

UYK-43 is modular, produced in A and B versions (enclosures). The A enclosure (20 $\times$ 22 $\times$ 69 in, 950 lb) has a single central processor, 1 I/O controller (throughput 3 MIPS), and 5 memory modules and is about 4 times as powerful as a UYK-7. The B version (20 $\times$ 22 $\times$ 72 in, 1795 lb when water cooled, or 29 $\times$ 22 $\times$ 72 in, 1865 lb when air cooled) has 2 central processors, 2 I/O controllers, and 10 memory modules and is about 9 times as powerful as a UYK-7. The A enclosure is designed to pass through a 25-in-diameter submarine hatch; it has the same footprint as a UYK-7. Ferrite-core memory is 32 kwords; semiconductor memory is available in 64k, 128k, 256k, and 512k, 1M, and 2M word modules. The last was first offered in 1987 as a direct replacement for the 512k module. At least in the case of the 512k and larger modules, a battery backup within the module saves data for 30 min in the event of power failure. Module read/write time is 450 nanosec, and the modules are built out of 256k memory chips. Presumably, larger modules will soon be offered, using the newer 1M memory chips.

Although the addressing scheme of UYK-43 allows for up to 4 Gwords, the original central processor was limited to 2 Mbytes (512 kwords). UNISYS developed an Expanded Memory Reach (EMR) Central Processor, which expanded memory reach to 2 Gbytes (512 Mwords). This modification adds 52 instructions to the original instruction set, and extends 8 of the existing instructions.

A UYK-43 can contain 2 central processors, 2 I/O controllers (throughput 3 MIPS each), and up to 10 memory modules. None of the existing memory modules allows the system to approach its theoretical capacity of 4 Gwords; the current maximum within the enclosure is 20 Mwords.

The multiple processors and I/O controllers can, in theory, try to access the same memory module simultaneously. This problem becomes serious as processor execution times drop below the memory bus cycle time, since then the memory cycle becomes the limiting factor in computer speed. UNISYS offers a high bandwidth memory (HBM) to overcome this problem. HBM employs eight 1-Mword memory blocks, each separately addressable; total memory is split into 2 groups of 4 blocks each,

each with its own scheduler. Scheduler rotation time is 0.3 microsec, but each scheduler has access to 4 separate blocks, so overall effective request time is 0.0375 microsec (as long as no 2 devices try to access the same word or the same subblock). In addition, HBM reads from (or writes to) the memory in 4-word bursts. Such bursts require 5 memory bus cycles (1 address, 4 data) rather than the current 8, for a 58% improvement in speed. The bursts write into the cache memory of the central processor. Overall memory performance is improved by a factor of up to 12.

UNISYS claims that UYK-43 is the most reliable military computer yet developed, with an MTBF of 56,000 hr. The original requirement was for a 6000-hr MTBF (MTTR of 15 min).

Sperry (UNISYS) and IBM were awarded competitive contracts for UYK-43 prototypes in December 1980. Engineering development models were delivered in March 1983, and Sperry was chosen in May 1983. Deliveries began in December 1983. Control Data was chosen as second-source producer in 1988 and will compete for 1990 production.

A preplanned product-improvement program added a 32k cache memory (16k instructions, 16k data) and 1024k and 2048k semiconductor memory units. The central processor was modified so that it could address more memory.

Typical applications:

	UYK-43	UYK-44
Aegis cruiser	6	23
Trident SSBN	2	4 or 5
Los Angeles	2	5 or 6

A UYK-43/44 upgrade program was begun in December 1988. It had been delayed in 1987-88 by Congress, pending completion of the NGCR (1996 computer) plan (see below), the fear being that the upgrade would preclude development of a new generation of machines. Plug-in upgrades will be phased in during 1990-94. UYK-43 will get an enhanced central processor (4-6 times more speed), a math coprocessor, and additional memory improvements (new standard mass-memory storage, i.e., a small disk drive). There will also be software upgrades. The coprocessor in UYK-43 was originally provided to improve self-noise monitoring in Trident submarines.

The math coprocessor (Time-Critical Subfunction Coprocessor, or TCS) carries a multifunction processor (MFP) and a vector processor (VP), plus independent memory, use of which does not conflict with the use of the main UYK-43 memory. The 2 processors are connected to the memory and to an interface adapter by a local bus. The MFP consists of a Motorola 68030 microprocessor, a Motorola 68882 floating-point coprocessor, cache memory, EEPROM, and the associated memory interface. Calculations are done in single (32-bit) or double (64-bit) precision, at 0.5 Mflops. The vector processor consists of an AT&T WEDSP32C digital signal processor and 1.5 kbytes of local memory. It can operate at up to 25 Mflops (sustained rate, 5 Mflops) and is under the control of the MFP, operating in parallel with it. TCS carries its own 8-Mbyte memory (expandable to 16 Mbytes). TCS is intended specifically for operations such as FFTs; up to 4 can be installed in a UYK-43 B enclosure. The standard form is 3 printed circuit assemblies: 1 for the processor, 1 for memory, and 1 for the interface adapter. A higher-performance version consists of 4: 2 memories and 2 processors.

◆ UYK-44

Word Length: 16 bits

Memory Capacity: 256 kwords (core); 4 Mwords (semiconductor memory)

Speed: throughput, up to 0.94 MIPS **I/O Channels:** 16

UNISYS' UYK-44 is the current standard U.S. Navy minicomputer (i.e., 16-bit computer). It will replace UYK-20. In addition to stand-alone functions, UYK-44 is embedded in other devices, such as the UYQ-34 multimode display and the SQS-53 and SQQ-32 sonars, as the Militarized Reconfigurable Processor (MRP) and the Militarized Reconfigurable Computer (MRC).

The MRP is designated OL-335(V) Data-Processing Group. The UYK-44 instruction set matches that of the AYK-14 airborne computer, which UYK-44 may ultimately replace. Actual word length, including check bits, is 22 bits.

Three alternative semiconductor memories can each be accommodated on a standard electronic module (SEM) card: 8 × 64k (512k), 8 × 256k (2M), or 4 × 1M (system maximum). Greater capacity means slower operation: the 64k SEM has a cycle time of 120 nanosec; the 256k, 250 nanosec; and the 1M, 350 nanosec. With the 64k SEM, the processor limits overall speed to about 0.930 MIPS; the 256k version runs at 0.934 MIPS, but the 1M version runs at 0.894 MIPS.

The original central processor directly addresses up to 64 kwords of memory. It uses 4 sets of 64 (256) -page registers (1 kword each) to address further memory via an executive mode program. Thus the maximum addressable memory is 256 kwords.

UNISYS offers an Expanded Memory Reach (EMR) version of UYK-44, which doubles the direct addressing ability of the computer by differentiating between instruction and data addresses. Using EMR, the computer can address 256 groups each of 64 code (instruction) pages plus 256 groups each of 64 data pages; each page consists of up to 1 kword. This is a total of 32 kpages (32 Mwords), 16 Mwords of data, and 16 Mwords of instructions. Four of the 64 data-page groups are reserved for I/O, so that I/O page address registers can be manipulated independently of central-processor page address registers.

EMR is standard in embedded versions of UYK-44 delivered after August 1989. The change requires 20 new instructions.

UNISYS won the UYK-44 contract in competition with IBM. Both companies received prototype contracts in September 1980, and UNISYS (then Sperry) won the contest in March 1983. Several Allied navies, including the Japanese, now use UYK-44. Raytheon, GE, and Microlithics have all qualified as second sources for the SEMs out of which the UYK-44 is built.

UNISYS claims that MTBF is 13,000 hr.

An upgrade program began in December 1988. UYK-44 will be fitted with an enhanced processor with 5-6 times greater processing speed, plus memory improvements. The improved processor meets requirements of the SQQ-89 program.

As of November 1988 UNISYS was offering a UYK-44EP (Enhanced Performance), which is probably the upgraded UYK-44. UYK-44EP can operate in either 16- or 32-bit mode and can address 8 Mbytes of memory (configured in words of either length). Using a page addressing scheme, it can address up to 32 Mbytes. The existing 9 UYK-44 processor cards are replaced by 2 UYK-44EP cards, and there is a new instruction set, by means of which the machine can emulate the UYK-20A, UYK-502, AYK-14, and UYK-44. The processor cards carry 64 kbytes of cache memory, as well as 32 kbytes of UVPRM (read-only memory, which can be reprogrammed when scanned with ultraviolet light) for its microcode. Speed is 5 MIPS.

◆ UYK-64(V)/Rolm 1666B/MSE/14

Word Length: 16 bits

Memory Capacity: core: 128 kbytes internal/1920 kbytes external; semiconductor: 2048 kbytes internal (1024 kwords)

Speed: memory access time, 0.4 microsec internal, 0.7 microsec external; core cycle time, 1 microsec internal, 1.1 microsec external; effective memory cycle time (4-way interleaved), 0.1 microsec (1 microsec core); semiconductor cycle time, 0.4 microsec; add time, 0.2 microsec (1.0 core); multiply, 4.4-7.4 microsec; divide, 4.4-7.4 microsec; floating-point divide, 5.0 microsec (9.8 in double precision); typical single-precision throughput, 0.441 MOPS (core 0.268 MOPS)

Instructions: 230

I/O: 59 addressable devices; I/O time: 1.25/0.25-Mbyte/sec core, 1.7/1.25-Mbyte/sec semiconductor

UYK-64 is in effect a second-generation UYK-19. Performance figures are given for 2 versions, 1 using ferrite-core memory and 1 using semiconductor memory of the type now common in small computers. The basic core version has 64 kbytes of internal memory, expandable to 128k; additional memory is con-

tained in external I/O devices or memory chassis. The semiconductor version is built up from 512-kbyte modules. Memory is allocated on the basis of 2-kbyte pages.

The 1666B is upward-compatible with existing UYK-19s, just as the UYK-44 is upward-compatible with UYK-20s. See below for details of the Rolm 1666, a related machine that has been used in TFCC and in the upgraded version of the Hughes Modular Combat System. The 1666B or UYK-64 can be upgraded to the Rolm MSE/14 by replacement of 1 CPU board and 1 optional FPU board.

Rolm offers a Micro 66 processor based on the 1666B instruction-set architecture and, therefore, is directly software compatible with the UYK-64 and upwardly compatible with the UYK-19. The module is the Rolm Model 1822 Micro. It can accommodate 64 kbytes of RAM on a single card, or up to 1984 kbytes (and 12 I/O slots) in a full ATR chassis (Rolm 1666C). Up to 2048 kbytes can be addressed. Memory is in 384k cards. The intermediate half-ATR chassis (Rolm 1866) accommodates up to 832 kbytes of RAM and 4 I/O slots (1 memory card can be replaced by an I/O slot, for 5 slots and 448 kbytes of memory). Estimated throughput rating is 1.5 MOPS (fixed-point). I/O is at rates up to 1.2 Mbytes/sec.

MSE/14 is directly software compatible with UYK-64 and the 1666 series. Model 1800 corresponds to Model 1866 above, and Model 7014 to the full Model 1666C described above. Typical execution times are add, 0.208 microsec; multiply, 0.917 microsec (with accelerator; 3.542 without); divide, 4.708 microsec; floating-point add, 8.125–11.834 microsec; floating-point multiply, 7.5 microsec (with accelerator; 19.384 without). Rolm claims a demonstrated MTBF of 15,000+ hr.

MSE/14 is offered with either a ferrite core (up to 128k) or semiconductor memory (up to 512k). Rolm also makes MSE/800, a 32-bit machine that competes with UYK-43.

◆ UYK-79 and R/VB-XXX-D

UYK-79 is a shipboard version of the Rugged Digital R/630B 32-bit MicroVAX computer, based on the Digital Equipment Corporation MicroVAX 3500. CPU performance is similar to that of the VAX 11/780. The company claims it costs $\frac{1}{3}$ – $\frac{1}{2}$ as much as standard U.S. Navy embedded computers. UYK-79 is being supplied to Sanders, UNISYS, and ESL for integration into 5 combat-support systems in carriers, battleships, *Wasp*-class amphibious ships, and *Spruance*- and *Arleigh Burke*-class destroyers; it is also being tested by the marines ashore. The chassis normally accommodates a MicroVAX II (1 MIPS) or MicroVAX III (3 MIPS) main processor and 16–64 Mbytes of memory. Its bus has 15 Q-Bus slots, configured for single or dual CPUs. Because UYK-79 uses standard commercial technology, it can accommodate numerous off-the-shelf commercial boards, including those that can link it to NTDS and to data links. It can accommodate four 5.25-in removable peripherals (disk or tape drives). Single disk capacity is 71–600 Mbytes; the slots can also accommodate single tape cartridges (95–295 Mbytes). Dimensions are 12.25 in high $\times$ 22 in deep $\times$ 19 in wide. Weight is 85–140 lb, depending on configuration.

R/VB-XXX-D is a new development of UYK-79 based on the IEEE 1014 VME architecture. It can accommodate four 5.25-in peripherals, which can be removable hard disks with a total of 1 Gbyte of mass storage. The related R/VS-XXX-D accommodates 18 VME-compatible cards.

The manufacturer, Rugged Digital Systems, Inc., was formed in August 1982 to develop, manufacture, and market military computer systems based on leading commercial architectures, to combine survivability with full software compatibility.

◆ UYS-1/2

See the ASW section. These are specialized signal processors.

◆ Next-Generation Computer Resources (NGCR)

For its next generation of computers, the navy has chosen to shift from a limited number of special designs to open standards that can be met by any number of functionally equivalent and

interchangeable modules. A data bus (backplane), an instruction-set architecture, and overall cabinet dimensions are specified, together with performance and interface standards. This approach is equivalent to that typified by the open architecture of the IBM PC: the user bought a box (a chassis) containing a data bus and could choose among many manufacturers' modules (cards) that could be inserted into the bus. IBM specified only the bus, the chassis dimensions, and the connection standards. In theory, this approach should make it much easier for the navy to exploit civilian hardware developments, though much depends upon whether the bus has sufficient capacity and sufficient similarity to civilian equipment. The new approach is also reminiscent of the French decision to purchase ruggedized civilian computers rather than specialized military types.

NGCR is intended for a family of machines to be bought from 1996 on, through the next 2 decades. Goals include the introduction of real-time parallel processing, artificial intelligence, fiber optics, and VHSIC technology, and the introduction of distributed operating systems (e.g., in combat direction). The NGCR project formally began in February 1988, and an operational requirement was established in August 1988. The lead command, the Space and Warfare Systems Command, announced in December 1988 that a commercially developed backplane called the "Futurebus" had been chosen; this choice in turn would allow the use of many commercial components. NGCR also uses the new SAFENET I LAN.

◆ BuOrd/NavOrd Computers

The Bureau of Ordnance and its successors gave computers Mark numbers; these devices are outside the normal AN series. Many are still in use, covering the entire range from electro-mechanical analog devices to digital machines. The analog computers were often limited to a single role (such as trigonometric computation to allow for roll and pitch) and also to specific ballistics (not merely for 1 weapon, but even for 1 type of shell). They often also required considerable weight to conduct what might now seem rather trivial computations. Stabilization computers took data from a gyroscope (which was, in effect, a system sensor) and converted it into stabilizing orders. True general-purpose computing came only with Mk 152. The number of distinct computers declined sharply with the introduction of general-purpose types (many fire-control systems use such standard machines as UYK-7 and UYK-20).

Many of the analog machines transmitted their data by synchro, i.e., by turning a dial to which a distant dial was synchronized, transmission between the 2 being electrical. For example, Computer Mk 112 Mod 2 transmitted fuze time orders in the form of 32 sec/revolution. When digital devices replaced the analog units, special synchro-drivers had to be interposed.

Dates indicated in the text are often the dates on which nomenclature was assigned. For an entirely new machine, that might be some time before development was completed. However, for a Mod, that date is probably about the time tests were completed.

The computer series *did not* include the separate Torpedo-Data Computers.

Mk 1 Electro-mechanical analog computer of the Mk 37 Gun Fire-Control System, the first such device to receive a special designation (about 1937). Mk 37 was the first U.S. secondary-battery fire-control device in which the above-decks director was separated from the associated computer. Earlier main-battery computers were designated range-keepers, and this practice persisted through World War II in the case of heavy-caliber fire-control systems. A Mk 1A version was included in the Mk 54 fire-control system installed in a few postwar cruisers. Total weight was 3200 lb (2900 lb in some versions). Available ballistics, in the Mk 37 system, were 8-in/55, 6-in/47, 5-in/54, and 5-in/38. Maximum computing range was 18,000 yd. Maximum speeds: 400 kt horizontally, 250 kt vertically. Mk 1 introduced fully automatic rate control to U.S. practice, and the Mk 37 fire-

control system was the first U.S. naval ordnance application of closed-loop servo practice (initially experiencing severe problems because its feedback made it unstable). Most U.S. ships used the Mk 1A version; Mk 1B was modified for British (Admiralty) use. Mk 1A (and gun fire-control system Mk 37) could generate orders for other calibers, feeding 5-in orders through a Mk 20 converter (1953) whose computing servos combined several Mk 1A outputs into offset differences between 5-in/38 and 3-in/50 trajectories.

Mk 42 Ballistic analog computer of the Mk 56 gun fire-control system. One computer was needed for each set of ballistics to be computed. It operated by a mechanical linkage of 5 mechanical inputs, 1 manual and the others by servo. The results were converted into electrical analog form by the rotation of potentiometers, for introduction into an electric computing network. The unit for primary ballistics weighed 640 lb; the secondary ballistics unit weighed 550 lb, the saving presumably being the result of avoiding duplication between the 2. Ballistics included fuze time computation. Available ballistics were 6-in/47, 5-in/54, 5-in/38, and 3-in/50. Computing range was 15,000 yd.

Mk 47 Electronic/electro-mechanical analog computer of the Mk 67 and 68 gun fire-control systems, successors to fire-control system Mk 37. Weight: 5400 lbs in Mod 3 version (about 1954), 6000 lbs in Mod 4 version for Mk 67 fire-control system. Ballistics were available for the 5-in/54, 5-in/38, 3-in/70, and 3-in/50, and computing range was 18,000 yd. The second set of ballistics (for 3-in/50 or 3-in/70 guns) was provided by a converter Mk 20. This computer had 2 mechanical and 1 electronic sections. Mod 5 was simplified and repackaged (weight was approximately halved). It entered service about 1958. Mod 7 (1961) extended the computing range to beyond 72,000 yd. Target elevation data were entered either by potentiometer (from a Mk 119 computer) or by synchros (from a Mk 100). Mod 8 (1961) had transistors in place of the electronic tubes of earlier versions, as well as new plug-in electronic units (for easier maintenance). This version was part of the Mk 68 Mod 4 fire-control system. Weight was 2450 lb. In this version, maximum target range was 35,000 yd, and maximum range for gun orders was 20,100 yd. CG 26 and later ships had Mod 9, similar to Mod 8 but modified to work with computer Mk 116 Mod 4. Mod 10 (1965) time-shares Horizontal Relative Target Bearing, Star Shell Gun-Train Order, Gun-Train Order, Gun-Elevation Order, and Star Shell-Elevation Order computations and so eliminates the need for a Mk 116 computer. It allowed for ballistics for a new reduced-charge 5-in/54 round. It was used in the Mk 68 Mod 13 fire-control systems of FF 1078-class ships. Mod 11 (1969) included ballistics for RAP shells. It was equivalent to ORDALT 6948 applied to the Mod 10.

Mk 60 Computer for Mk 15 Hedgehog; it calculates and transmits projector train order and indicates time to fire from inputs of target angle, speed, range, depth, and bearing. Firing orders can be corrected to allow for target maneuvers almost up to the moment of firing. Mk 60 weighed 205 lb (plus 350 lb for the associated amplifier).

Mk 93 Surface gun computer (prediction, ballistic computation, trunnion-tilt correction) to supplement small antiaircraft systems (such as fire-control systems Mk 56, 63, and 69). It handles only 1 set of ballistics at a time, but those can easily be changed (ca. 1951).

Mk 101 Analog (magnetic amplifier) fire-control computer for the F-8D/E Crusader (AWG-4 system), to control guns, rockets, and Sidewinder missiles. AWG-4 included a Mk 11 computing sight and was typical of preintegrated airborne fire controls. The pilot selects the commence-firing range before taking off. Because there is no HUD, the pilot cannot see radar data and must, therefore, rely on tones in the headphones: a transfer tone (to indicate that the system has switched from fixed ranging to radar ranging), an alert tone, and a breakaway tone. The alert tone (1200 Hz) indicates that the pilot is half a second from the

firing point; it continues to sound until the breakaway tone (alternating 400/1200 Hz) sounds half a second before the pilot must pull away from the target. Before taking off, the pilot selects transfer ranges of 0, 600, 900, 1200, 1500, and 1800 ft, and breakaway ranges of 1500, 1200, 900, and 600 ft. The sight unit provides a lead angle, the pilot comparing the image of the target and an image centered in the sight. The gyro is initially caged, the pilot in effect estimating the angular speed of the target and pointing the airplane sufficiently off center to lead it. The gyro is then uncaged; and if the lead angle has been correctly estimated, the gyro image will move onto the target. This operation tacitly assumes a fixed value for the preset open-fire range, and the radar tone is used to indicate that the preset range has been met. Typically, a pilot has to track smoothly for 1–4 sec to line up the gyro sufficiently.

The computer causes the sight unit to generate the lead angle for obtaining hits. It controls the sensitivity (kinematic lead) and elevation and azimuth offsets of the gyro. It solves for projectile time of flight (lead time), with additional small corrections related to sight dome temperature. Average shell speed is computed from air density, aircraft velocity (fixed for a given type of airplane at the most probable combat speed), and gun or rocket ballistics. The computer calculates range rate from radar range. It must also take into account such factors as aircraft acceleration and angle of attack.

Mk 101 was a standardized computer, and different airplanes (and, for that matter, different weapons) used it with different adapter computers (not in the main computer series). Mk 101 differed from some previous aircraft fire-control computers in using direct rather than alternating currents; it worked in logarithmic terms largely using a summing or subtracting magnetic amplifier (numbers were converted into logarithmic form by passing currents proportional to them through a network whose output was logarithmic in form).

This computer is probably still in use on board French Navy F-8E(N) Crusaders. The degree of specialization is typical of an analog computer (although it was relatively easy to change the ballistics and other constants in this one, by inserting different adapters). Many aircraft, such as the F-4, had separate bombing and airborne fire-control sets.

Mk 108 Stabilizing computer for the Mk 105 underwater fire-control system (for the SQS-4 sonar and the Mk 11 Hedgehog), 1955.

Mk 110 Stabilizer for a Mk 15 Hedgehog projector, 1955.

Mk 116 Computer (750 lb) to supplement Mk 47 (and thus part of the Mk 68 fire-control system), to produce star-shell orders, 1950; later (about 1959) it was also used to compute gun orders and horizontal-bearing orders for RAT. Mod 3 was installed on *Charles F. Adams*-class destroyers. Mod 4 was the solid-state-electronics version, part of Mk 68 Mod 8 fire-control systems (1962). It could provide surface control only, for 3-in/50 guns.

Mk 118 Analog computer producing missile and launcher orders for Tartar (later SM-1MR) missiles, 1956; installed on board frigates and French Tartar ships. It was part of missile fire-control system Mk 74. The Mod 2 version (1963) eliminated the gun-order section and changed the launcher blind-zone computed output. Mod 4 was part of the Tartar fire-control system (Mk 74) planned for the carrier *Kennedy* (1964, 2000 lb).

Mk 119 Computer of the Mk 76 Terrier (later SM-1ER) missile fire-control system. Weight 4000 lb. It developed launcher and missile orders. The Mod 1 version, for the cruiser *Long Beach*, was compatible with WDS Mk 2. Mod 2 doubled the range (in response to Terrier development) and incorporated an up-and-over (proportional navigation) missile trajectory (1961). It was installed on board CG 26–28 and the carrier CVA 66. Mod 4 (1964) was designed to work with NTDS (about 3100 lb).

Mk 121 Stabilization computer to adapt the Mk 56 fire-control

system for use with the Mk 111 fire-control group and the ASROC missile (1959, about 150 lb).

Mk 123 Computer group for Polaris submarines (*George Washington*-class). A modified version (1963) could control all 3 versions of the missile (A1/A2 and A3).

Mk 124 Computer group for Polaris submarines. It incorporated a target-data input unit, which received ballistic data, bearings, trajectories, and wind spots.

Mk 125 Computer group for Polaris submarines.

Mk 126 Computer group for Polaris submarines.

Mk 128 Digital computer (1959) for analog-to-digital conversion and digital processing. Mod 1 (1962), for weapons-direction equipment Mk 2 (1962, six 600-lb cabinets), added a buffer for interface to NTDS; it included a cabinet that checked the processor. Total weight of this version was 3300 lbs.

Mk 129 Leveling computer (1963, 971 lb) for the level guidance platform and anti-circular-run gyros controlled by underwater fire-control systems Mk 113 and 117 (for torpedoes and SUBROC missiles). It initializes the SUBROC missile and prevents launches that would endanger the submarine.

Mk 130 Digital computer of the underwater fire-control system Mk 113 (1964, 1365 lb). Mk 113 was the first submarine fire-control system to incorporate a digital computer. Mk 130 received data via analyzer console Mk 51, calculating data for multiple targets and also for a consort (i.e., for tactics involving several submarines communicating with one another). There were 6 classes of data: (1) bearings; (2) bearings and range; (3) bearings and range rate; (4) bearings, range, and range rate; (5) target parameter constraints; and (6) bearings, range, range rate to consort, plus bearing of consort to target. Mod 1 (1972, 1372 lb) was part of Mk 113 Mod 8. It calculated target range by TMA, correcting input data by estimating sonar acoustic path, all under the control of analyzer consoles and the attack-control console.

Mk 134 Stabilization computer for underwater fire-control system Mk 114, 1960. Total weight was 160 lb. Mk 114 was an analog system; its successor, Mk 116, used a standard UYK-7 computer weighing 535 lb. Actual fire-control data processing was conducted in an attack console (Mk 53, in this case).

Mk 138 Designation applied (in 1960, long after it had become standard) to the standard submarine circular slide rule, a quintessential analog device. It calculated any 1 of 4 variables from the other 3: bearing rate, speed, range, angle on bow. Speed limits were 1–35 kt. The fixed part was 8 in in diameter, with a 4 $\frac{3}{4}$ -in moving disk showing bearing rate and angle on the bow on log and log-sine scales.

Mk 143 Position-keeping computer for wire-guided torpedo fire, providing command guidance and showing torpedo run and gyro errors. It replaced angle solver Mk 17 and torpedo director Mk 37 in the Mk 114 fire-control system. Mod 1 was for fire-control system Mk 105; Mod 2 was for Mk 111. This computer set torpedoes and displayed the set parameters. The original version incorporated ballistics for Mk 37 Mod 0 and Mod 1 (both high-speed) torpedoes. Mod 3 added ballistics for Mk 48 torpedoes (1965, 1275 lb). Mk 143 combined solid-state electronic and electro-mechanical components; it was programmed by relay switching. Target speed could be up to 60 kt, target range up to 35,000 yds, and target depth down to 3000 ft; torpedo range could be as great as 40,000 yds, and torpedo range rate up to 100 kt. The prototypes were installed on board the first 2 *Garcia*-class frigates in 1963.

Mk 146 Computer group for Mk 84 Polaris free-control system (1961).

Mk 148 Target card computer for Polaris (Mk 80 fire-control system, 1964). It computed geoballistic target information, producing punched cards that could then be inserted into the Mk

80 system. These calculations required 3 cabinets, measuring, together, 33 × 72 × 130 in.

Mk 151 Computer power supply for the Sea Sparrow (BPDMS) fire-control system (1966).

Mk 152 See CP-848, above.

Mk 153 Slide-rule computer for an antiswimmer weapons system (1967), providing elevation-angle data to fire an antiswimmer cartridge from a standard 81-mm mortar.

Mk 154 Digital solid-state computer for SPG-53A and B radars (Ordalt 6894) of the Mk 68 fire-control system. It replaced the 6G synchro unit (75 lb, 1968).

Mk 155 Supplementary ballistic computer (for extended-range and RAP shells) for the Mk 47 computer (1968).

Mk 157 Norwegian-built SM-3 digital computer of the Mk 91 (NATO Sea Sparrow) fire-control system (see the Norwegian section, above). It has DMA NTDS-compatible I/O channels and a teletype for on-line data entry (printed at 10 characters/sec). Input was by paper-tape reader. Mod 0 had a 16k memory. Mod 1 had a 24k memory and a magnetic tape reader (1200 rather than 300 characters/sec) (898 lb, 1981). In Mod 2, memory was increased from 24k to 32k. In Mod 3, ferrite cores were replaced by CMOS chips, and memory capacity was doubled (to 64 kwords, i.e., to 128 kbytes). Processing efficiency increased at least 25%. This computer is used in Mk 91 Mods 2 and 3 for the RIM-7M missile (1988, 898 lb).

Mk 159 Dutch Signaal computer (1972), for the Mk 94 fire-control system (WM 28); the Americanized version, using a UYK-7 computer, is Mk 92. This computer uses a 30-bit word (32 kword capacity, including 512 words of ROM and has 16 I/O channels. Clock rate is 102.4 kHz (i.e., 0.1 MHz). Dimensions: 52 in high × 20 in wide × 24 in deep.

Mk 160 Current standard gunfire-control digital computer, conceived to replace Mk 47 Mod 3 and Mk 116 Mod 3 (1974, originally 1290 lbs). It is the key feature of the Mk 68 Mod 15 fire-control system of modernized *C. F. Adams*-class destroyers and incorporates a UYK-20(V) computer (1290 lbs, 1977). Mod 1 is in the Mod 16 version of the same fire-control system. Mod 4, for the *Arleigh Burke* class (1985), incorporates the UYK-44 minicomputer (2170 lbs, vs. 2045 for Mod 3). Mod 5, for the *Iowa*-class weapons system, has 2 UYK-44 computers and a UYQ-21 display (2200 lbs, 1989).

Mk 161 On-board computer of the Sea Lance missile (5.2 lbs, designated 1985).

◆ A-12 Avionics Computers

IBM is responsible for all of the mission computers and common modules of the new A-12 attack bomber. Deliveries began in November 1989. Reportedly, the standard chassis is a $\frac{3}{4}$ ATR (air-transportable-rack) enclosure, which can carry up to 13 SEM-E modules (circuit cards) with a maximum total performance of up to 13 MIPS. There are 5 standard modules: a CPU running at over 3 MIPS, with 1.4 Mwords of memory; a data-processor module (DPM); a MIL-STD-1750A processor (approx 4 MIPS, 512k program memory, 16k EEPROM, and 4 standard I/O interfaces); a nonvolatile bulk-memory module (BMM), carrying 512k of CMOS memory, 16k of EEPROM for diagnostics, and 4 standard I/O interfaces; a multiplexed data module (MDM), carrying 2 dual-redundant 1553B channels, a MIL-STD-1750A processor, 128k of program memory, 16k of EEPROM, and 4 standard I/O interfaces; and a power-supply module (PSM) on a single SEM-E card. The MDM is based on IBM components already used in the LAMPS III helicopter and the B-1B bomber.

As of early 1990, A-12 avionics development was reportedly running behind schedule, and at least the first aircraft were expected to use A-6 avionics.

◆ DTC I

Hewlett-Packard HP 9020A/C (Model 500) workstation/computer, adopted as a standard naval machine in July 1984, is used in several major systems, including JOTS I. The 2 versions differ primarily in the quality of their color monitors, 9020C offering higher performance. The 32-bit microprocessor is a proprietary Hewlett-Packard chip containing 450,000 transistors, which was an order of magnitude greater than the level of integration achieved by competitors when the machine was introduced. Internal (RAM) memory: 2 Mbyte basic version, expandable to 14 Mbytes (naval versions typically carry up to 8 Mbytes). The machine normally accommodates two 5.25-in floppy disks and 1 or more (up to 7) hard disks (initially 20 Mbyte, but now typically 55 or 130 Mbyte; the final version [1989] could accommodate 304-Mbyte hard disks). HP 9020 was the first multiple-CPU 32-bit workstation; it can accommodate up to 3 floating-point math chips. Each CPU can directly address up to 500 Mbytes. Speed of the single-CPU version is 1.5 MIPS (based on an industry-standard mix of instructions, in which a VAX 11/780 runs at 1 MIPS); the 2-CPU version runs at 2.9 and the 3-CPU version at 4.3 MIPS. Other measures of speed: microinstruction cycle time, 55 nanosec; addition of two 64-bit floating-point numbers, 1.17 microsec; multiplication of two 32-bit integers, 1.25 microsec; multiplication of two 64-bit floating-point numbers, 1.28 microsec; load a register from memory, 550 nanosec.

DTC I was sold to the navy by Tetrtech, which added software and some minor hardware to the basic HP 9020. About 2500–3000 DTC Is were bought, for programs including FFIST (see separate entry), ICADS (integrated carrier ASW prediction system), JOTS I, POST (prototype ocean-surveillance terminal), SCATS (squadron-commander ASW tactical system), SIMAS (sonar condition prediction for SQS-53 sonars), SFMPL (submarine force mission-planning library), SPAR, TAWSIT (tactical ASW interim trainer), and TEPEE (see separate entry).

In each case, procurement of a non-MIL-STD computer, which was presumably less survivable than a standard military machine, was justified on the grounds that it was not mission-essential that a ship or force could still function (albeit on a degraded basis) if the computer failed. This practice is really justified by the sheer ruggedness of modern commercial equipment. In the CS@SE experiment described above, Sun 4/260 workstations and dual hard-disk drives were hard-mounted to the decks of both a missile cruiser and a carrier, with no apparent ill effects despite the lack of shock-mounting. The associated large-screen display did have to be realigned weekly or more often if the cruiser fired her 5-in gun. Compared to the UYK-series machines used in NTDS, CDS, and ACDS, the DTCs tend to have much less I/O capacity. Their availability inspired the development of powerful planning and tactical systems, such as JOTS.

DTC I succeeded HP 9845, a very similar but slower (about $\frac{1}{3}$ as fast) workstation introduced in 1977. HP 9845 was the navy commercial computer of choice, bought through the GSA. The DTC I contract enforced standardization in what was then termed a tactical decision aid.

Hewlett-Packard's Model 835, a follow-on to the 9020, was a competitor for the DTC II contract won by the ruggedized Sun-4. The Model 800 series uses a RISC-based architecture. A typical Model 835 runs at 6 MIPS and has a maximum RAM capacity of 112 Mbytes, with a maximum disk storage capacity of 9.1 Gbytes.

◆ DTC II

DTC II is a desktop tactical computer of the Flag Data Display System (FDDS), a ruggedized C3-4/110 manufactured by C3, Inc. of Herndon, Virginia. DTC II is based on the Sun Series-4/110 32-bit SPARC (RISC technology) microprocessor and has a VME internal bus (backplane) with 9 slots and a patented memory management unit (MMU). The MMU supports rapid switching among 8 register-resident processes. The microprocessor is capable of 7.5 MIPS when operating on integers. Clock rate is

14.28 MHz. Memory is 8, 16, 20, or 32 Mbytes; memory cache is 16 kbytes. The address bus is 28 bits wide (the data bus is 32 bits wide). The computer can support 15-, 19-, and 25-in monitors. Resolution is 1152×900 pixels, with a refresh rate of 66 frames/sec and a bandwidth of 93 Mhz. It can display 256 colors.

DTC II was chosen to succeed DTC I in applications such as JOTS because it was adapted to a much more widely used language (Unix rather than Rocky Mountain Basic) and because it incorporated a standard VME backplane. As in the commercial world, the backplane made it possible to incorporate special-purpose boards. For example, the version of DTC II used in FDDS has perhaps only 1 board in common with a standard DTC II computer. Reportedly, DTC II has proven less than sufficiently rugged in service, and it is not powerful enough to meet currently projected requirements.

◆ DTC III

As of the spring of 1990, a next-generation DTC was in the proposal stage, with a contract award expected in 6–12 months. The next-generation workstation is to embody much more powerful graphics, with a processing rate of 50–100 MIPS (as in DTC I/II, on a scale on which a VAX 11/780 has a speed of 1 MIPS).

The RFP for DTC III had not yet been issued as of August 1990. The question was whether it would be more than an upgraded Sun workstation, a more rugged and faster equivalent to DTC II. When the draft RFP, calling for a modified Sun, was issued, several RISC computer manufacturers protested that they could offer something more powerful, particularly in the area of hardware-implemented 3D graphics. The existing DTC II has relatively little graphics capability, and 3D graphics calculations are all done through software, consuming both memory and time. Originally, the RFP called only for a somewhat better equivalent to DTC II, which would have sufficed for existing applications. However, many potentially important future applications, such as integrated strike planning (see ISPS, below), involve inherently 3D data and extensive calculations (which amounts to graphics) using those data.

◆ AT&T Ultra-Dense Processor/DSP3

Developed under contract to DARPA, this new, compact, parallel processor is rated at 800 MFLOPS. The prototype, 9.5 cm square (12.7 cm including cooling fins), should begin tests in the fourth quarter of 1990, and production examples will be delivered beginning in 1992. The first planned application is to the planned upgraded version of the Mk 48 ADCAP torpedo. The processor consists of 8 stacked boards, each 150 mils (3.8 mm) thick, separated by rubber pads, with the controller and I/O board at the base. Each board carries 4 processing "tiles," and each tile is rated at 100 MFLOPS, using scalable DSP3 parallel-processing architecture (DSP3 was recently delivered by AT&T to DARPA). Each tile incorporates 64 kwords of 32-bit, 25-nanosec, static RAM. AT&T uses metal core boards to conduct heat and ground each set of processors; vertical interconnection to eliminate backplane losses (and to achieve a savings of 10:1 in volume); silicon-on-silicon technology (for high thermal conductivity and a 4:1 savings in board area); and low-dielectric insulation (for low interconnection capacitance and, thus, low power consumption). Although the current system has 8 boards, the controller can accommodate up to 10 (40 nodes, 1 GFLOP throughput). AT&T sees the computer not only as valuable in its own right but also as a building block of a future 1-TeraFLOP (1000-GFLOP) machine.

DSP3 (Digital Signal Processor 3) itself is a fast parallel processor developed by DARPA. Because the new machine has the same architecture, DSP3 can be used to develop its programs. DSP3 accommodates up to 8 processor boards as well as a 68030 control board and a 160-Mbyte hard disk, plus an Ethernet board and 4 VME expansion slots. The computer is built up from AT&T's 32-bit, floating-point DSP32C processors, each of which is associated with a routing chip (ASIC) and 256 kbytes–1 Mbyte of fast memory to form a processing node; each node runs at 40 Mbytes/sec on 4 channels, for a total of up to 160

Mbytes/sec. Throughput per chip is 25 MFLOPS. Each processor board contains 16 nodes and has a throughput of 400 MFLOPS (3.2 GFLOPS, then, for all 8 boards).

The processors communicate via a fast (40-Mbyte/sec) backbone that can be reconfigured for alternative processing topologies (linear mesh, linear systolic, binary and nonbinary tree, and hybrid) to handle different problems. Each processing element has 4 independent ports; the software changes the effective system topology by deciding which port to turn on. This flexibility, which is made possible by the software-controlled ASIC, gives DSP3 its processing power.

Likely applications for DSP3 are beamforming (including adaptive), neural networks, speech recognition, synthetic-aperture-radar processing, solution of large systems of linear equations, and image processing/object recognition.

AT&T also offers a related parallel processor intended specifically for pattern recognition, BT-100, in which the processors are linked into a binary tree structure (each has 1 input and 2 outputs into 2 other processors). Each board carries 8 DSP32 processors (64 MFLOPS of throughput). DSP32 is a 32-bit, 16-MHz chip with a speed of 4 MIPS/8 MFLOPS, and each processing element also contains 64 kbytes of local memory. The links between elements operate at 1 Mbyte/sec. The chip carries 2048 bytes of ROM and 4096 bytes of RAM and can connect to another 56 kbytes of external memory; it has 3 I/O ports: serial, parallel, and external-memory interface. The tree architecture makes for a series of comparisons with a widening range of options. BT-100 is designed to function as a peripheral to a host computer, containing 1-16 boards (56 MFLOPS for the first board, 64 for each additional board).

♦ Massively Parallel Computer/DAP

AMT's distributed array of processors was announced in 1990. A version was displayed at the October 1990 Association of Old Crows meeting, with the claim that something very close to a Cray supercomputer could be packaged in the guidance section of a Sidewinder missile (see Sidewinder in the Antiaircraft Warfare section for this application). DAP was designed specifically for image and signal processing. There are 2 versions, DAP 510 with 1024 processors (32 × 32 array) and DAP 610 (4096 processors, 64 × 64 array, nominally 400% of DAP 510's performance). Both systems are programmed identically, and application software written for 1 can be transferred directly to the other. Claimed specifications for DAP 510 are operation rate 10,000 MOPS, memory 4-128 Mbytes, internal bandwidth 1.3 Gbytes/sec, and I/O rate (concurrent input and output) 80 Mbytes/sec. For DAP 610 these figures are multiplied by 4, except that I/O is 160 Mbytes/sec.

Current experimental applications include SAR data compression (SARCOM) for transmission of radar ice pictures from Alaska to the Fleet Weather Center in Maryland and also for sonar applications. DAP was originally developed for SDI but is probably a key to effective image processing for staring, focal-plane, IR arrays.

The existing DAP computers are fairly large, but AMT plans to package a 4096-processor machine in 4 × 4 × 3 in. Projected characteristics: clock rate 20 MHz, master control unit 2 Mbytes of program storage, internal bandwidth 10 Gbytes/sec, I/O 320 Mbytes/sec, data memory 16-64 Mbytes, 1-bit performance 80,000 MIPS, 8-bit performance 40,000 MIPS, 32-bit floating-point performance 1.2 GFLOPS, power consumption 120-160 W. This is presumably the machine shown in the Sidewinder mock-up.

♦ HAP 1600

Word Length: 16 bits

Memory Capacity: 64 kwords of data, 2 kwords (80-bit words) of microcode (ROM), and 2 kwords of constants (ROM)

Speed: add time, 133 nanosec; multiply, 133 nanosec; divide, 6.0 microsec; 128-pt complex FFT, 450 microsec; 1024-pt complex FFT, 8.3 msec; 1024-pt IIR, 1.2 msec; 1024-pt FIR, 8.2 msec; memory cycle (16 bits), 267 nanosec (32 bits, 400 nanosec)

Instructions: 113 **I/O:** A-NEW channel at up to 1 Mword/sec

Honeywell's auxiliary processors (chips) are intended to supplement standard computers such as AYK-14. HAP 1601, a 16-bit pipelined fixed-point array processor, is the acoustic processor of the Mk 50 torpedo. HAP has also been embedded in a UYK-20 and in an Intel microprocessor. It calculates virtually any algorithm at 20 MOPS. Honeywell claims that throughput is boosted by a factor of up to 35, depending on application.

♦ L-304 (USQ-501)

Word Length: 32 bits

Memory Capacity: 4 kwords, expandable to 128k in 4k or 8k increments (ferrite cores)

Speed: memory cycle time, 1.6 microsec (4 kwords) or 1.8 microsec (8 kwords); add/subtract time, 14 microsec; multiply time, 44-72 microsec

Instructions: 62

I/O Channels: 64 (maximum transfer rate, 312 kwords/sec)

Litton's general-purpose computer is used by the Canadian and U.S. Navies. The technology is small-scale integration. The L-304 series was announced in mid-1965. Two L-304s form the central tactical computer of the E-2C. The Canadian version (USQ-501) is used in the CC-280 ("Tribal"-class) command/control system. The architecture of this machine is similar to that of the somewhat earlier U.S. CP-642 series, which performed an analogous role in NTDS.

L-304F has 5 memory modules, each containing 8k 32-bit words (only 4 of the 5 may be addressed at a time, a software instruction activating or deactivating a given module). The basic computer was designed so that it could be expanded to 80 kwords, but this option was not exercised. Input and output are exercised in blocks of 4095 words (32- or 8-bit), the length of the word depending on the number of data lines in the particular interface.

The central processor and memory connect to 4 buffer/controllers: a recorder/reproducer controller (RRC), an exchange buffer (EXB), an NTDS buffer, and a computer-control drawer (CDR).

The RRC connects to a 9-track magnetic tape unit, unpacking 32-bit computer words for storage in 8-bit form on tape; 8 data lines in each direction connect it with the tape unit. The tape unit is the system mass-storage device and can be used to read system programs into running memory.

The EXB connects with the ship sensors: the radar switchboard, the radar simulator, the ship's log and gyro (via a synchro-digital converter), the surface and air weapons, the EW system, and the underwater combat system. The EXB is known as an L-304F standard interface and provides ship sensors with direct access to the tactical data system. There are 32 bidirectional data lines.

The NTDS buffer has 4 NTDS fast channels; it connects the computer with Link 11, Link 14, and a 1532 (printer and paper-tape reader) console and has a spare connection (32-bit interface) that can be used to link it to another tactical-data-system computer. Link 14 is an output channel only (8 data lines). The Link 11 interface is a 2-way 32-bit channel, including an interface that changes the NTDS fast output of the computer to the NTDS slow mode of Link 11.

The CDR connects the computer to the displays. It connects directly to an electronic marker generator (EMG), fed by the situation display consoles (SDCs) and digital data indicators (DDIs). The system accommodates 2 DDIs and 8-10 SDCs.

System hardware is designed to time-share the different operational programs, allowing for up to 64 independent program levels, each allocated 2 status bits (active/inactive, executing or not) and 8 general-purpose registers. A program level may be active and executing, active and suspended, or inactive (and nonexecuting). Programs are assigned priority levels, and the executive program searches for the highest active level and starts it, suspending any other program levels. The search clock rate is 2 msec (i.e., the rate at which the master executive directs the hardware to search for and run the highest-priority active-program level).

The main operational program consists of 16 work tasks, each of which has a specified minimum period between consecutive cycles.

◆ Rolm 1666

Memory Capacity: up to 1024 kwords in 16-kword modules (plus 512-word ROM)

Speed: add time, 1.1 microsec; multiply, 5.3–5.5 microsec; divide, 9.3–12.7 microsec; floating-point divide, 15.9–16.7 microsec (single precision)

Instructions: 234

This microcomputer replaces the earlier UYK-19 in the current upgraded version of the Hughes Modular Combat System. It is used in the U.S. TFCC (initial version). It is identical to the earlier Rolm 1606 except that the former lacks a floating-point arithmetic processor. There are 3 degrees of precision: 32-bit single precision, 48-bit, and 64-bit double precision.

Memory can be divided into up to 8 distinct sections: the operating system, the DMA processor, and 6 user memories (up to 64 kwords each). These memory areas may be shared or they may be limited to each user. Of the total 1024 kwords, 64 kwords are 1 microsec core memory.

◆ System/4 Pi

The IBM military and space-program computer series was introduced in 1966; at that time it was unusual because it was an off-the-shelf modular series. System/4 Pi computers are used in the A-6E (TC-3), A-7E (TC-2), EA-6B, and AV-8B ARBS (SP-1); the LAMPS III display is run by an embedded System/4 Pi CP-3. These are all basically 16-bit machines (17 bits including the parity bit). System/4 Pi also appears in numerous missiles. There are 3 families: tactical computer (TC), customized processor (CP), and extended-performance computer (SP). IBM hoped to sell CP-series for shipboard fire-control systems but apparently did not enjoy any success.

Characteristics (as originally announced, 1966)

	TC	CP	SP
Data Word	16 or 32 bits	16 or 32 bits	16, 32, or 64 bits
Instruction	8 or 16 bits	16 or 32 bits	16, 32, or 48 bits
Memory	16–64 kbytes	8–32 kwords*	16–128 kwords*
Memory cycle	2.5 microsec	2.5 microsec	2.5 microsec
Add time	9–18 microsec	5–10 microsec	2.1–5.0 microsec
Multiply time	48–54 microsec	29.6–34.6 microsec	9.2–10.4 microsec

*32-bit words

A more powerful 32-bit Advanced System/4 Pi was introduced in 1970 and is used in the F-14. The advanced series consists of 3 families: advanced processor (AP), command/control (CC), and subsystem processor (SP). Applications include the space shuttle (AP-101) and the E-3 AWACS (CC-1), the latter being the most powerful of the series.

IBM's 1966 success in selling a version of System/4 Pi to the air force for the F-111 (a computer ultimately designated AYK-6) helped it displace North American Autonetics as the leading U.S. airborne-digital-computer manufacturer. System/4 Pi was conceived in the spring of 1965 as an alternative to the proliferation of special-purpose airborne computers, pressed by the new manager of the Federal Systems Division, B. O. Evans, against considerable internal opposition. During the next 18 months the originally planned family of 5 types was reduced to 3. Machines within families were differentiated in part by the addition of microprogrammed special-purpose processors. For example, a special sine-cosine calculator reduced computation time for these functions by 60%. IBM claimed that time for data correlation, e.g., in tracking, could be reduced by better

than an order of magnitude. From the first, System/4 Pi was designed to run programs that could be written and tested on commercial Series 360 computers.

◆ Intel Chips (iAx86 Series)

Intel produced the 8-bit microprocessor chips that began the personal-computer industry (8080, 8085). Military machines use 16- or 32-bit chips, which offer more processing power and also a larger number of potential memory addresses. The entire series is designed so that each later version can use programs written for the earlier ones. The important chips are the following:

8080 is the original 8-bit microcomputer chip. It appeared in 1974 and had 111 instructions. Because the address bus is 16 bits wide, it can address up to 64 kwords of memory, even though those words are only 8 bits in length. The bus bandwidth, a measure of maximum operating speed, is 0.75 Mbytes/sec, and register-to-register add time is 1.3 microsec. The chip has 256 I/O ports.

8085 is an 8-bit microprocessor, software compatible with 8080 but faster, with a 1.3-microsec instruction cycle.

8086 has the same architecture, addressing modes, and instruction set as 8088 (see below), but it has a 16-bit external bus and incorporates data pipelining for simulated coprocessing (time-sharing). Bus bandwidth is 5 Mbytes/sec, and register-to-register add time is 0.3 microsec. This chip appeared in 1978; it is the basis of the IBM PC XT. As a measure of relative speed, the clock rate of the XT, which has an architecture similar to that of the original PC, is 4.77 MHz, for an 8088-2 chip. Maximum clock rates: 5 MHz for 8086, 8 MHz for 8086-2. The associated math coprocessor is 8087.

8088 is the chip of the IBM PC and its clones. The chip is designed to connect to an external data bus 8 bits wide, but its internal bus is 16 bits wide, for faster and more precise processing. The chip uses a 20-bit address field so that it can address up to 1 Mbyte. There are 165 instructions. As a measure of speed, clock rate of the original PC was 2.0 MHz.

80186 is a faster version of 8086, made in 6- and 8-MHz versions. It enjoys twice the overall throughput of the 8086, partly because it has a faster bus interface (4 Mbytes/sec). It combines 15–20 of the most used 8086 system components into 1. Compared to the earlier machines, it adds 10 new instructions. The associated math coprocessor is 8087.

80286 is related to 8086 but uses 24-bit addresses and can thus directly address up to 16 Mbytes. Memory management (paging) allows 80286 to address up to 1 Gbyte in all. The instruction set has 24 instructions added to that of the 8088/8086. This chip is the basis of the IBM PC AT and AT clones. As a measure of relative speed, the clock rate of these machines is 8 MHz, although some clones have speeds as high as 12 MHz. Intel calculated that an 8-MHz 80286 has at least 6 times the throughput of a 5-MHz 8086. A special memory-protection feature separates data from system code and permits the separation of programs and data from different tasks running through the processor.

80386 is a full 32-bit microprocessor, capable of handling 32-bit words as units rather than as double-precision entities. It can, therefore, address 4 Gbytes of memory. Bus bandwidth is 32 Mbytes/sec, and register-to-register add time is 0.125 microsec. There are 154 instructions. 80386 is the processor of the IBM PS 2 Model 70. In comparison with the earlier 8088, the

Model 70 has an overall clock rate of 20 MHz. The Intel 80386 was introduced in 1985.

80486 is an even faster chip, in which an improved 80386 processor is combined with an improved 80387 coprocessor and 8 kbytes of cache memory, the total requiring 1.2 million transistors. The current 80486 runs at 25 MHz, compared to 33 MHz for the fastest version of the 80386; however, it has a much greater capacity because of integration within 1 chip. The new chip uses pipelining, whereas previous chips in the series took in their data 1 word at a time, the processor often having to wait until main memory could disgorge the data it needed. This waiting becomes more significant as the speed of the chip increases relative to the speed of the main memory, as a memory access must be made within an integer number of clock beats. As a result, many 80386 systems use fast cache memory, just as in larger computers. In an 80486, data are transferred to the processor twice as quickly as in the 80386 (1 vs. 2 clock cycles). Speed is also increased by widening the path from memory to chip, from 32 to 64 bits (i.e., taking in 2 words of data at a time).

As an indication of relative speed, an IBM PS 2 Model 70 with a 486 chip has a clock speed of 25 MHz.

Intel also produces a series of math coprocessors: 8087, 80287, 80387.

8087 is the 2-chip math coprocessor intended to work with the 8086. 8087 adds hard-wired arithmetic, trigonometric, exponential, and logarithmic functions, amounting to a total of 68 more instructions. It is a bit-slice processor, operating on numbers represented by 8-, 16-, 32-, and 64-bit integers and on 32-, 64-, and 80-bit floating-point numbers (the internal architecture of the chip is arranged in terms of 64-bit words). It has eight 80-bit individually addressable register stacks and 14 general-purpose registers. The net effect of 8087 is to multiply the arithmetic performance of 8086 by a factor of 100.

80287 is the coprocessor intended for the 80286. It operates on 32-, 64-, and 80-bit floating-point numbers and on 32- and 64-bit integers. It incorporates over 50 mathematical instructions beyond those in the 80286 repertoire. Clock rate is 6, 8, or 10 MHz, and it incorporates eight 80-bit registers (internal architecture uses 80-bit words).

80387 is the coprocessor intended for the 80386. Total capacity is 108 bytes.

◆ Intel RISC Chips

The i860 (80860) is a 64-bit, 33-MHz (it has performed at up to 50 MHz) RISC processor. The chip contains a RISC core, a floating-point unit (FPU), a memory-management unit (MMU), a graphics unit, and separate data and instruction caches; the entire chip contains over a million transistors. Several of the units employ pipelining to increase their speed; the RISC core pipeline consists of the fetch, decode, execute, and write instruction stages. The floating-point adder and multiplier each use a 3-stage pipeline, and there is a 3-stage pipeline to the external bus (for 3 instruction cycles). The core also uses a dual-instruction mode, executing 2 instructions at once (1 for the core, 1 for the FPU).

The chip has a total of 85 instructions, well down from its predecessors, but quite comparable with total instruction sets of the late 1960s.

Operating at 40 MHz, the chip can execute VAX instructions at 33 MIPS, which is faster than a standard VAX (see below). At peak (which cannot be sustained in a normal program), it executes 80 Mflops in single-precision mode and 60 Mflops in double-precision. This chip can execute a single-precision 1024-point FFT in 1 msec, which is faster than many current dedicated chips. In comparison, a new specialized IBM FFT chip, FTM-4, which is to become available late in 1990, can execute the same operation in 0.078 msec (78 microsec) or a 4096-point transform in 333 microsec. In one current application, i860 is credited with a processing speed of 66 Mflops.

One reason for the very high speed is that the chip can execute

more than one instruction per clock cycle, a performance previously not attainable in a microcomputer chip.

◆ Motorola Chips (68000 Series)

The Motorola chips were first mass produced as the basis of the Macintosh personal computers; their high speed made possible extensive graphics. All of the chips in the series are upward compatible (e.g., 68030 can execute 68000 programs, but not necessarily the other way around). The important chips in the series are the following:

68000, the first in the series, could bit-slice, handling data in segments of 8, 16, and 32 bits. The basic word is 16 bits, but the chip also operates on long words (32 bits). The chip is unusual in having 2 different operating modes, a supervisor mode and a user mode. Supervisor mode instructions, which are used to run the screen in a Macintosh, take priority over user instructions, such as those for computation. Presumably, the bit-slicing is designed for fast graphics since the screen pixels generally are not specified by full 32-bit (or even 16-bit) words. Heavy use of the supervisor mode would slow computing, as many Macintosh users have found. There are 203 instructions. As an indication of speed, the original Macintosh ran at a clock rate of 8 MHz. This chip has a 16-bit data bus and a 24-bit address bus; it is a 16/32-bit microprocessor. The 24-bit address bus suffices for 4 Mwords (although the original Macintosh was limited to 512 kbytes). There are 2 other versions, 68008 (8-bit data bus, 20-bit address bus) and 68010 (which introduces virtual addressing and uses some different instructions).

68020 was the first full 32-bit microprocessor in the series. It could directly address up to 4 Gbytes of memory. The chip includes a 256-byte instruction cache for higher operating speed, and it uses pipelining. Alternative processing speeds are 12.5, 16.67, 20, 25, and 33.33 MHz. This chip can be combined with the 68881 and 68882 math coprocessors and also with the 688851 paged memory-management unit. Up to 8 coprocessors can be accommodated.

68030 is a faster equivalent to 68020, with both instruction and data caches (256 bytes each), and it has more sophisticated pipelining compared to that of 68020. Processor speeds are 16.67, 20, 25, and 33.33 MHz. This chip can be combined with the 68881 and 68882 math coprocessors, up to 8 of which can be accommodated.

68040 is the latest in the series, employing several parallel processors within 1 chip. It combines a main (integer) processor comparable to 68030 with a floating-point unit (FPU), which in effect replaces a coprocessor; memory-management units; and 4-kbyte instruction and data caches. The chip uses multiple independent pipelines and multiple internal buses. The main processor operates at 20 MIPS, and the FPU operates at 3.5 Mflops.

68881 is a floating-point coprocessor designed to operate with 68020 or 68030. It uses 2 kinds of extended-precision data, a long word (80 bits: 15-bit exponent, 64-bit mantissa, 1-bit mantissa sign) and a shorter word (67 bits), the latter for intermediate-precision operation at very high speed. The chip uses 46 instructions (including 35 arithmetic operations), and it carries 22 constants in on-chip read-only memory (e.g., pi, e, and powers of 10).

68882 is an alternative math coprocessor that operates nonconcurrently with the main chip; it can control the bus in the chip independent of the main processor, a feature that can make for higher overall performance.

◆ Motorola RISC Chips (88000 series)

The current 32-bit RISC units are the MC88100 CPU (including a floating-point unit) and the 88200 cache and memory-management unit (CMMU). Typically, one 88100 is connected to two 88200s by a 100-Mbyte/sec bus; the two 88200s provide separate 16-kbyte caches of instructions and data. Motorola

calls the integer and floating-point arithmetic units special-function units (SFUs), and the instruction and physical architecture of the 3-unit chip are designed to accommodate up to 8 SFUs, some of which may be special purpose. Up to eight CMMUs can be attached, for a total cache of 128 kbytes. Other current RISC chips do not have on-board floating-point capability; typically, the central processor and a separate floating-point unit are paired. The 88100 processor has 51 instructions (and uses 7 data types). It has 4 separate buses: a 30-bit data address bus (1G addresses), a 32-bit data bus, a 32-bit instruction address bus, and a 32-bit instruction bus.

In a typical application, the 88100 runs at 20 MIPS (microcomputers using it run at 25- or 33-MHz clock speed). Motorola has indicated that in the future it may redesign the basic RISC chip with a 64-bit bus for faster floating-point arithmetic. It may also move a 16-kbyte cache onto the basic chip. Data General and Motorola have announced an enhanced version of the 88000, for delivery in 1992, which should have up to 10 times the performance of the current version.

◆ VAX

Some current machines are described as micro-VAX types. VAX itself is a Digital Equipment Corporation 32-bit minicomputer series replacing the earlier 16-bit PDP-8 and -11 series. Micro-VAX refers to a word length and an instruction set; 1 advantage of a micro-VAX is that its software can be developed on a standard VAX machine. The current VAX 8842 accommodates 0.256-1 Gbytes of memory and executes instructions at a rate of 22 MIPS.

TACTICAL DATA SYSTEMS

Tactical data-handling systems, or combat-direction systems, perform 2 related functions. First, they integrate available sensor data into a meaningful tactical picture, generally in the form of a 2D summary (or compiled) plot of the surrounding sea and air area. Such a plot includes some attempt to identify the occupants of that surrounding area, at least as friendly vs. enemy. In this sense tactical data systems are command-decision aids.

Second, they often partially or completely automate the results of decisions taken by means of the plot. For example, using an electronic plot, an officer may designate a target for attack. This designation at a console in CIC will result automatically in the proper orders being given to, say, a surface-to-surface missile launcher. In some systems automation extends further. The combat system identifies particularly urgent threats and initiates reactions (such as missile firings) against them. In such cases the display allows the monitoring officer to abort the reaction while it is being made.

The sensors provide instantaneous data: current locations of targets or, in the case of passive sensors (ESM and sonar), lines of bearing. In many cases automatic combination of different sensor data (including data from off-board sensors, such as radars or passive devices on other ships or aircraft) can materially improve the total picture. However, *no* instantaneous picture is really useful for tactical decision making since the essence of the tactical situation is its dynamic. The value of the plot is that it shows not only where everything is at any precise moment, but also enough of the history of the movement of any target to permit projection ahead. Integration of ESM and active-sensor data may also be valuable as a means of *identifying* given tracks.

Much of the purpose of the system is often threat evaluation and weapons assignment (TEWA). Many current systems claim to offer a degree of TEWA, but their capabilities often entail little more than a comparison of range and rate of approach, on the theory that a fast-moving inbound object is likely to be a more serious threat than a slower object farther out. That assumption is relatively naive. The next stage is for the system to try to identify targets by type and then to use an internal data base to advise the monitoring officer (in U.S. practice, the TAO) of what threat each target represents.

Plots long antedated electronics, and the development of computerized tactical data-handling systems was driven initially by the need to compile tracks more rapidly than could be done by hand. That requirement particularly applied to complex air situations, which developed very rapidly and demanded rapid decision making and quick responses. Surface and ASW automation were slower to develop, and indeed many modern frig-

The World War II CIC was a manual means of summarizing all available tactical data; a modern system, such as NTDS, automates the process. Here a vertical plot is maintained on board the battleship *Iowa* in 1984; standard NTDS symbols are used. (U.S. Navy)

A computer can draw synthetic video on a screen. This is a cursive display, in which the synthetic video is superimposed over raw radar video. The next stage is a full raster-scan display, in which the computer can process the raw video on the screen. This ASA-70 console is on board a P-3C Orion. (U.S. Navy)

ates lack automated plots of any type. It may be that the driver toward automation in smaller ships, such as large fast attack boats, is primarily the need to limit manpower while still taking advantage of external sources of data, such as data links both to shore and to airborne radars. Only in recent years has automation become so inexpensive that it can easily be applied to fast attack boats.

The big, digital, tactical data systems (such as the U.S. NTDS) began as air-defense systems, oriented toward the control of interceptor aircraft. They, therefore, emphasized the ability to keep track of numerous relatively distant airborne targets and could tolerate some imprecision in tracking since the pilot (usually assisted by the aircraft's radar) could make up for inaccuracies of a few miles.

There was also a separate line of development, coming out of gun (and then missile) fire control. Typical World War II practice was to assign 1 director (i.e., 1 fire-control channel) directly from CIC or the Operations Room to a target. That practice made for good tracking, but reassignment of the fire-control channel after a target was shot down was necessarily slow since the air-search radars feeding the CIC had broad beams. The solution was to provide a narrow-beam TWS radar dedicated to gun fire control and to maintain more tracks than fire-control channels. When any fire channel (weapon plus director) destroyed a target, it could be reassigned (designated) from 1 of the tracking channels. This practice was scaled up when surface-to-air missiles were introduced; in both cases, the tracking channels were carried by a WDS (U.S. systems of this type are described in the Antiaircraft Warfare section). The U.S. Navy developed one short-range radar specifically for gun designation, SPS-3; the longer-range pencil-beam air-search radars (SPS-39/52) were, in effect, missile-designation radars. These sensors were equivalent to British target-indication radars; the Royal Navy introduced its narrow-beam designation radars earlier because its wartime and early postwar air-search radars had much wider beams than equivalent U.S. sets.

WDSs naturally required a much higher degree of accuracy than the longer-range fighter-oriented combat-direction systems. Ultimately, however, they had much the same function. In most cases the ship's CIC fed targets to the WDS; and when the former was automated (in the U.S. case, using NTDS), the latter could be integrated into it in the form of WDS Mk 11. As missile ranges increased, and as the available battle space expanded, however, the distinction between a long-range air-search radar and a radar suitable for designating shipboard weapons lost much of its logic. The first U.S. attempt to grow a shipboard sensor/combatt system up out of the shipboard weapons was the abortive Typhon, which used an electronically scanned SPG-59 radar. The successful attempt was Aegis. The SPY-1 Aegis radar has a very narrow beam because it is primarily a weapons-designation and -control radar. That characteristic in turn makes for very effective air surveillance, since the radar very rarely sees 2 objects in any 1 search cell (range $\times$ bearing $\times$ altitude) and thus rarely confuses tracks.

The big Western automated, digital, fighter-oriented systems are all descended from a Canadian project, DATAR, conceived in 1949. At that time the U.S. Navy was working on an analog air-plot-compiling system, EDS (Electronic Display System), and the Royal Navy was working on 2 analog plot-compiling systems, CDS (Comprehensive Display System) for air plotting and Cambria for ASW. In each case, the objective was no more than a faster and more accurate compiled plot; any use of the data in the compiled plot would have to be by the officers on watch because of the limits inherent in analog operation. In each case, too, the system was initially based on own-ship inputs only, without any provision for an external data link (although EDS did include a data link in its operational form). The inventors of DATAR chose to represent data in digital form because they could be processed beyond the plot, and also because they were easier to store for protracted periods (analog data had to be stored in delay lines). From the first, DATAR included a digital-data-link concept.

In 1950 and 1951 the Royal Canadian Navy let a contract to CDC for a digital tactical trainer (the Canadian Radar Action Trainer, CRAT), and to Ferranti Canada for the tactical management system, Digital Automatic Training and Remoting (DATAR). The associated digital link was first demonstrated in Ottawa in 1950, data being transmitted from Toronto at 500 bits/sec. At this time both the U.S. and Royal Navies considered the approach far too complex for shipboard use, and the Royal Navy tried to sell its CDS to the U.S. Navy. However, the Canadians persevered and demonstrated a crude form of DATAR—with hard-wired logic, a magnetic-drum memory, and a UHF data link—in August and September 1953 on Lake Ontario, aboard the minesweepers *Digby* and *Granby*.

This demonstration included the first use of the ball tracker now universal in Western tactical data systems. As in the later NTDS, the operator could strobe and hook selected targets, transmitting digitized information into the system. System capacity was 64 targets in a tactical area of 80×80 miles with 40 yd resolution. The computer outfit occupied nearly the entire aft end of each sweeper, using 3800 vacuum tubes per ship (transistors were not yet mature enough); there were severe overheating problems. Considerable interest was shown by both the Royal Navy and the U.S. Navy, but the Canadians suspended work in 1955 because of a lack of funds. At that time the associated computer was a proposed 1-kbyte solid-state machine. DATAR was turned down for the *St. Laurent* class and for the carrier *Bonaventure* in 1955, and then for the *Restigouche* class in 1958.

However, with the appearance of transistors, it was clear to both the Royal Navy and the U.S. Navy that digital systems were practicable; DATAR showed how they could be built. In 1954 the Royal Navy halted work on CDS and Cambria and began design of a hard-wired digital system, ADA. It was based on the centralized CDS approach, with data broadcast by a master ship to other ships of a group. ADA was approved for fitting on board carriers in 1955 and ultimately led to the present ADAWS.

The U.S. Navy established Project Cosmos at the Fleet Programming Center at San Diego; it produced NTDS, which was heavily influenced by DATAR experience (and also by DATAR personnel, such as Stan Knights, the developer of DATAR and its trackball, who was acknowledged in 1960 as the father of NTDS). DATAR also heavily influenced the land-based SAGE air-defense system. Litton sketched an airborne data-handling system based on DATAR in the latter part of 1956; it ultimately became the U.S. ATDS system, carried by E-2s.

Both in Britain and in the United States, the service or the associated defense ministry was the system integrator. It selected contractors for the components, such as the computers and displays, but it retained responsibility for overall system design. Programming was a particular problem, especially since the early systems had to be written in machine language rather than in higher-level language. As a result, program maintenance was extremely difficult: machine-language programs are difficult to understand and thus to debug.

The U.S. approach was to accept commercial software production, with maintenance by naval personnel. However, because so much programming was done in machine language, maintenance was a serious problem, and contractor personnel had to remain at the Fleet Programming Center for many years. The Royal Navy used a team of naval officers to set down specifications for ADA and then ADAWS clear enough to enable contractors to program. That approach proved extremely laborious, and the result was inflexible and difficult to maintain. The Canadians later opted to teach naval officers to write the required software.

The U.S. Navy transferred expertise to France and Italy; early French SENIT and Italian SADO systems are essentially NTDS clones. In each case a national naval programming center was set up. The West Germans initially collaborated with the French, and their SATIR can be considered a second-generation NTDS clone. The newer Spanish TRITAN is also essentially

NTDS. All of these systems employ (or originally employed) standard U.S. Navy or UNISYS computers.

The Dutch SEWACO system is broadly analogous to NTDS but differs considerably in computer configuration.

The major architectural choice in centralized systems is the extent to which the single central computer conducts calculations beyond maintaining a coherent current tactical picture. In the U.S. system, there was a very limited degree of threat analysis, but assigned targets were handled by local computers (fire-control systems) separate from the central computer. The Royal Navy chose a very different approach, in which the central computer was responsible not only for the tactical picture but also for fire-control calculations: many British ships lack any separate fire-control system.

The U.S. choice was driven by the desire to simplify, so as to get NTDS into service as soon as possible, and also probably by fears that such centralization would make it very difficult to program the same sort of system for such radically different applications as carriers and missile cruisers. Moreover, it was easier to insert a relatively decentralized system into ships originally built with separate fire-control systems. The U.S. Navy was also willing to buy a larger number of separate computers. The British applied their ADAWS, initially at first, to ships that would be newly built, so they could make their choice more freely. They also almost certainly wanted to minimize the number of computers required. Hence the need for so many specialized versions of ADAWS.

The boundary between a highly automated fire-control system (which can be fed by a command/control tactical data system) and a full command/control system incorporating fire-control calculations is not very clear. For example, British Type 21 frigates use the CAAIS tactical data system in combination with a WSA 4 automated fire-control system, but some systems descended from WSA 4 can carry out tactical-data (i.e., CIC) functions by themselves. Similarly, it is not always clear whether the Swedish 9LV-series systems are pure fire controls fed by a separate tactical data-handling system, or are themselves highly integrated tactical data/fire-control systems.

The next stage was federated processing, using the naval equivalent of the minicomputers of the late 1960s and early 1970s. At this stage distribution implied considerable degradation in performance, and it was rarely complete. The original impetus was probably British, reflected in the CAAIS systems and then in the Ferranti WSA series. In these systems much of the processing is done by dedicated computers, to reduce the load on the central computer. However, the central computer is still essential as the repository of the compiled tactical picture.

Compared to a fully centralized one, a federated system has a very important advantage. Each console can be programmed independently, so new systems and new functions are relatively easy to fit into the system. Only the channel between the console and the central picture-keeping computer is firmly specified (e.g., the protocols by means of which the console changes the central picture and by means of which it taps that picture). Presumably, the consoles can be separately wired to the sensors feeding them and to the systems they control.

In a federated system, then, the different computers are all directly wired together. Each, therefore, must control system I/O, as well as its own specialized operations. As the load on the system as a whole rises, message handling comes to occupy more and more of the time and power of each of the computers. The system as a whole may be difficult to program (and its behavior difficult to predict) because the operation of any computer in the network depends so intimately on calculations conducted by the others. For example, in a system such as CAAIS, the picture-keeping computer feeds the fire-control computer with target-position data. However, when the latter fires a weapon, it must report weapon trajectory back to the picture-keeper, so that the latter will not count the fired weapon (or, say, its dropped booster) as a new and legitimate target.

There are 2 quite distinct federated architectures. One is star-

like: the picture-keeper connects to a series of secondary machines, each of which connects to particular sensors and/or weapons. CAAIS is a case in point. The other is a linear or ringlike combination of computers, each assigned a particular role, and all wired tightly and directly together. The latter architecture is a step toward a fully distributed system, but it is very different because of the tight relationship between the computers in the network. In the latter case the key feature is that messages are sent directly from computer to computer, without any intervening data bus. Some messages may have to pass through several computers (which may not operate on them) before reaching the appropriate address. The effect of a data bus, if it is combined with the appropriate software, is to separate messages and message handling from the main computers. As in a telephone system, messages need not pass through machines that do not need to hear them.

Federated systems were invented because totally centralized ones have several major drawbacks:

First, the I/O channel of the picture-keeping computer is a choke point whose capacity may be easy to exceed, given modern automatic-detection radar systems.

Second, the more centralized the computer, the more separate functions it must perform on a time-shared basis. The greater the load of data running through the system, the more difficult such time-sharing becomes, as ultimately there is only 1 processor to carry out all the different functions. The British CACS system failed for exactly this reason: as functions were added, it just did not have the capacity to accommodate all of them. It had been just sufficient for a pure ASW ship, but the addition of Sea Wolf must have created problems. The addition of a 4.5-in gun, itself imposing no great computing load, even so was reportedly the final straw.

Third, the computer itself is a point of vulnerability. If it dies, so does the system. In some cases the central computer is really 2 or more machines sharing the computing load. If 1 dies for some reason, the system can be reconfigured to run on the remaining machines. However, reconfiguration normally takes some time, even if some of the machines are running (rather than quiescent) spares. Any temporary loss of the overall tactical picture can be disastrous since platforms reasonably close together may be confused once the system is revived. This is not a new problem, and it has never really been solved.

Fourth, a highly centralized system is not amenable to quick modification. The more centralized the system, the more all-embracing its program and thus the less it can accommodate changes, such as changes in the details of a missile that it controls. This problem also applies to sensors and consoles effectively hard-wired into the central machine.

Against these disadvantages, the central machine has a very important advantage. Since both the tactical picture and at least some of the system functions are bundled together in one machine, it can (at least in theory) execute those functions very quickly to respond to a rapidly developing tactical situation. Clearly such speed can be achieved only if the number of bundled functions is carefully controlled, so the ideal may be a compromise between a fully centralized system and something more federated. The argument against full federation is that each application must wait until it can ingest the tactical picture (or a portion thereof) from the picture-holding (plot-compiling) computer. The argument against full distribution (no central processor at all) will be that each subprocessor must bundle what amounts to a tactical picture and its own application, and that it must lose processing time while amending the tactical picture it holds (using messages from the other processors).

At present, of the major Western combat-system developers, the Netherlands (Signaal) and the United States (NTDS) have opted for more or less fully centralized systems, although considerable amounts of sensor and weapon processing are done outside the central computer. Japanese combat systems are very similar in outline to NTDS. France and Italy have opted for federated systems (TAVITAC, IPN series). Britain, which in the

past favored centralized systems, has opted for fully distributed ones. Of the major foreign buyers, Taiwan has used the H930 modular (distributed) system for some time, and it appears that Korea has similar views. At least in the case of Taiwan, the survivability of the system is an important consideration in making a modular system attractive.

As minicomputers became more powerful, a greater degree of distribution became attractive. The main exemplars are probably the Canadian SHINPADS, the U.S. (Honeywell/Hughes) H930 Modular Combat System, and the British Ferranti 500 and NAUTIS. These systems operate without any central computer at all. The consoles all link to a high-capacity data bus, and all benefit from data-base modifications initiated by any console. This scheme is similar to that employed in fleet-level NTDS, in which all ships share a common tactical picture, but the picture as a whole is not refreshed periodically. Instead, changes are propagated through the system.

For details of the operation of such a distributed system, see the discussion below of the U.S. H930/MCS.

Current distributed systems are based on modern minicomputer technology, the de facto standard apparently being the 68000- or 80286-series processor and the VME internal bus. Examples include the British MINOS, the new Litton console, and the new standard German console.

There are 2 quite different distributed architectures. In 1, weapons, sensors, and processors all ride a common ship bus. Examples are the Hughes H930 and the Plessey NAUTIS. Such a system has no bottlenecks at all. Each processor can execute any function (e.g., track keeping or gun fire control), since all share the same stream of data and messages.

The alternative is to arrange the processors in an LAN, a special-purpose data bus. This bus in turn connects to the weapon/sensor bus or buses. The LAN acts as a central computer complex; but unlike a single-computer system, it degrades gracefully. Each machine in the LAN carries its own version of the tactical picture, updated by actions taken by the other processors (and transmitted within the LAN). Such a system has the advantage that intra-LAN message traffic need not compete with the traffic along the weapon and sensor buses, so picture updates can be quicker and more complete. On the other hand, the nodes at which the LAN connects to the weapon/sensor bus(es) form points of vulnerability. The LAN type of architecture is typified by the Dowty-SEMA SSCS (British) and by the Contraves Cosys 200 (Swiss).

Aside from computer power, perhaps the single central issue in combat-system design is the operator-machine interface. Information must be presented in a manner best suited to very rapid decision. Just as a computer is limited in its throughput, a human operator is limited in the ability to process data presented visually. Different manufacturers have had markedly different responses to this problem. In the case of on-line data, there is a real question as to just how much supplementary data an officer in combat can or should absorb. Some alternatives are described in greater detail below.

In at least 2 systems, the U.S. ACDS (Hughes) and the British Ferranti System 500, effort has gone into supplementing the usual track information with on-line data describing the various targets. The on-line information may be limited to what can be presented in tabular form, or in a very powerful system it may be applied automatically to the track plot. For example, a typical system shows only that an enemy submarine is present at a particular place and that it is traveling at X kt along heading Y. The next stage would be to permit the system to register that the submarine is, say, an Oscar. Once a detailed identification had been made, the system might have an on-line data base that an operator could read. The ultimate stage would be for the system to react automatically to identification by showing, for example, the keep-out zone within which the Oscar might be expected to fire, or perhaps the optimum sonobuoy field locations required for successful prosecution, or even the expected flight profiles of the Oscar's missiles.

Console displays have gone through 3 generations.

The first are radar (analog displays), on which some digital symbols can be superimposed. They can be described, then, as analog with digital injection. The electron guns creating the analog and digital symbols are entirely separate, and the only connection is through the brain of the operator. Many early NTDS consoles exemplify this type of operation. Some early ESM (strobe) displays, on which signal digital data could be superimposed, are of this type.

Then there are pure synthetic-video displays, equivalent to early personal-computer displays. These displays are often described as *cursive* because each symbol is separately written out. They can show symbols and line elements, but they cannot address each pixel of the screen and thus cannot easily combine pictures from alternative sensors. Such displays cannot easily fulfill multiple functions since they cannot be used to dissect or display raw video of any type. Most current displays are of this type.

Then there are pure raster-scan displays, in which the display computer can separately address each pixel on screen. Unlike the earlier radar-cum-symbol displays, raster-scan displays are not synchronized to any particular mechanical radar scan rate. Instead, radar-video data are scan converted to a form compatible with raster display. After such conversion, two dissimilar radar pictures can be displayed simultaneously (e.g., superimposed in different colors). A fully rastered display can show different pictures side by side (windowing) in different scales. Such displays are probably ideal for cross-matching sensor data and are the current trend. They require vast processing power since there are no (physical) hardware character generators.

An important current issue is the value of color. It is argued that the use of color greatly increases the density of information that can be presented, and that monochrome displays cannot begin to provide enough. On the other hand, many people are moderately color-blind, and it may be that a very complicated display overloads the brain of the observer. This is a very difficult practical problem since the issue is one of overload *in combat*, i.e., under great stress that cannot readily be duplicated in a peacetime experiment.

There is also the much larger issue of man-machine interface in the combat system as a whole. The displays are there to help operators compile a tactical picture usable by a decision-making officer (a TAO in U.S. parlance, a PWO in British parlance). That officer may want a composite or summary display physically large enough so others, such as the CO, can discuss the tactical situation. It is difficult to build very large CRTs; this is the same limit that applies to large-screen televisions. At least as of a few years ago, the effective limit on CRT diameter was about 22 in, which is why 22-in displays are so common in the catalog that follows. The current U.S. solution, as manifested in the Aegis system, is a projection screen, similar to that used in current large-screen televisions. Its lines of sight will vary because of vibration, so the image may not be clear, especially during a hot action. At one time the British used a small CRT, photographed it, rapidly developed the film (in about 4 sec), and projected the slightly time late result over a 3-ft distance as the summary (PWO) plot. Some other systems, such as TAVITAC, drive an electronic plotting board, which becomes a summary display.

The ultimate solution to this problem, a large flat-screen television using LCDs, is still some time in the future.

There are also important ergonomic issues. Before computers, the summary plot was a horizontal plotting table, marked up in grease pencil. Generations of naval officers became familiar with it and expected its electronic equivalent to look roughly the same. Numerous systems, therefore, employ horizontal displays, sometimes with several operator positions arranged around them. On the other hand, when CICs were invented, so were vertical plots. A vertical glass board was easier to plot against, and the plotters could work on 1 side while the tactical officers read the other.

It is probably easier for a single operator to read a vertical plot while seated at an associated keyboard. As long as each operator

has a personal console, then, vertical CRTs (similar to those in computer workstations) are probably preferable. Certainly U.S. and U.S.-inspired systems are so configured. As soon as multiple operators must interact at a single summary display (e.g., to save CIC space), then presumably the horizontal or near-horizontal display comes into its own. This choice might be exemplified by the Swedish CEPLO (but note that the Danes are replacing CEPLO with a Terma TDS incorporating vertical screens).

One other line of development deserves mention here: the development up from simple navigational plotting tables. The most elaborate current version is the British CANE. Before World War II, both the Royal Navy and the U.S. Navy developed dead-reckoning tracers, devices in which a spot of light representing a ship's position was driven over a chart. The inputs were ship's speed and bearing. The British version was the ARL (Admiralty Research Laboratory) plotter; the U.S. version was the DRT.

The postwar U.S. NC-2 is the main plot of ships, such as *Knox*-class frigates, which are not equipped with a fully electronic tactical data system. Besides the spot indicating ship's position, 4 targets can be indicated by other spots of light. Inputs are sonar, standard radar indicators (SPA-25 and -50), and a fire-control radar. The points thus displayed are tracked manually, and the only outputs are manual. NC-2 is used primarily for ASW.

DES Defence Equipment and Systems, Ltd., formerly Laurence Scott Defence Systems, Ltd., which manufactured the ARL table, produces the British equivalents of NC-2, the SPL series plotting tables. The current versions store and display own-ship position with automatic scale calculation and chart alignment correction. They can add such tactical features as processing, display, and prediction of contact and target-vessel positions. The simplest of the current series, the "DRT" version, displays own-ship position as a point of light (as in earlier systems) but can also automatically plot using a pen driven by the same X-Y carriage as the light projector. As in the U.S. NC-2, ship's navigational data are taken from the compass and log via synchros (200 pulses/nm, 360°/rev of the compass synchro); it can also be inserted via a keyboard. Radio navigational aids can be connected as an option. The associated chart can be as large as 1016 × 675 mm (40 × 26.6 in); plotting area is 935 × 650 mm (36.8 × 25.6 in), and scale is 1:2000–1:5,000,000.

The more elaborate "AIO" version uses a white spot to indicate own-ship tracks and red and green spots for contacts; tactical information from ship sensors is fed in via the keyboard. The automatic pen provides tracks on demand, and a plasma display screen provides stored and calculated data, such as track histories. Tactical information can be provided to ship sensors. DES considers the AIO table an inexpensive alternative to CANE, a statement that shows to what extent the 2 categories, the simple plots and the tactical data systems, have merged.

DES also offers an "MCM" version of its basic plotter, driven by a 16-bit microprocessor. The plot is more precise than in the other systems (large scale is 1:1000, and plot accuracy is to within 1 mm, corresponding to 1 m of real distance). All position and classification data are stored on disk. The paper or film on which data are plotted is scrolled across the plotter by tractor feed. A roller ball allows the operator to transfer topographical features from a working chart to a larger-scale sweep chart. Inputs include navigational aids such as Loran, selected by the operator. The "MCM" table can show a standoff radius (SOR) from a designated point and also warns of drift from a fixed station.

CANADA

◆ SHINPADS

Shipboard Integrated Processing and Display System was developed as the result of a 1974 study of alternative architectures for combat systems. SHINPADS was one of the earliest fully distributed (data bus) systems, chosen because digital equip-

A typical, modern, automated CIC in a small combatant. The vertical console in the background is fed by a sensor (or connected to a weapon). The console in turn is connected to the horizontal summary display in the foreground. The captain or executive officer can use this display to see the tactical picture and to assign weapons to targets. Note the trackball toward the front of the display: such communication is almost completely electronic, targets being entered by ball and keyboard. (CMN)

ment was no longer so expensive that all processing had to be concentrated in a single central computer. All users have access to the entire data base, and consoles are interchangeable (for graceful degradation in case of damage or breakdown). The data bus itself was designed to be transparent to standard NATO interfaces; thus, existing equipment could be connected to the bus.

Although SHINPADS was conceived in 1974, it is only now being implemented, in *Tribal*-class destroyers, under the TRUMP program. In these ships it supersedes the centralized NTDS-like system, CCS-280, which was built around a single Litton USQ-501 (L-304F) computer. SHINPADS is also being installed in the new "City"-class frigates.

Distribution is on 3 levels: by location throughout the ship (for survivability), by function, and by control. All of the mini-computers of the system can be applied to any role, e.g., to processing an array's data. The only difference between, for example, a fire-control computer and an engine-control computer is the software that they are executing. All of the computers are UYK-20s.

The data bus is designed to accommodate up to 256 users, with a maximum length of 300 m. Up to 16 users can be given priority access, if their functions are particularly time-critical. For example, fire-control equipment requires updated information about every 50 millisecc (i.e., about 20 times/sec). That rate can be achieved because the average user's access time is less than 100 microsec. An analysis of typical frigate requirements showed that the data bus would have to pass at least 3 million bits/sec, and the design capacity is over twice that rate (actually 8 million bits/sec [10-MHz clock rate]) to prevent delays. The standard message may have as many as 254 16-bit words, although a special block mode allows much longer messages to be sent.

The bus uses a pair of triaxial cables but is compatible with a future upgrade to fiber optics. To ensure survivability, 1–4 additional bus cables can be added for redundancy. Any 2 of the cables can then be selected as the operating or primary bus. Bus control can be assigned to any node (user interface); if the control node fails, another can replace it.

Messages are sent broadcast, i.e., through the entire data bus, and addressed so that each user can pick off its own messages. Messages intended for several users do not, therefore, have to be retransmitted. There is also a point-to-point signal mode, in which a message is sent to a specific user.

SHINPADS is designated UYC-501(V).

The display is the Computing Devices Company UYQ-501(V),

navalized version of the company's MSD-7001. UYQ-501 is part of a standard Canadian Navy family of digital equipment, using a 19-in, 1024 × 1024-pixel CRT, with 4 Mbits of RAM to service its display. It can, therefore, show complex overlays. The associated graphics processor has 8 Mbits of RAM and can operate in 8 colors. Alternative modes are 525, 625, 875, and 1025 lines of television resolution. This standard console is used in the current Canadian Navy programs: DELEX, TRUMP, and the new frigate.

CDC describes MSD-7001 as part of a line of MAGICS (Multimode Advanced Graphics and Imaging Systems) consoles for command and control. The next version, MAGICS 2, is built around 68020 processors, which allow for simultaneous display of up to 14 outputs on a 19-in screen. Two screens are accommodated vertically in a 24-in console, with a standard VME-bus chassis below. MAGICS 2, intended for the German requirement won by AEG (see the German section below), began tests early in 1989.

◆ CCS-280

CCS-280 is the *Tribal* (DDH 280) class's command/control system, now being superseded as the ships are rebuilt. These ships were intended as squadron flagships and as such can send and receive Link 11 messages as well as Link 14. CCS-280 is built around a single Litton USQ-501 (L-304F) computer, connected to 7 multifunction situation-display consoles (SDC) in the operations room (CIC), connected in series, i.e., sharing the same data base held by the main computer. One console is used for command; the others can shift in role from situation to situation. Typically, 1 is used for air and 1 for surface detection and tracking. One might be used to control the ship's helicopter; others might be used for target evaluation, intercept direction, weapons coordination, and engagement monitoring. There are separate dedicated consoles for sonar (feeding the ASW computer), for fire control (feeding a fire-control computer, for the 5-in gun and the Sea Sparrow missiles), and for EW (feeding a data processor). Link 11 also feeds directly into CCS-280, as do the main navigational sensors (gyro and log). The 32-bit computer has a capacity of 40 kwords (expandable to 80k), and the displays can show objects at ranges of up to 152 nm. This system was 1 of the earliest applications of fault-isolation software.

The consoles show both raw and synthetic video. Operators communicate with the consoles via light pen, keyboard, and trackball. Tracking is manual with update (i.e., rate-aided), and the system can handle surface-target speeds of up to 64 kt and air-target altitudes up to 64,000 ft. CCS-280 can store up to 237 tracks (of which 50 may be targets). Like NTDS, CCS-280 conducts TEWA and also directs interceptions (in this case by both aircraft and the assigned ASW helicopter). The system can also display alternative tactical options.

CCS-280 was installed on board the 2 *Annapolis*-class frigates as part of their DELEX (Destroyer Life Extension) modernization.

CCS-280, then, is a small-ship NTDS equivalent, roughly contemporary with the German SATIR. The Canadian Navy described it as the first operational micro-electronic tactical data system for shipboard situation assessment and control.

A recent Canadian tactical-data history remarks that the "Tribal" design was the first in which the operational requirement emphasized adequate data-exchange capability. The design was federated: the central command/control system interfaced with autonomous weapons- and ship-control subsystems. Thus, the subsystems could continue to function if CCS-280 failed. They would lose their ability to communicate by data link with other ships. Similarly, the failure of any subsystem would not crash the system as a whole. CCS-280 was also intended to support a group commander as well as a commanding officer. This modular design was a new concept, and presumably it was conceived as a way to avoid the computer-capacity squeeze experienced in the fully centralized AIS 240.

The design contract was awarded to Litton (Canada) in September 1966; the main combat subsystems were UCS 280

(ASW), SAWS (surface- and air-warfare system), and EWIS 280 (EW system).

◆ ADLIPS

Automatic Data Link Plotting System, a "poor man's NTDS," was developed as part of the Canadian DELEX (Destroyer Life Extension) program. Like NTDS, ADLIPS integrates shipboard sensors and provides both Link 11 and Link 14 capability. Until ADLIPS had been installed, only the 4 *Tribal*-class destroyers had Link 11 capability. Thus, the older ships could not rapidly exchange ASW data, nor could these ships fully integrate with the *Tribals*. The ADLIPS contract was awarded to Litton of Canada.

Like NTDS, ADLIPS displays both raw radar data and synthetic video, including data received over Links 11 and 14; it also replaces existing obsolete electro-mechanical plotting tables (such as dead-reckoning tracers). ADLIPS was developed using only existing components, which had to be integrated with the existing sensors.

The central computer is the standard U.S. UYK-20(V) mini-computer, rather than the UYK-7 used in contemporary versions of NTDS. The key system decisions seem to have been to minimize the actual computing load (e.g., in target evaluation), and also to distribute that load (e.g., to rely on the existing computerized EW and ASW systems). The only weapons directly controlled by the UYK-20 are the gun and any missile the ship might carry (the ships involved carry only ASROC).

Link 14 data are entered directly (which is unusual in NTDS systems) through a special interface. There is an analog-to-digital converter for radar, log/gyro, and sonar data (the converter transmits data to the gun), and the UYK-20 connects directly to the Canadian ASW Data System (ASWDS), where that system has been installed. A similar computer-to-computer channel connects the ship's EW system with ADLIPS. Finally, Link 11 and other encrypted digital data links feed directly into the computer via a modem and a decrypter.

The main display is the Situation Information Display (SID), a 20-in CRT showing raw video, IFF data, and synthetic video. There are 3 operating stations around the horizontal SID, each with its own trackball and alphanumeric keyboard. This type of display was chosen to minimize space requirements in a relatively crowded operations room (CIC) already filled with radar and sonar displays. There are also 22 × 22-cm plasma displays, which show only synthetic video (bridge, EW control room). The system can carry 140 tracks (100 moving, 40 static) plus 6-min track-position histories for 25 targets and velocity vectors for the 100 tracks. As in NTDS, the operators at the consoles detect the targets, so that each SID can insert 3 targets into the system simultaneously.

The system is federated, in that each SID carries its own replica of the data base and carries out its own display-related computations. However, most of the computing power of the system resides in its central computer. Litton sees the duplication of the data base in the SIDs as insurance against the failure of the central computer.

Development began in August 1979 to replace manual plots in non-TDS ships. ADLIPS is interesting as the simplest and least expensive mechanization of such plots and, thus, should have had considerable export potential. In fact, it never sold abroad, but Litton Canada is trying again with ADLIPS 90. The Canadian Navy bought a total of 19 systems, 3 for its Fleet School and 16 for installation in the *St. Laurent* (2 SIDs, 2 plasma displays), *Modified Restigouche* (2 SIDs, 2 plasma displays), *Mackenzie* (1 SID, 2 plasma displays), and *Annapolis* (2 SIDs, 2 plasma displays) classes. Installation required only about 10 weeks.

The ADLIPS concept was first proposed in a Fleet Operations Study in 1968; the problem as then understood was that ships without a Link 11 capacity could not take full advantage of information available to those with modern tactical data systems. In 1969 the Canadian Navy headquarters proposed a solution in which Link 14 data were automatically projected opti-

An ADLIPS situation information display (SID) in the operations room of a Canadian escort, showing 2 of the 3 sets of keyboards and trackballs. (Litton Systems Canada)

cally onto a perspex surface. That idea, in turn, led to a Canadian Navy Operational Requirement (OER M3/72), released on 8 February 1973, calling for a system that could receive, filter, and plot either Link 11 or Link 14 data (but not both), with Link 11 (digital information) the first priority. In fact, as installed, ADLIPS can receive and display both types of information. The first R&D contract was awarded in June 1973 to Computing Devices Co. of Ottawa, and a prototype system was delivered for initial tests in August 1975. A shipboard prototype went to sea aboard HMCS *Athabaskan* in July 1976. The first production installation was in HMCS *Skeena* in October 1981; the last was in 1985.

The designers sought to limit costs by avoiding any new equipment; hence the use of the standard UYK-20 computer. The only entirely new elements are some unique interface cards and the software.

◆ ADLIPS 90

Like the original ADLIPS, ADLIPS 90 is conceived as a minimum-cost tactical data system. It is built around a UYK-44 (programmed in CMS-2M) and, like ADLIPS, uses a combination of 3-operator SIDs and 1-operator plasma displays. This centralized tactical data system achieves low cost (and, it would appear, software simplicity) by avoiding distributed processing. The design can accommodate a second UYK-44, and each computer has a battery backup in its cabinet. These computers can have up to 1 Mbyte of static RAM.

The system maintains a series of plots (air, surface, subsurface) and can designate targets to own-ship weapons. It can also conduct TEWA; and given its 2-way links, it can coordinate operations with other platforms. The stored tactical plot covers a 1000-nm area. Capacity is 200 dynamic and 80 static tracks (including number, position, and symbol), 6-min history trails for 50 tracks, and velocity vectors for the 200 dynamic tracks. Available graphics include engagement lines, bearing lines, sector screens, intercept lines (presumably ESM bearings), furthest-on circles, and torpedo danger zones.

DENMARK

◆ StanFlex 300 System

Standard Flexible 300 is the first combat-information system designed specifically for rapid reconfiguration. StanFlex 300 consists of 3 standard 2-position multipurpose consoles (each including its own ruggedized commercial-type VLSI computer) on a data bus that also connects the consoles to modular weapons and sensors. The latter can be replaced, using only dockyard

cranes, in 24 hr, and the system reconfigured by software substitution. Up to 3 additional consoles can be added to control additional weapons or other systems. All weapons control is centralized in the Operations Room (there is no local control at all in a classical sense). This type of operation requires very high computing capacity at each machine; the Danish Navy states that the total computing capacity of a StanFlex is 30,000 times that of the first Danish small-ship system, which entered service as recently as 1978. A fiber-optic data bus was considered and tested, but instead a conventional 10-Mbit/sec shielded cable has been used. The bus is duplicated to ensure its reliability.

It was originally expected that the machinery would be monitored and controlled from the single data bus so that the ship could operate with an unmanned engine room. The full integration of machinery with the command/control system proved too difficult, and instead the machinery forms a separate subsystem that feeds into the main data bus.

The StanFlex program began as a feasibility study in 1982; project definition followed in 1983, and funds for 7 ships were approved in 1984. The first ship, *Flyvefisken*, was delivered in December 1988. The number "300" is the nominal displacement of the ship (actual displacement depends upon which weapons and sensors are installed at any time). The Royal Danish Navy hopes to fit a similar system to a frigate-sized ship. As an indication of the degree of flexibility built into StanFlex, the same ships are intended to function as missile- or torpedo-armed fast attack craft and also as minehunters, roles that in the past have been absolutely incompatible. In this case, minehunting is possible only because the ship can deploy and control remotely operated vehicles, such as the Swedish SAM and the German Troika, and submarines comparable to the German Pinguin. The minehunting sonar system is the French IBIS 43.

Terma was responsible for the basic system, which employs a Swedish (PEAB 9LV200 Mk 3) fire-control system.

◆ TDS

Terma's Tactical Data System grew out of a Plot Data System (PDS) developed for fishery protection ships; the prototype was aboard the *Vaedderen* in 1982. The Royal Danish Navy saw PDS as a possible approach to a low-cost tactical data system (much like the British CANE) and let a contract in December 1984. The first unit was installed on the fast patrol boat *Bille*.

The Terma tactical data system, with 2 local operational plots (LOPs) flanking a General Operations Plot (GOP). Each LOP has a system terminal (ST) underneath; the ST consists of a pair of plasma displays, a roller ball, and a keyboard. The console between the 2 LOPs handles the data link. (Terma)

The system uses a Motorola 68000-series microprocessor, a VME bus, and Pascal and C-language software. The main elements are the local operator plot (LOP) and the general operational plot (GOP). In a typical installation (*Hvidbjørnen*), the GOP is flanked by 2 LOPs, each of the latter incorporating a system terminal (ST) for data entry.

The LOPs are the operating consoles; the GOP is the summary plot. The latter is a 20-in, color, raster-scan CRT, showing up to 240 tracks (including those received via data link). It stores 1 large and up to 8 small maps, and up to 400 mine positions. Because the GOP is a summary display using external data, it incorporates a latitude-longitude grid (rather than a polar grid centered on the ship). It can display data in 8 colors, and range scales are 2–512 nm.

Each LOP carries a 16-in CRT showing both raw and superimposed synthetic video and up to 50 tracks. Its memory can store up to 8 small maps, each composed of up to 20 vectors. The display also incorporates 2 vectors for measurement purposes and 2 index lines for navigational purposes, as well as optical sight lines and helicopter approach patterns. There are 8 range scales (0.5–128 nm). The associated ST is a keyboard with dedicated function keys, a roller ball, and 2 alphanumeric plasma displays (totes).

The Royal Danish Navy has ordered 20 TDSs to replace the CEPLO systems in its fast patrol boats and fishery-protection ships, and the system has been offered for export. PDS, the forerunner of TDS, was itself a conversion of the Danish version of the Swedish CEPLO. Terma added the tactical aspect to form TDS. The version in the StanFlex corvettes uses TDS components but adds a new computer.

FRANCE

◆ SENIT/TAVITAC/Vega/CTH

Système d'Exploitation Naval des Informations Tactiques, SENIT, is equivalent to and derived from the U.S. NTDS. As with NTDS, SENIT is a national system developed by the government laboratory system. The associated CPM (Navy Programming Center) was established in 1963. TAVITAC (*Traitement Automatique et Visualisation Tactique*) is the Thomson-CSF export version of SENIT. The current type is also known as Vega IIC, Vega having been an earlier Thomson-CSF combat system for fast attack boats.

Versions:

SENIT 1 is for *Suffren*-class anti-aircraft cruisers with a 3D radar. The radar has an automatic plot extractor, and the system as a whole uses 3 Univac 1212 (CP-642) computers: 1 carries the 3D air picture and provides TEWA; a second is provided for redundancy; and the third controls the Malafon ASW missile. The version in the cruiser *Colbert* incorporates a data link to other SENIT-equipped ships. Each UYA-4 console (built under license by Thomson-CSF) shows up to 70 tracks and 96 symbols.

SENIT 2 is a destroyer-size version of SENIT, developed in collaboration with West Germany and thus leading to the German SATIR system. There were 2 versions, 1 for fleet air defense and 1 for a radar picket linked (by radio teletype) to the French national air-defense system, STRIDA. This version has 1 computer. A version incorporating the Tartar surface-to-air missile has 3 computers. SENIT 2 was installed on board 8 destroyers: 3 modified radar pickets (*Surcouf* T53 class), 4 destroyers fitted with the Tartar anti-aircraft missile (*Surcouf* T47 class), and the ASW destroyer *Duperre*. The Tartar refit included replacement of analog fire-control computers with digital units adapted to SENIT. The carrier *Clemenceau* was fitted with the SENIT 2 system taken from the inactivated destroyer *Jauréguiberry* during a September 1977–November 1978 refit. *Foch* was fitted with the SENIT 2 system of the inactivated destroyer *Tartu* during a July 1980–December 1981 refit. SENIT 2 was also planned for the helicopter carrier *Jeanne d'Arc*, but by 1987 this project had been dropped. The computer is Univac 1212 (CP-642).

TAVITAC CIC, showing the command-and-control consoles in place. (Thomson-CSF)

Typical TAVITAC display (western Mediterranean). (Thomson-CSF)

SENIT 3 is a 2- or 3-computer version (with memory extensions) for ASW ships, capable of also handling a tactical air picture. There are 8 tactical consoles, corresponding to the sensors, plus weapons consoles and a computer-driven plotting table. The associated computers are Univac 1230s, and the displays are UYA-4s. This system is on board the destroyer *Aconit* and the 3 F67 (*Tourville*)-class frigates.

SENIT 1, 2, 3 all employ American computers and Hughes UYA-4 consoles and, thus, are fully analogous to NTDS. These are central-computer systems (in some cases, computers are ganged together). Later versions of SENIT introduced French computers.

SENIT 4 is a French-designed system built around the IRIS 55M computer and a new Vizir display with 16-in CRT, keyboard, and trackball. The software language is Maxiris or LTR. There are 10 consoles, each of which can display 130 tracks, plus up to 12 lines each of 18 alphanumeric characters, and 23 lines of target vectors. This is the system in the *Georges Leygues* class. It was planned for the 2 carriers, but existing SENIT 2s were installed instead.

SENIT 5 is a small-ship (2000–6000 ton) version announced in 1976. This is the first federated-architecture version, employing the 64k CII 15M computer. This architecture replaced a central-processor design built around an IRIS 35M computer (16–256k) with 5 Vizir displays, each of which could carry 40 tracks. In the federal-architecture form it consists of a computer, a tape drive, a 3-function RVP (plot extractor), an analog/digital interface, and 2–5 consoles. This modular design allowed for relatively easy addition of facilities, e.g., ASW helicopter control, automatic IFF code extraction, computer extension for Link 11 management, interfaces with weapons-system computers, and disk storage management. There was to have been a PLAD automatic plotting table connected to the system. In the federated version, each console could carry 40 tracks plus 20 symbols and 3 lines each of 18 alphanumeric characters. The system as a whole could carry 60 tracks. SENIT 5 was planned for the A69-class corvette, but it was never used. It is therefore of interest mainly as a step toward SENIT 6

SENIT 6 is a federated system for the *Cassard*-class AAW frigates, built around six 15M/125X minicomputers. A seventh is kept in reserve, and ships have sufficient space to add an eighth (which will be required to handle Link 16). The computers are located in 2 separate rooms, fore and aft. The ship is arranged in 6 subsystems, each presumably served by 1 of the 6 running main computers. Each subsystem has several 15M05E computers for local processing and constitutes an LAN. The subsystems, in turn, are linked by a 1-Mbit/sec Digibus.

One of the main computers runs the display subsystem, carrying the tactical picture, and is connected to 11 single-operator consoles, one 2-operator console (for CO and TAO), and 2 Precilac navigational tables (for ASW: each can carry up to 20 tracks).

The other main computers are dedicated, respectively, to sensor processing, TEWA (for self-defense), area air defense, ESM/ECM, and the data links. The ASW function is autonomous, linked to the system bus. Much of the processing for each weapon and sensor is done locally, outside the system bus.

TAVITAC, also known as Vega IIC, is an export version of SENIT 5, using a less capable microprocessor (15M/125F, with a capacity of 128k, expandable to 512k). TAVITAC has been exported to Saudi Arabia, Colombia (FS-1500-type frigates), and Tunisia. In the Colombian and Tunisian version, the standard console can automatically track up to 16 targets, air or surface. The standard destroyer or frigate installation is 2- or 4-operator consoles, plus a summary console for the TAO. Each console can display 16–32 tracks. There is also provision for a non-NATO data link (e.g., Link W). An expanded version, with 10 consoles, is equivalent to a large-ship SENIT installation.

The Saudi version is more elaborate, with 6 consoles plus an E7000 tactical table. Each console consists of a CRT plus a second display (alphanumeric, television, or plasma), a keyboard, a roller ball, and a video-display panel. The CRT can be monochromatic or color, circular or rectangular. It can carry up to 200 tracks and 100 symbols.

The PRC navy ordered TAVITAC in 1986 for the modernization of 2 Luda-class destroyers.

The next-generation development is TAVITAC 2000. Its main new feature is that it uses hardened civilian equipment instead of specialized military types. Reportedly, TAVITAC 2000 costs half as much as an equivalent system using specialized computers. Economies are so great that Thomson-CSF claims that the cost of the new FL 3000 (*La Fayette*)-class frigate's command/control system will be less than 5% of total cost.

Like earlier SENITs and TAVITACs, TAVITAC 2000 is a federated system built around 1 (in the *La Fayette* class, 2) tactical picture-keeping computers [each with 6 Mbytes of active memory and two 40-Mbyte hard disks]. However, other subsystem computing will be conducted by microprocessors in the Vista consoles. A *La Fayette* system will employ 5 consoles (with space for a sixth); TAVITAC 2000 architecture can accommodate up to 15. All are connected by a 5-Mbyte/sec VME bus, and all are programmed in ADA. Each console contains several 68020-series microprocessors and carries up to 3 displays stacked vertically: two 20-in, high-resolution, raster-scan units (1024 lines $\times$ 1280 pixels) and, below them, a smaller CRT to display alphanumeric data.

The system as a whole can carry up to 800 tracks within a 512 nm radius. Up to 32 ESM and 5 local sonar tracks can be carried and displayed as synthetic video. Each console can handle the entire track file, and the tactical picture is updated through a double buffer (the system need not wait while the picture in the central computer is being updated). A full picture (300 tracks, 30 circles, 30 ellipses, 500 vectors, 2000 shoreline elements, and 2000 characters) can be built up in less than 0.3 sec. Raw radar video can be superimposed on the synthetic video of the displays.

The next-generation Thomson-CSF Cimsa Sintra display is VLX, with a 14- or 19-in color or monochromatic raster display (2000 $\times$ 2000 pixels.) Each such CRT can be supplemented with 9-, 12-, or 15-in plasma, liquid crystal, or electro-luminescent screens.

SISC (*Système Intégré du Système de Combat*) is another SENIT 6 development, in this case being conducted by CPM, for the new French nuclear carriers. The design is still incomplete, but CPM hopes to use 5 to 6 ruggedized civilian computers, each with 5 or 6 times the power of the SENIT 6 computers. One will be a spare, and another will service a new flagship command-assistance system, Aidcomer, broadly comparable to the U.S. FDDS. There will be 20–22 display terminals, each more powerful than the TAVITAC 2000 terminal, and 3 tactical tables. SISC will be tied together by 5 Ethernet D buses. Software may be a mix of ADA and the CPM-written LTR 3.

Vega is a series of modular, small-ship, weapons-control systems and tactical data systems. It is comparable in concept to the contemporary Dutch M20/WM20 series (and to their extensions as mini-combat systems), to the Swiss Sea Hunter, and to the Swedish 9LV200 series. In each case a dedicated air tracker (Castor, Castor II, or Pollux) is combined with a surface-search radar (Triton). In the basic version, targets detected by the main search radar are designated to the dedicated tracker. Versions designed to control Exocet missiles and/or wire-guided torpedoes use the surface-search radar in TWS mode, the main system computer conducting the associated calculations. Vega is unusual in that it is often extended to a full CDS.

Thomson-CSF chose a nonstabilized TWS antenna (Triton) because it can be mounted higher in a ship, for a gain of about 4 km in range, equivalent to 3 min of warning on a 40-kt target. Overall, the system's ECCM benefits from the use of 2 dissim-

lar radars (Triton and Castor/Pollux). Doppler filtering is used to reject clutter, and the system is partly digital.

Vega systems can be divided into Vega I, which uses a hybrid digital-analog computer (BCH), and Vega II, which uses a digital computer (CDE). Before Vega II appeared, Thomson-CSF designated different versions by which search radar and which weapons they use. Vega Triton versions lack any search radar, relying instead on a Lynx optical director. Thomson-CSF designates later versions of Vega I, which use an optical tracker, as Canopus, Canopus A being the simplest (with only the optronic tracker and a TWS radar; it is broadly comparable to the Radop FCS). Canopus B is Canopus A with an associated SATIN B computer; it can handle 16 targets. Canopus C is the same system with a Pollux tracker. Pollux is also the designation for an earlier fully analog system, now apparently extinct. All versions except Vega Pollux PCET (Exocet/Torpedo) incorporate a Lynx optical director.

Vega I typically employs 3 vertical consoles side by side: the fire-control computer, a large-CRT (14-in PPI) search-radar/target-designation console, and a small-CRT console with 1 or 2 joysticks (the air tracker). An additional console can be added to control wire-guided torpedoes.

Vega Castor and Vega Pollux use a digital gunfire-control computer. The simpler Vega Pollux PC/PCET uses an analog gunfire-control computer (for calibers of 57 mm and smaller). The Exocet and torpedo versions of the system (Vega Pollux PCE and PCET) provide the search radar with TWS capability; the main system computer also calculates launching data. In the case of torpedoes, guidance data are displayed on the main surveillance PPI. In these versions the big PPI shows the relative bearing and range between the radar-carrying craft and the target (RBL); it also shows the collision course, the time to intercept a track (CTS), and the CPA. It extrapolates target tracks, generates fixed points, and calculates time since initiation. Data are entered by keyboard. The associated modular (analog/digital) BCH computer has a typical operating time of 2–5 microsec. It conducts FCS calculations for guns and wire-guided torpedoes and can also be adapted to the Bofors 375-mm rocket. BCH also stabilizes the display (when an unstabilized search antenna is used); controls and stabilizes the tracking radar(s) in autonomous search mode; and conducts memory tracking (rate-aided or coasting tracking), constant altitude tracking, elevation search, and ship's speed compensation for MTI receivers.

By about 1974 Thomson-CSF offered 2 search radars as alternatives to Triton: Saturne II and Sea Tiger. The Saturne II version was presumably intended for a possible refit of Swedish destroyers that had originally been equipped with Saturne I radars, but it never entered production. Sea Tiger was used in large-ship versions of the Vega II system by Colombia and Saudi Arabia. At this time the company distinguished between 2 alternative tactical information units (TIUs), Vega I and Vega II, and the company assumed that both versions would use the BCH computer.

The original Vega could be combined with a tactical data system to form SATIN (*Système de Traitement Automatique de l'Information Navale*). SATIN A provides rate-aided tracking of 6 air or surface targets and can also show 1 sonar track and 1 ECM strobe; labels can be applied to all the tracks, and they can be handed off to weapons. The system can solve simple tactical problems, such as azimuth/range to slew to a position or CPA. It uses the main 16-in CRT. SATIN B employs a second hard-wired computer. It automatically tracks 16 air or surface targets by means of a plot extractor (it can revert to rate-aided manual tracking when clutter confuses its automatic tracker), and it automatically displays IFF data. The computer can support 1–6 multipurpose operator consoles (command, weapons allocation, surface and air search, helicopter control). This is a true small-ship CDS, complete with data link (Link W). Capabilities include true-motion display, geographic squaring (conversion from own-ship coordinates, a function that is necessary for data linking), target designation, and tactical computations such as CPA, track extrapolation (time to go), and vectoring to

intercept. SATIN B was derived from equipment developed for a mobile land-based air-defense system, MIDAS. It became Vega II.

Development of Vega I began in 1967, with first sea trials in 1971 on board the Greek *Ipoploiarhos Konidis* (formerly *Kymothoi*), followed by Exocet trials in 1972. This version was designated Vega Pollux PCET (Pollux radar, E for Exocet, T for torpedoes; PC indicated a single rather than dual optical target designators). The first major customer was the German navy, which bought Vega I/43 for its Type 148 missile boats. In this series, Vega Triton lacked any fire-control radar, and Vega Castor used the Castor rather than the Pollux FC radar.

As of 1976, more than 80 Vega systems had either been delivered or were being manufactured; the total is now about 100. Included are 4 for the Greek Combattante II-class missile/torpedo boats (and the first 4 Combattante IIIs) and 20 for German S148s. Other versions:

Vega Canopus A Ghanaian TNC-45 and PB-57 classes.

Vega Pollux Ecuadorian *Manta* class (FPB-36 type; navigational radar and Pollux only); Ecuadorian *Quito* class (TNC-45 type: Triton search radar); Malaysian Combattante IID (*Perdana* class); Portuguese *Baptiste de Andrade* class (using AWS-2 search radar and Diodon sonar; can be fitted with Exocet missiles).

Vega Triton (no tracker) Libyan *Ibn Ouf*-class landing ships.

CTH Because Vega is essentially an FCS, the French navy designates it as CTH (*Conduite de Tir Hybride*). In this form it equips the *Georges Leygues*, *Tourville*, modified T53, and *d'Estienne d'Orves* classes. This version uses the DRBV 51 (higher-gain Triton) and DRBC 32 (instead of Castor) radars.

Vega II was initially the SATIN B system described above. As initially offered in 1974, it was an alternative version of the same basic system (TIU II instead of TIU I); all Vega systems were built up from surveillance radar, tracking radar (including TWS for the search radar), TIU (I, II, and an optional plotting table), computer (BCH plus an optional BCH for ASW), and weapons. The TIU could include an ECM console and a navigational display fed by a navigational radar separate from the 2 main radars.

The Vega II prototype was completed in 1975. The system used a new vertical console with a 16-in display, and it could accommodate a horizontal summary console (22-in CRT) that could carry 16–64 tracks. Versions so fitted were called TAVITAC, in analogy with the earlier SATIN (see TAVITAC, above). As with SATIN B, they could use Link W. It seems unlikely that the non-TAVITAC versions could use any data link since they would lack the capacity to translate coordinates automatically from rectangular to own-ship form. Thomson-CSF offered Link 11 as an option, but the only NATO navy definitely to have bought Vega II, the Greek navy, bought it in non-TAVITAC form.

Vega II added MTI for the Triton TWS radar, a new X-band monopulse tracker (Castor II), and a much more powerful fire-control computer capable of handling 16 rather than 2 targets simultaneously (so that it could engage several targets simultaneously, or shift very rapidly to a second target once the first had been destroyed). The FCS radar had an associated television, the screen for which was on the fire-control console. Unlike the earlier fire-control console, this one had 3 square screens, which might mean there was a radar B-scan alongside the television image, with an optronic director image on the upper screen.

All versions of Vega II currently employ a pair of optronic directors. The fast-attack versions listed below use Pandas (NAJAs in the II/83 version for Tunisia). Only II/53 and II/73 are TAVITAC versions.

Versions:

Vega II/12 The simplest version, without any fire-control radar. This version may be identical to the Radop described under FCSs in the Antiaircraft Warfare section.

Vega II/43 Large strike-craft version, with both radars and 2 consoles (surveillance and fire control). On board Greek Combattante III missile boats (Triton II MTI and Pollux radars). This is probably the Libyan form of Vega II (but with Triton II MTI and Castor IIB radars), on board Combattante IIG-class fast attack boats.

Vega II/53 Fast missile boat version, adding a tactical table to II/43. On board Qatar Combattante IIIM-class fast attack boats (with Triton S and Castor IIB radars).

Vega II/73 Fast patrol boat/ASW corvette version, capable of controlling antimissile weapons (Triton S, Castor II radars); 2 display consoles and 1 fire-control console, with 1 tactical table. Triton S is a coherent radar with much-improved MTI and can detect and track incoming antiship missiles. On board Nigerian Combattante IIIG-class missile boats (using Triton MTI radar).

Vega II/83 Fast patrol boat version with Triton S and Castor IIB, but without the tactical table. On board Tunisian Combattante IIIB missile boats.

Vega II/89 Frigate version, with plotting table, sonar, and 2 BCH computers; the radars are Sea Tigers (TWS) and Castor II, and there is also a Canopus director aft. Each radar/optronic director feeds its own fire-control console, and there are 2 tactical tables and 3 display consoles. The use of 2 high-performance, MTI/doppler, fire-control radars in different bands makes for good capability against sea-skimming missiles. Signal separation between these radars is not as good as in versions using Triton search radar (30 dB rather than 50 dB), but because it is frequency-agile, Castor is less vulnerable to ECM. This is the version on board the Colombian *Almirante Padilla* class.

In addition, the Peruvian PR72P class FCS (Triton and Castor II radars) is probably a Vega II.

Vega III is the large-ship version of TAVITAC developed for the Saudi frigates; it is also presumably the version sold to the PRC navy.

A new version of Vega is currently under development, presumably incorporating the MRR radar in place of both the search and tracker radars of the earlier version (it is described as a coherent tracker). The associated console will probably be the Thomson-CSF color VLX (2000 × 2000 pixels) first shown at Bourget Naval in 1990.

This system may be associated with the low-cost, small-ship, command/control system that the French navy was reported considering in 1989, to allow small ships and aircraft to benefit from Link 11. Presumably, it would be applicable to the new surveillance frigates.

GERMANY (WEST)

◆ AGIS

This command/control system for fast attack boats (*Automatische Gefechts und Informations-system Schnellboote*) uses a data link to exchange data with shore stations, with SATIR-equipped surface ships, and with surveillance aircraft. The ship-board end of the system employs 2 programmable computers, 1 to generate and utilize the tactical situation and to assign targets to the various units of the flotilla, and the other to regulate fire control for the ship carrying the system. AGIS supports 2 torpedo-control consoles, 1 gun-control console, a horizontal tactical display, and a vertical plot. It was designed specifically for Type 143 boats, which were intended to act as flotilla leaders for Types 142 and 148; hence the need for sophisticated data processing, including input from external command systems (via Link 11). The computers are Univac 1830Bs, programmed in the Sycol language. They feed Signaal consoles.

AGIS entered service in 1976, providing a link with the central German maritime headquarters (MHQ) ashore. That link in turn permitted MHQ to form mixed battle groups, including both fast attack craft and aircraft, because MHQ could be sure of the precise location of each during combat. Otherwise, the aircraft might well have killed the fast attack boats by mistake.

The original Type 143 boat carried 2 torpedo tubes aft and required a pair of specialized torpedo-control consoles to control their wire-guided weapons. A modified Type 143A lacks the torpedo tubes (which, with the after 76-mm gun, are replaced by a RAM defensive missile launcher). The space freed by the elimination of the 2 torpedo-control consoles is used to expand AGIS into a Mk II configuration; a multifunction display console is installed. It in turn makes possible combined helicopter-attack boat operations, and this installation of AGIS II is associated with the program to modify German Sea King helicopters to fire antiship missiles. Boats fitted with AGIS II have active and passive ECM integrated into their combat systems.

The German Navy plans ultimately to convert all Type 143 boats to AGIS II configuration, with improved air defense (RAM and ECM). These boats will cooperate with 20 Sea Kings, converted from the search-and-rescue (SAR) role to the surface-attack role, using new radars and carrying Sea Skua missiles. The helicopters will also provide OTH-T for attack boats using Link 11.

From 1982 on the older Type 148 boats were fitted with PALIS, the passive-active link data transmission (and sharing) system. It had been developed during the AGIS program and was intended to unify the tactics of the German fast attack boats. With PALIS, any fast attack boat could cooperate with other units, even dissimilar ones such as destroyers, and with MHQ. Given this system, Link 11 information for the construction of a current tactical picture could be relayed, stored, and correlated with own-ship data as well as with own-ship sensor information. By using electronic data processing, reaction time could be drastically reduced.

PALIS is also installed on board German Type 323 (*Hamel*-class) mine-countermeasures craft.

The specially built ashore MHQ supporting the deployed boats originally used 2 IBM 370/168 computers, which could handle 40 plots/sec. Development of the new MHQ information system began in 1972; the basic system was ready in 1980. As of 1986, work was proceeding on an enlargement to handle all NATO BALTAP command/control, bringing the modernized coastal-radar chain into the system.

◆ SATIR

System zur Auswertung Taktischer Informationen auf Raketenzerstören is a command/control system for the 3 German *Lutjens*-class missile destroyers and for the Type 122 *Bremen*-class frigates. As originally developed for the *Lutjens* class (which entered service in 1969–70), SATIR is a more compact substitute for NTDS, which in the U.S. Navy was limited to much larger ships. SATIR in turn inspired a U.S. project to extend NTDS to such ships and thus indirectly led to the RVP installation in Australian missile destroyers (see RVP under U.S. radar systems in the Antiaircraft Warfare section). SATIR employs U.S. hardware (USQ-20B computers and UYA-4 displays, as in NTDS, albeit on a more compact scale) and is based on experience with NTDS and with its French equivalent, SENIT. SATIR was the first NTDS-like system on a destroyer, proving sufficiently successful for the German Navy to choose a derivative for its *Bremen*-class (Type 122) frigates (using UYK-7).

When the *Lutjens* class was modernized in 1983–86, a U.S.-type SYS-1 radar integrator was fitted. These ships also have an NTDS data link designated SATIR-1, presumably equivalent to Link 11.

This system was adapted to the *Bremen* class. The ships are very similar to the Dutch "Standard" frigates, but reportedly the introduction of a wholly new combat system (instead of the Dutch SEWACO) was extremely expensive, equivalent to the cost of 2 ships. The Type 122 version differs from the original SATIR in using digital links to sensors, weapons, the integrated navigation system, and CIC displays. Presumably, this integration includes ATD to feed targets into the combat system.

A third iteration has been adopted for the new German Type 123 frigates, ordered late in 1988. This time the central com-

The KAE BM 802 family of workstation consoles is now standard throughout the German military; they are used in the SATIR system of the new Type 123 frigates and also in the COSYS system. BM 802-52 is a double-screen CIC console. This photograph shows it with a medium-size CRT (14 in) above a larger (20 in) CRT. Both are raster-scan color CRTs (1365 × 1024 addressable pixels, equivalent in clarity to a 2000-line display). The console is driven by a 32-bit KAE multiprocessor computer (MPR 2300) using 68030 chips. Others in the series differ in the number and type of displays. BM 802-1/2 have 15-in cursive color CRTs (1440 × 1120 addressable locations on screen, equivalent to 4000 lines); -3 has a 14-in raster color CRT (720 × 560 pixels, 1000 lines equivalent); -4 has the full 14-in raster color CRT. Of these versions, BM 802-2, -3, and -4 can have either 1 or 2 displays. BM 802-51 and -52 each have 2 displays, and BM 802-61 has 1. All but -51 and -52 use both 16- and 32-bit microprocessors (KAE EPR 1300 and MPR 2300). EPR 1300 has a throughput of about 0.3 MIPS and can be expanded to 8 Mbytes. BM 802-51 and -52 can be further upgraded by adding plug-in processor assemblies. All versions have trackballs and keyboards. In addition, the upper and lower screens can be flanked by control panels carrying keys, push-button switches, rotary switches, potentiometers, shaft-encoders, annunciators, and an audio channel (not visible in the console illustrated here). (KAE)

puter is the U.S.-built UYK-43 (successor to the UYK-7). The consoles are probably the new standard German type described under the COSYS system (see entry for Switzerland).

As in the case of NTDS, the navy is the system integrator, and a special official organization is responsible for programming. The developers were the Bundesamt für Wehrtechnik und Beschaffung (BWB) and the Kommando Marine Führungssysteme (KdoMFuSys).

♦ MTDS

The Modular Tactical Data System is proposed for the modernization of existing ships. The baseline MTDS consists of an information processor, a display (a microprocessor controlled workstation), a data link (HF and UHF), radar and navigation

BM 802-61 is the new standard German CIC display console, for tactical display, assessment of the tactical situation, and weapons-control planning. It can accept both digital computer data and raw radar video (it incorporates a radar scan converter). It carries a 20-in monochrome raster-scan CRT (940 × 700 pixels, equivalent to 700 lines). (KAE)

interfaces, and a general-purpose interface to a ship's weapons and sensors. The processor is a single militarized general-purpose computer with a mass storage device. All of these items are connected to a data bus, and the tactical computer is powerful enough to run separate software modules for its different functions, on a time-shared (multitasking) basis. For the computer, the main expansion option is to add a plot extractor and a track computer, both of which feed into the main bus. The display subsystem can be built up to more consoles (a drawing shows 4).

The general-purpose interface is a modular unit with plug-in interfaces adapted to the various ship sensors and weapons.

The data link subsystem combines a fast encrypted digital link in both HF and UHF/VHF (presumably much like Link 11) with a slow teletype link (presumably much like Link 14).

Telefunken Systemtechnik began to advertise MTDS late in 1989; its brochure identifies neither the general-purpose computer nor the planned workstation. Presumably, the bulk of the work done so far has been software development, which would be applicable to a wide range of machines. By early 1990 Telefunken and its partner, AEG, were divesting themselves of their naval activities (as part of a German antitrust decision), and MTDS had been taken over by a new entity, DMT Marinetechnik. No sales have been reported to date, but the existing brochures prominently feature a Chinese *Chengdu*-class frigate (i.e., a *Riga* with HY-2 missiles in place of her torpedo tubes).

ISRAEL

♦ Elbit NTCCS/AIO

Naval Tactical Command-and-Control System was described in 1989 as having been in service aboard the missile boats of two navies for some years. The navies were probably Israel and South Africa or Chile, the boats being Saar 4s. Elbit states that NTCCS has also been marketed as the Elbit AIO.

The system functions partly as a link to a shore headquarters. There are 2 separate data links, 1 to the other deployed units and 1 to the naval headquarters ashore. Both are serviced through a SACU, the Elbit stand-alone communications link.

NTCCS is built around a standard Elbit naval console (NAVSCON) containing a 19-in, color, raster-scan CRT and a plasma alphanumeric screen, with a trackball, touch-sensitive keyboard, and 2 banks of special-purpose keys. A typical load would be 300 tracks, 200 history points, 100 CPAs, 4 EW bearing lines, 1500 mapping vectors, and 400 alphanumeric vectors. The standard system also employs a tabular display console, e.g., alongside the graphic NAVSCON console. Presumably, the console is used for target assignment.

NTCCS as defined by Elbit includes the radar automatic plot extractor(s) and scan converter(s) that feed directly into the NAVSCON console.

The published description is quite limited, but it appears that the system is built around a central computer with a diskette memory for the tactical picture, feeding both a graphic console and a tabular console. Elbit's list of functions includes target-data processing (but not fire control) and correlation of radar and ESM data; the system also computes appropriate chaff rocket patterns. Presumably, this latter calculation is so urgent that it must be carried out by the central computer, whereas target designation and engagement can be relegated to a separate system, e.g., the IAI Gabriel fire-control system (a subset of Reshet, below).

◆ Reshet

Reshet is IAI's command/control system for destroyers. This system first appeared in the early 1980s as the Target Acquisition and Designation System (TADS). It uses a central processor plus 1 or more tactical display consoles (TDCs) and, in some versions, a data-management terminal. Software includes TEWA on the basis of operator-defined criteria. If that description is accurate, it is relatively unusual; most TEWAs are fully embedded in software delivered with the tactical data system.

A typical system consists of a target acquisition and designation (TAD) position, a tactical editor position, and a commander's tactical console. The tactical editor position, which may be unique to this system, would seem to correspond to an Israeli view that only a human operator can be relied upon to sort out false targets caused by jamming and deception. Alternatively, it might be considered a combination of the air, surface, and subsurface tracker positions employed by other navies on larger ships. The simplification implied here is possible because modern radars and sonars often automatically detect and track; in many cases the dedicated trackers find themselves underutilized.

The tactical editor console (tactical display system, TDS) contains a color, raster-scan monitor, with a small alphanumeric panel under it, surrounded by special-purpose entry buttons. There is also a trackball. Typically, it is used for synthetic video. This computer carries the tactical picture and the computing power of the system as a whole.

There are 2 alternative simpler versions for smaller ships:

- single-graphic-console configuration, in which the tactical-editor graphic display is replaced by a tabular display (a data-management terminal, DMT); the commanding officer retains the graphics display. The DMT is responsible for filtering tactical data and also for managing tactical and navigational computation.
- minimal configuration (Reshet TADS/Data Link), in which the processor and target-acquisition display share a common console. A separate computer manages the data link.

The tactical-display console (TDC) can be used as an independent, fully computerized, multifunction unit, showing maps, grids, zones, automatic update of own position, local processing of operator requests, definition of targets, and track histories.

This system is an extension of the earlier IAI-manufactured Gabriel target-acquisition and fire-control system, TADS. TADS consisted of an operator console incorporating a large CRT, fed by an automatic radar detector/tracker, the Automatic Tracking Computer (ATC). The CRT could display raw radar video as well as computer-generated symbology (synthetic video). Given its date of origin and its circular shape, it was almost certainly an analog unit with superimposed cursive symbology. The symbols showed target inputs from other sensors (optical and EW), but almost certainly not raw optical video.

There was also an alphanumeric display, surrounded by special-purpose keys, with a separate roller ball. The console could automatically track up to 20 targets simultaneously; alternatively, it could provide manual rate-aided tracking of up to 10 targets, the operator performing the usual CIC tasks of classifying and identifying radar targets. The system as a whole was intended to localize targets with an accuracy of 70 m in range and 0.5 deg in bearing. The operator communicated with the system by keypad and roller ball.

In the most compact version of the system, it appears that the fire-control radar is entirely unmanned, slewed onto its target on the basis of TADS commands. The TADS radar computer also provided all other system calculations, including those required for gun fire control; this is a highly centralized tactical data system.

Most of the Israeli missile boats also have a separate topside optical fire-control and manual tracking system, located on the bridge. Presumably, it can be coached onto a target designated by the TADS.

There is also a special, very compact Gabriel system, designed for the *Dvora* class and exported to Taiwan. This system requires 2 separate operators, 1 for the display control processing unit equivalent to the TADS, and 1 for a stabilized optical (periscopic) sight (OS). The optical sight is probably a periscope-based director developed by Kollmorgen, an American company, for a U.S. small-combatant program. This system also incorporates a vertical reference unit (VRU).

As of 1989, 110 Gabriel fire-control systems had reportedly been manufactured, 80 for export to customers such as Chile, Kenya, South Africa, and Taiwan. Reshet has probably been bought by Taiwan.

◆ Sa'ar V and Dolphin Systems

The new Sa'ar V corvettes are to have a fully distributed combat system, using Elta EL/S-9000 computers based on the Motorola 68020 microprocessor. Multifunction consoles will be connected with the ship's systems via multiple triple buses.

The Sa'ar V design includes a secondary (emergency) CIC aft, and the main CIC is buried in the hull for survivability. The combat system can also be operated, to some extent, from the bridge, although it appears that the CIC is the CO's battle station. The system can also accommodate a unit commander.

The *Dolphin*-class combat system was apparently designed along parallel lines; in contrast to earlier Israeli submarines, this one will have a separate CIC (with 5-14 operators, at 9 consoles, 8 for combat systems and 1 for radar).

The standard workstation console, both in the Sa'ar V and in the new *Dolphin*-class submarine, is the Operational Control Console (OCC) developed by Astronautics Corp. of America, Ltd., under Israeli navy contract. It incorporates a 19-in screen (1280 × 1024 pixels) plus either a second such screen or 2 × 9-in screens for 60-Hz raster-scan data. Each workstation is built around a VME bus carrying 3 processors: operator-machine interface, display, and a dual graphics engine; each graphics engine contains 3 processors operating in parallel to generate 6 million pixels/sec of random graphics. The workstation can accept 40-Hz digital data or analog video (e.g., raw radar video).

In a Sa'ar V, the main display includes the current tactical picture and alphanumeric data. One of the small displays carries information required to cooperate with other consoles or operators; the other carries system status information.

ITALY

◆ SADOc/IPN Series

SADOc (*Systema Dirizione della Operazioni di Combattimento*) was the general designation for the Italian version of NTDS. The same designation was extended to later Italian Navy tactical data systems. SADOc 1 was presumably equivalent to NTDS, with a single central computer. Later versions are federated; they combine 2 central computers (CP-7010 or -7020) served by a tape-cassette unit (TCU) with a series of consoles, each of which incorporates a microcomputer (typically an NDC 160/E). In at least 1 version, radar data are transmitted directly to the consoles (rather than to the main computers) via a radar central unit (RCU). The computers and the consoles are all connected to a dual serial bus (10 Mbit/sec on each bus), which is also connected to external equipment, such as guns. The main computers presumably carry the tactical picture.

Versions:

SADOc 1 is the U.S. NTDS adapted to the *Doria*-class missile cruisers.

SADOc 2 is a small-ship modular system, developed for the *Maestrale* and *Lupo* classes, that uses Italian equipment and ideas. It has been widely exported under the designation IPN-10. This Selenia-Elsag modular distributed system uses a 10-Mbit/sec data bus. There are 2 types of multifunction consoles, a single-operator vertical console with a 16-in CRT (SVC-16) and a 3-operator horizontal console with a 22-in console (MHC-22). There is still a dual central computer carrying the system data base, but each console contains its own NDC 160/E 16-bit minicomputer (replaced in newer installations by a MARA 286 computer, programmed in ADA). A version for a fast attack boat would have 1 SVC, and a corvette 2; an export frigate has 5 in all. Italian Navy *Lupos* and *Maestrale*s have 6, including 2 Selenia CDG-3032 (CP-7010) computers. The Italian Navy also has a 3-console mini-SADOc (*Minerva* class).

SVC-16 incorporates a keyboard and roller ball and can be used as an independent radar repeater. MHC-22 has 3 flat screens, at least 1 of which is used for alphanumeric, and 3 keyboards with roller balls; it incorporates an NDC-160E computer.

The system is tied together by a 10-Mbit/sec serial bus.

The latest version, under development since 1984, incorporates a MARA 286 computer (using an Intel 80286 processor) and is programmed using the same YMS operating system as the Digital VAX computers; the language is ADA. A new MAGICs console has been offered in place of the SVC-16; it has an embedded MARA 286 and twin 19-in, high-resolution, raster-scan screens (1024 lines $\times$ 1280 pixels) stacked vertically. This display is also incorporated in the Selenia NA-25 fire-control (and command/control) system and in Selenia's Submarine Integrated Combat System (SISC).

IPN-10 was exported to India for the carrier *Vikrant* and the *Godavari*-class frigate. The FPB version is installed aboard CNR 600-class corvettes such as the Ecuadorian *Esmeraldas*. It has also been reported in the Taiwanese *Lung Chiang*-class fast patrol boats. SADOc-2 is also installed on board the private-venture patrol boat *Saettia* and the new *Minerva*-class corvettes.

Selenia-Elsag offers a modernized version under the designation TBA (based on SEN-300).

SADOc 3 is the current large-ship system, exported as IPN-20. It is on board the carrier *Garibaldi*, the *Animoso* class, and the modernized *Audace*-class missile destroyers. In the carrier *Garibaldi*, this system incorporates 2 multioperator horizontal consoles (supervision, command/control) and 9 single-operator vertical consoles (EW, track management, air operations control). In this case SADOc 3 supports Links 1 (to NADGE, the NATO shore-based air-defense system), 11, 14, and 16; the NADGE link permits the ship to control shore-based aircraft. This version can handle 200 tracks.

The IPN series horizontal console shows the three data entry stations with their keypads and trackballs. (Selenia)

The IPN series vertical console, with its keyboard, keypads, and joystick. (Selenia)

SADOC replaces 2 earlier Selenia naval tactical data systems, SES, for missile cruisers (produced 1961–65) and SIDA (naval integrated defense system, 1963–66).

◆ IPN-S

IPN-S is the next-generation successor to the IPN series, which the Italian government proposed for the NATO frigate. Now that Italy has withdrawn from the NATO-frigate project, IPN-S will presumably end up on board the 2 new missile destroyers. No details have been released, except for the statement that this will be a distributed rather than a federated system, i.e., a radical break with past Italian combat-system architecture. However, official Italian statements also list Selenia as responsible for the central computer and the data bus, so the degree of decentralization may not be complete. The computer will be based on a Selenia multiprocessor architecture. Consoles will be by Selenia-Elsag, and software by Datamat. It is possible that the official statement has been poorly phrased and that each console will contain, or will be connected to, a Selenia computer.

◆ SEN Series

The Selenia-Elsag small-ship combat systems were announced in 1984.

SEN-100 is based on the Elsag NA18 optronic director, expanded to provide some command/control facilities. Intended for small craft of up to about 200 tons, SEN-100 controls 2 guns of different calibers. As of 1984 this system had been offered to Indonesia for use on board 4 projected fast patrol craft (it is presumed that they were the German Lurssen PB 57 type ordered in 1982, 2 of which were completed in 1985–86 and 2 of which have not yet been completed). The system is built around a single 1-operator vertical console, which normally shows radar PPI data but which can switch to a fire-control display.

The SEN-200 designation was reserved for ships of up to about 600 tons, but no such system was designed.

SEN-300 is intended for ships of up to about 1000 tons, to control a surface-to-air missile and 2 guns of different calibers. SEN-300 is based on Dardo E (an anti-aircraft fire-control system, described in the AAW section) and on the Selenia IPN-10 command/control system; the associated search radar will be based on the Orion RTN-30X electronics. The system uses 1 horizontal (tactical) and 1 vertical multipurpose console, thus requiring a minimum of 2 operators for all functions, including both active and passive surveillance.

◆ SER 100

SER 100 is Selenia's tactical data system, jointly developed with Racal in Britain. It will use the Racal 2459/1 radar integrated with NA-series optronic fire-control systems.

◆ TBA

The Selenia-Elsag combat system based on SEN-300, for larger ships (about 1000 tons and up), is effectively a modernized version of the *Maestrale/Lupo* system (SADOC 2/IPN-10).

◆ MAGICS

MAGICS is Selenia-Elsag's new Modular Architecture for Graphic and Imaging Console System workstation, used in SICS, in the NA-25 fire-control system, in the Italian version of FAMS, and in command/control systems. The standard console accommodates one or two 19-in color monitors (1280 × 1024 pixels), each driven by a MARA 286 computer. The MARA acts as display processor/controller, carrying application software and providing data to the internal graphic resources of the console. There are also a video processor and a graphics unit. The video processor accepts raw sensor data, to form radar (PPI, A-scope, B-scope) and sonar (B-scope) images and also provides an image memory. The separate graphics unit does geometric processing, produces geometric shapes (such as lines, cones, polygons), can transform sensor data from format to format, can

digitally mix 2 video channels (for windowing or mosaic-type image superposition), and provides an image memory. This unit can also function in other image formats, from 580 × 780 pixels interlaced (equivalent to 625-line European television) to 1280 × 1530 pixels (60 frames/sec).

MAGICS can function directly as a sensor display. It can accept radar data at a PRF of up to 16 kHz centered, or 8 kHz off centered. Radar video-sampling rate is up to 25 MHz, with 8 bits/sample (analog-to-digital conversion). Standard television and IR video can be accepted at 512–1024 lines/frame, and in this case video sampling rate is up to 40 MHz (6 bits/sample). Range scale can be 0.5–1024 km or nm. Time to change a pixel is 6 nanosec (0.006 microsec).

The basic MAGICS console also carries a magnetic-tape cartridge. There is also a tabletop configuration for limited space. The keyboard can have programmable flat panels, a joystick, or a trackball.

JAPAN

Japanese naval tactical data systems (CDSs) are designated in an OYQ series:

OYQ-2 was described as a Weapon Entry System (WES); it was fitted to the destroyer *Asakaze*. WES succeeded Weapons Direction Equipment (WDE) on board the first Japanese area-defense destroyer, *Amatsukaze*.

OYQ-3 was originally installed on board the *Haruna* but has now been replaced by OQS-6. OYQ-3 was described as a Tactical Data Processing System (TDPS).

OYQ-4 Mod 1 is found in the *Hatakaze*-class area (standard missile) air-defense ships. All air-defense sensors (radars and ESM) feed into the OYQ-4, which also receives Link 11 and Link 14 data directly. Only the sonar, OQS-4, bypasses OYQ-4, to feed directly into the underwater fire-control system (SFCS-6A), which controls ASROC and Type 68 12.75-in torpedo tubes. In contrast to U.S. systems, there is no WDS as such embedded in the tactical data system; the OYQ-4 communicates directly with the missile fire-control system (Mk 74 Mod 13). Earlier Japanese area-defense missile destroyers (*Tachikaze* and *Amatsukaze* classes) are not credited with tactical data systems, and in this sense correspond to the U.S. *Charles F. Adams* class. Presumably, OYQ-4 is approximately comparable to the German SATIR. OYQ-4 is described as a CDS.

OYQ-5 in the *Asagiri*, *Hatsuyuki*, and *Shirane* classes uses the U.S. UYK-20 computer. This system employs U.S. NTDS-type (OJ-194B) consoles; see the entry on NTDS for details. A block diagram of the *Asagiri* class's weapons system shows all the radars feeding into OYQ-5. However, sonar data are fed separately into an underwater fire-control system (SFCS-6B), which receives heading and gyro data from OYQ-5. Although the NOLR-6C ESM system feeds OYQ-5, the other major ESM sensor, OLR-9B, feeds directly into a jammer (OLT-3) and does not feed into the main combat system's computer at all. OYQ-5 controls guns and anti-aircraft missiles through their respective fire-control systems (FCS 2-21A and 2-12, respectively). The only associated data link is Link 14. However, the *Shirane* class has Link 11 as well as Link 14. OYQ-5 is described as a tactical data-processing system (TDPS).

OYQ-6 in the *Haruna* class, replacing OYQ-3, uses the U.S. UYK-20A computer. OYQ-6 is described as a CDS.

Tactical data systems are also designated in a Type series, so that, as modernized, the *Takatsuki*-class destroyer has TDS 3-2 with provision for Link 14.

Submarine combat data systems are designated in a ZYQ series.

NETHERLANDS

As of late 1990, Signaal is developing a new distributed combat system for frigates, competitive with the French TAVITAC.

◆ SEWACO/DAISY/FORESEE

These are Signaal's Sensor, Weapon, Control System (a designation applied by the Dutch Navy). Signaal distinguishes between SEWACO (which includes sensors and weapons) and DAISY (Digital Action Information System), which is the control system proper. At one time Signaal distinguished further and described DAISY as a computer plus its proprietary Combat Information Display System (CIDIS). FORESEE is the combination of DAISY hardware with the appropriate command/control software. The name is a pun on 4C: command, control, communication, and coordination. However, both the command/control system and the full-up combat system are generally denoted by the term SEWACO. Like NTDS, SEWACO is based on a single central computer, although later versions place considerable computing power in the consoles and so may be considered more federated than fully centralized.

SEWACO was originally developed in the mid-1960s, entering service in 1975-76 on board the two *Tromp*-class missile destroyers, serving their elaborate 3D radars. Architecturally it was much like the contemporary U.S. NTDS, but the symbology and the program architecture were quite different. SEWACO uses alphanumeric track identifiers.

The detailed data that follow describe the original form of the system. SEWACO VII and the related STACOS use a later-generation SMR-4 computer and workstation consoles (SIGHT, Signaal general-purpose high-resolution tactical) incorporating some local processing capability in the form of 68000-series chips.

The standard computer is the Signaal SMR (the smaller but compatible SMR-S1 in some versions). At least in the original SEWACO, radar-video data were automatically extracted and inserted into the computer memory; early versions of SEWACO differed in the number of separate radar-video extractors and in the number of consoles. In some cases the system also served a DES electronic plotting table. Physically, the system is built around a data-handling cabinet and consoles. The cabinet contains the tactical computer, the sensor data distribution unit or SDDU (which feeds sensor data to the consoles), a computer data distribution unit or CDDU (which feeds synthetic video to the consoles), and 1 or more radar-video extractors. The video extractor takes radar information from the SDDU and feeds it to the computer via the CDDU. Up to 10 consoles can be served.

Standard Signaal horizontal display console (HDC) on board the Dutch air-defense frigate *Jacob van Heemskerck*. (Signaal)

Standard horizontal display consoles of the missile-control system on board a Dutch L-class air-defense frigate. (Signaal)

In all versions of SEWACO, the computer interfaces with both the weapons and the sensors, using 24-bit I/O channels.

The design concept was to build different systems around a common core, so that about 75% of the software modules and data-base (tactical-picture) elements of any version of DAISY would be identical. This modular programming concept made it relatively easy to develop new members of the family and to ensure their reliability and efficiency. Signaal also claimed that its modular programming approach made later modernization relatively simple. Such programming should, however, be relatively inefficient in terms of core usage.

The system carries 2 types of tracks: 225 point tracks (i.e., tracks of objects for which range and bearing are both known) and 30 bearing tracks (ESM, passive sonar, and visual bearings). Tracks can be automatic, manual, or dead reckoned. For air tracks, the system maintains a track history over the last 2½ min, and for surface and subsurface tracks over the last 40 min. In each case the track file includes course and speed (and height for an air target, depth and doppler for a subsurface target), as well as link status/correlation and ESM-bearing association data. Bearing tracks are characterized as ESM/ECM, ASW/torpedo, or visual.

Threats can be ranked in relation to own-ship, escorted high-value unit, or vital area center. Calculations are based on target hostility criteria, including category, identity, position, course, and speed; target identity can be derived from the target electronic signatures, IFF responses, or data from external sources. DAISY automatically computes the best pairing of targets with the highest threat rank with own-ship or own-force weapons (including missiles and fighters). Free-fire boundaries are entered manually, and some versions of the system can respond automatically within those limits. Up to 2 airborne weapons systems can be controlled locally by a DAISY system, the ship-board controller selecting the mode of attack (e.g., frontal, rear, up-and-over). A version of DAISY was developed for carrier use, presumably for the Dutch carrier *Karel Doorman*, but it seems not to have been installed. It included facilities for carrier-controlled approach.

DAISY is designed to operate with Link 10 or 11, incorporating manually set filters that restrict linked information to an area of interest and thus protect the system from overloading. Filter categories are the number of automatically accepted tracks, target category, and range. The software is designed to

accommodate up to 24 units in the data-link net. The system is also designed to format its own data for rebroadcast on Link 14 (teletype link); up to 45 tracks can be broadcast in this way.

There are 2 types of multifunction consoles, a vertical display console (VDC) and a horizontal type (HDC). Each carries a 16-in-diameter, labeled position display (CRT). The VDC also carries a 7-in alphanumeric display. The HDC can carry a 16–20-in PPI as an alternative to the labeled 16-in display, and there are one or two 7- or 15-in alphanumerics. Such a display normally accommodates a supervisor and 2 operators. These displays carry keyboards, programmable quick-action (i.e., special-function) keys, roller balls, and handwheels for communication with the system. Each console can be configured for any system task simply by changing the overlay (designation) of its special-function keys. There are 2 types of vertical display consoles, 1 for radar and 1 for sonar video. The HDC is a radar display console.

Signaal also describes the HDC as a tactical display console (TDC); it is an analog/cursive device (labeled plan display, LPD) capable of displaying video from 3 radars. Range scales are 2–256 nm. The VDC offers similar ranges.

Signaal currently offers a new general-purpose workstation, SIGHT (Signaal general-purpose high-resolution tactical) with raster scan. It can use laser disks to store maps, manuals, and procedures. SIGHT can have up to 4 system functions linked to it. It uses a multiple version of Ethernet with a total capacity of 40 Mbits/sec.

Versions of SEWACO: (Note: The Royal Netherlands Navy and some NATO versions are numbered, but there are also numerous export variants that are not listed.)

SEWACO I was for *Tromp*-class AAW destroyers and was ordered in 1971. Reportedly, the SEWACO project was started when a Dutch-British joint-development program, which included the SPS-01 radar, died with the cancellation of the British carrier CVA.01 in 1966. The radar had been planned for the *Bristol* (Type 82)-class missile destroyer and would have served a complementary ADAWS tactical data system. Instead, the Dutch decided to continue work on the advanced 3D SPS-01 radar and to develop their own suitable tactical data system. Thus, SEWACO almost certainly shares a common centralization concept with ADAWS and also shares the great weakness of the ADAWS systems, their inability to accommodate major system change and growth. It is possible that SEWACO VII solves part of the problem through greater modularity.

SEWACO II was for the Dutch "Standard"-class frigates (ASW version) and was ordered in 1975. There are 2 horizontal and 5 vertical radar displays, 1 vertical sonar display, separate WM25 and STIR (Signaal tracker/illuminator) weapons-control consoles, and a separate ESM-control console.

SEWACO III was an unsuccessful Signaal configuration, for a frigate similar to the "Standard" (ZW-06 and LW-08 radar, WM25 fire control, SQS-505 sonar, guns, Exocet, and Sea Sparrow). This system had 12 operator consoles: command/control, air- and surface-situation displays, EW/data-link control, weapons direction, helicopter control, ASW, hull sonar, VDS, sonar-signal injector, weapons control, and television.

SEWACO IV was for the Belgian *Westhinder*-class frigates and was ordered in 1974. There are 3 horizontal displays, a sonar display, and a radar plotting table (with true-motion indicator). There are separate fire-control consoles for missiles, guns, and ASW rockets.

SEWACO V was for the mid-life modernization of the Dutch *Van Speijk* class (now sold to Indonesia). There are 4 horizontal tactical displays and a plotting table. SEWACO V was ordered in 1976.

SEWACO VI is for Dutch "Standard"-class frigates (AAW version). There are 6 vertical consoles, 2 horizontal consoles, and a sonar display console. This version includes both primary and secondary radar-video extractors and was ordered in 1985.

General-purpose operator station (GOS) of an M-class (*Karel Doorman*-class) frigate. Several such stations are arranged side by side in the frigate's operations room. (Signaal)

SEWACO VII is for Dutch *Karel Doorman*-class (M-class) frigates. It is described as a next-generation system, with a higher degree of automation and integration. Since the new consoles are workstations (i.e., have some processing capability of their own), SEWACO VII is more a federated than a fully centralized system.

SEWACO VIII is for Dutch *Walrus*-class submarines and was ordered in 1979.

Other frigate installations include (order date in parentheses) Spanish *Descubierta* class (1974), Egyptian *El Suez* class (1978), Nigerian *Aradu* class (1978), Moroccan *Errhamani* class (1979), Argentine *Almirante Brown* class (1980), and Argentine *Espora* class (1980). Of these ships, the Spanish, Egyptian, and Moroccan ships are essentially sisters.

Unit cost of a current SEWACO is probably about \$2 million, based on extrapolation from the stated costs of equivalent systems rather than from Signaal published data.

◆ SINTACS

SINTACS is the Signaal combat data system proposed for the Australian–New Zealand frigates, in competition with the *Feranti 500* and the Swedish 9LV453 Mk 3. Although no details were published, SINTACS was probably a variant of the SEWACO VII system of the new M-class frigates. The Swedish system was chosen: it combined the command/control function with the weapons controls.

◆ STACOS

STACOS is the Signaal combat system for the Greek, Portuguese, and Turkish MEKO frigates. The Turkish MEKOs differ in that their Signaal combat-data systems are connected to Sea Guard point-defense systems (with associated Plessey short-range radar). The basic STACOS architecture is somewhat different from that of earlier DAISY/SEWACO systems. Data buses are employed. In a typical version, Mod II, a Signaal Data-Handling Cabinet is connected to 2 data buses: a dual combat-system bus and a dual display bus. Each of the vertical multi-purpose consoles (probably SIGHT units) is connected to both the video-distribution bus and the display bus. As in other Signaal combat systems, the data-handling cabinet contains a data-handling computer (DHC) with its interfaces, plus a sensor-data

Full-scale mock-up of the M-frigate operations room at the Netherlands Institute of Perception at Soesterberg, showing the new standard consoles in use. Note the video (the helicopter) displayed on the console in the foreground. The full CIC (operations room) contains 14 GOS consoles. (Signaal)

distribution unit (SDDU) for radar video. It also drives an SPL182 plotting table. STACOS Mod II incorporates 8 multifunction consoles (with 1 more optional).

The Turkish ships, the first of this generation to be completed, introduced the SMR-4 computer. Presumably, it is common to the other STACOS installations, for the Portuguese and Greek navies.

Signaal defines 5 separate tactical pictures that STACOS must compile and maintain: air, surface, subsurface, electromagnetic (i.e., ESM), and link (i.e., externally provided). The system as a whole provides command support in the form of threat evaluation, target designation (to AAW and antisurface fire-control channels, and to Harpoon missiles), ECM system monitoring, Link 11 message handling, and evasion advice upon torpedo or close contact detection. Helicopter and torpedo target designations are off line (i.e., via plotting table rather than automated). The system can vector a helicopter or maritime-patrol aircraft to attack a contact made by the ship (e.g., with a towed array) or to fly over a reference point, and the same vectoring function can also be used to recover the shipboard helicopter. There is also a tactical navigation function, which uses information from the ship's log and compass. Presumably, in the future a GPS receiver would be connected directly with the central system. Typical outputs are stationing calculation, CPA, and calculation of the ship's geographical position.

A Signaal block diagram of the overall system shows STACOS connected to 7 operational functions, which presumably match the consoles: track management (which might take up more than 1 console since the air and subsurface pictures would presumably be monitored separately), platform control, communications control, threat evaluation, resource monitoring, sensor control, and weapons control. Resource monitoring presents the status of own-ship and force weapons systems, as well as threat targets and current engagements.

Platform control means both own-ship control and the control of an associated helicopter or maritime-patrol aircraft, which the system handles as logical extensions of the ship. In each case, the track-handling software is the basis for control, which is exerted by display (STACOS does not steer the ship directly). Own-ship control includes steering advice for close contact evasion, torpedo evasion, chaff launching, torpedo launching, and helicopter recovery. Inputs include wind and drift as well as compass and log. One ship can control 2 auxiliary

platforms (helicopter or airplane), and auxiliary-platform control includes a ship-controlled approach (SCA) or a poor-visibility approach (PVA). As in the case of ship control, STACOS does not generate the actual commands. Instead, there is a display that is used to assist the controller talking to the pilot by radio.

The system as a whole can handle 512 tracks, which are carried in a separate track store. It divides tracks into 3 categories: sensor tracks (carried by a single sensor), system tracks (multisensor, own platform), and network tracks (based on data from other platforms, and of interest to a group of platforms). The system also carries special or reference points, which it handles like system tracks. They may include ESM fixes. As in earlier SEWACO systems, this one can use filters to match particular areas of interest and, so, to avoid overloading the track store. Filter operation is based on the number of automatically accepted tracks, track category, and range; the operator sets range filters for air and nonair targets. The total track capacity, however, is a system parameter that the operator cannot alter.

The key sensors are digital, and they create their own track files. System tracks are created by assigning such sensor tracks to system track numbers. Alternatively, the track manager can associate 1 or more sensor tracks to an existing system track, adding new data to it. The manager can also correlate a system track with data-link data and can shift responsibility for tracking from 1 sensor to another, e.g., from a long-range air-search radar to a shorter-range unit. Track files include the tracking source and an assessment of track quality, as well as engagement status, threat ranking (air tracks only), and time of last update (GMT).

Threat evaluation of air targets is automatic and can be computed with respect either to the ship or to a high-value target she escorts. Criteria include target category, identity, position, course, and speed. Identification is manual, based on data such as ESM and IFF, as well as data-link information. Thus, the STACOS form of TEWA is more sophisticated than that in, say, NTDS (which relies mainly on the ratio between closing rate and range). The ability to evaluate threats with respect to the nearby high-value target is important; in the Falklands, British Type 22 (Sea Wolf) ships escorting carriers were hampered by TEWA software that concentrated on targets heading directly for the ship, rather than for the unit she was protecting. STACOS displays the 8 most threatening air targets. The ship can engage only 2 at once, but the display is needed for rapid reengagement.

Weapons control includes monitoring. The system is decentralized in that the Sea Sparrow surface-to-air missile is autonomous. In this case STACOS designates targets, and the tell-backs from the system are used to update the overall situation picture. Harpoon firing data (e.g., way points, trajectory) are passed back into the overall tactical picture (to, among other reasons, avoid confusing the missile with an unknown air target). For the ship-launched lightweight torpedoes, STACOS shows danger areas, torpedo trajectories, and predicted hitting points, as well as course to steer, time to go (before impact), and duration. For a helicopter-dropped torpedo, STACOS presents a drop point and danger area, as well as data such as course to fly, range to go, etc. For the chaff launcher, STACOS presents wind direction and speed (from the navigational inputs) and advises which launcher to use and which course to steer. Actual launcher use (as well as actual course steered) is not controlled automatically. STACOS commands the APECS II jammer to start or stop operation against a target sent by the APECS system when it is in the automatic or semiautomatic mode. However, the jammer controls its own operation once it has been started.

In the Portuguese ships, STACOS employs a DA-08 long-range, digital, air-search radar; an MW-08 short-range, digital, 3D radar; an analog (Racal 2690) navigational radar; an analog IFF; a digital sonar; a digital APECS II EW system; a digital Dual Director Weapons-Control System (DDWCS, using two STIRs);

a Signaal VESTA helicopter digital data link; Link 11; Link 14 (which uses an analog modem); and Harpoon missiles (which are digital). The chaff launcher, torpedo tubes, and helicopter are all off line, not automatically controlled by STACOS. This division is probably typical of modern practice, and it is interesting to note how many essential elements are still not digital.

In the Greek ships, a weapons-control console is installed beside the two STIR consoles so that the STIRs can act as an independent, redundant, command/control unit.

In the Turkish version there are 3 vertical displays for tactical-picture compilation, a horizontal conference display for command decision making, and an automatic plotting table.

◆ Signaal Mini and Compact Combat Systems

These systems are extensions of the WM-series fire-control systems described in the Anti-air Warfare section. In a mini-combat system, a standard Signaal horizontal tactical display (described above under SEWACO) is connected to the weapons-control console, which contains the SMR-S1 computer (the same type as in the corresponding WM-series fire-control system). Signaal describes a compact system as one in which the computer feeds 2 or 3 horizontal consoles. In each case, the computer is installed in the standard Signaal weapons-control console.

Signaal mini-combat systems have been installed on board the Korean *An Yang Ho* (KCX) and the Thai *Ratanakosin*-class (PSMM Mk 16-type) corvettes. The corresponding fire-control systems are, respectively, WM-28 and WM-25.

No installations of the compact system have been reported.

NORWAY

◆ MSI-80S

MSI-80S is a fast attack (missile) boat tactical system, manufactured by NFT. It employs a single 3-operator tactical console (tactical operator, weapons-control operator, and passive-sensor operator); the officer in tactical control occupies a fourth position. The tactical operator initiates and controls target-data calculations and updates the tactical situation display. The system entered service in 1977 on board Norwegian *Hauk*-class fast attack boats.

The computer is a KS 500, using the Mary language. Some of the software is based on that developed for the MSI-70U submarine system (see the ASW section). The console itself incorporates a 23-in horizontal (main tactical) display that shows raw and synthetic video, plus a 12-in CRT. The latter normally shows alphanumeric but can act as a backup for the main display. Displays are manufactured by GEC Sensors.

MSI-80S on board the Norwegian fast attack boat *Hauk*. A smaller derivative is used on board Greek "La Combattante"-class fast attack boats. (NFT)

The associated sensors are twin Decca TM 1226 navigational radars and an electro-optical tracker (GEC V334 LLLTV camera, laser range-finder, IR scanner), optical sights, and ESM.

◆ MSI-3100

This combat system for the modernized *Oslo*-class frigates was first installed in February 1987. The contract was awarded in 1985. MSI-3100 incorporates two 2-operator KMC 9000 consoles, 1 for tactical control and 1 for weapons control. Tracking can be manual (via trackball) or automatic, the former mode permitting the operator to modify raw-video inputs. In the latter mode, radar data are inserted by an REX II radar plot extractor. As a whole, the system can handle up to 99 self-generated and 48 link-reported tracks. The 2 consoles communicate via a Budos data bus. There are no dedicated fire-control systems as such because all directors feed the weapons-control console, which in turn connects to the guns and missile launchers.

The first MSI-3100 system, in the operations room of HNMS *Trondheim*, September 1988. The console on the left is for weapons control (with one position for above-water warfare and the other for gun control); that on the right, for tactical control. The tactical-control console is responsible for surveillance and for target tracking (i.e., for evaluation of the tactical situation) and also for underwater warfare. Tracking can be manual (via a trackball) or automatic. Both consoles are connected by a data bus. Each screen is a 20-inch (diagonal) multicolor digital raster (television-like) display; the two to the left show a combination of raw and processed video. As a whole, the system can handle up to 99 self-generated and 48 link-reported tracks. (NFT)

Each console accommodates 2 KS 500 computers, 1 for general operation (256k) and 1 dedicated (128k). A KS 800 is used as a scan converter and display controller. In the weapons console, the dedicated computer is used for Terne (ASW mortar) fire control; in the tactical console, for air defense and antiship fire control. All use the Norwegian Mary computer language.

Taken together, the consoles amount to a federated system.

The same KMC 9000 multipurpose console is used in MSI-3100, in the MS-90U submarine system, in the NOAH ARCS control system for the improved Hawk missile, and in the FENRIS radar data-integration system.

◆ MSI-340/350

This development of MSI-3100 was announced in 1987. It employs the same KMC 9000 two-operator console, with either KS 500 or KS 900 processors. The software is written in either Mary, Pascal, or ADA. MSI-340 is a single-operator system with a 20-in CRT; it uses the NFT REX II radar plot extractor. MSI-350 is a 2-operator extension of -340. Generally, the console accommodates 1 weapons operator and 1 tactical (command/control) operator.

Reportedly, MSI-340/350 is the tactical command system envisaged for the next generation of Norwegian fast attack craft. Units intended for group command will have 2-console installations.

◆ NAVKIS

Kongsberg's (now NFT's) Navigation Command Control and Information System is installed in the *Nordkapp*-class coastal-patrol ships (EEZ enforcement ships). The system was ordered in November 1978. Priorities were (i) accurate navigation, so that the borders of the EEZ could be maintained; (ii) command/control; (iii) air surveillance and gun control. Each function is served by its own console (2 in the case of navigation: 1 in CIC and 1 on the bridge), and the consoles are connected by a data bus, which also receives sonar data directly.

The main console is the Command, Control, and Information System (CCIS), which can identify and automatically track 16 targets and identify and automatically plot up to 64 fixed points. It can display the air targets picked up by the air surveillance console, and it can define and display local geography (including fishery grid, oil block, and similar data). This console is also responsible for antisubmarine weapons control (sonar input, drop-point calculation and plotting for mining, and target-intercept calculation for torpedoes), and it provides a navigation backup (correlates data from the ship's sensors with known geographical points in the display of navigation data). The air-search radar feeds into the CCIS console, as does the ESM receiver.

Navigation was considered particularly important because radio-navigational-aid coverage of the Norwegian Sea is relatively poor. The ships, therefore, use 3-axis main gyros, 2-axis secondary gyros, a passive log, TRANSIT (satellite), Decca, Loran C, an echo-sounder, X-band navigational radars, and GPS. A navigational computer monitors the receivers and sensors, filtering their data to produce a best estimate of ship's position. The navigational computer also has access to surveillance radar, LLLTV, and optical-sight data normally fed to the CCIS console.

Finally, the air-surveillance and gun-control console directly controls air engagements and the ship's helicopter. Up to 8 air, surface, or subsurface targets can be tracked manually, and the air display includes IFF data. This console receives data from the air-search radar via a radar switchboard, which also feeds data to the CCIS.

The data bus is Budos, operating at about 30 MHz (bandwidth 10 MHz), with a capacity of 1–3 Mbits/sec.

SPAIN

◆ Alcor

Alcor is Bazan's small-ship combat system. Development reportedly began early in 1986, with shore trials early in 1988 and sea trials late that year. The initial-production version provides optronic fire control for 40-mm guns, but an expanded Alcor M is intended for corvettes and frigates. It incorporates a radar-video extractor and uses 2 parallel redundant data buses. The Alcor project is being funded largely to develop a combat system-architecture capability at Bazan.

The small-ship version consists of a COAR weapons console and a CONTAC tactical console; the current fire-control sensor is a stabilized television connected to a video tracker. The ship also carries navigation and surface-search radars, as well as an auxiliary optical target designator.

The system is tied together by a Cormonet data bus, which reportedly differs from the usual type in that it takes into account the priority of each user.

The CONTAC console contains 2 ruggedized IBM PC/AT-compatible computers, 1 carrying the tactical picture and the other providing the general-purpose computing power of the system. In this particular case, the second computer is responsible for gun fire control. The main tactical display, on the right hand side of the console, is a 20-in (diagonal), high-resolution

color monitor (1024 × 800 pixels); it is flanked by a 9-in monochrome display, presumably for raw sensor video. The operator communicates with the system by means of software-defined keys plus a standard keyboard and a roller ball. The programming language is Pascal 86.

The COAR console carries 2-monochrome monitors, 1 for alphanumeric and the other for video (e.g., television monitor video). Three separate keyboards control the video tracker, the configuration of the fire-control system, and data entry; the data-entry keys can be used to reconfigure the system, e.g., for stand-alone gun operation in the event that the system cannot obtain fire-control solutions from the tactical console. It seems unlikely that the COAR console has any local computing capability at all.

Alcor was developed as SPCVZ (*Sistema de Combate para Patrullero de Vigilancia de Zona*) for offshore patrol vessels; it was tested at sea, in partial form, in 1987. It will be the optronic FCS of the Spanish *Atrevido*-class patrol ships, entering service in 1991.

◆ Tritan-1

Tritan-1 is the Spanish navy's tactical data system, developed by the Spanish Naval Observatory at Cadiz. It was installed on board the carrier *Principe de Asturias* and the new *Santa Maria*-class frigates as built, and is being installed on board the *Baleares*-class frigates as part of their modernization. It is essentially NTDS plus Italian- and Spanish-built components. Selenia IPN-10 series consoles are provided to control the Meroka close-in weapons and to act as monitors for Selenia radars. There are also separate Elettronica ECM consoles. The main consoles are OJ-194/UYA-4s, built under license.

The *Principe de Asturias* has a UYK-7 central computer, supplemented by UYK-20s. She has 10 OJ-194 operations consoles; 2 OJ-197 command/control consoles; 4 Selenia IPN-10 consoles (for Meroka); 3 Elettronica consoles for that company's ESM, ECM, and ELINT systems; and communications consoles.

The *Baleares*-class frigates have a UYK-20 central processor, 5 OJ-194 consoles, 4 Selenia tactical and weapons-control consoles, a radar-data integrator (apparently broadly analogous to the U.S. SYS-1), and a Rockwell 2-way data link (presumably for at least Links 11 and 4). Modernization of the frigates is to be completed by 1991. The associated EW system is also new: it is Deneb, manufactured by Ceselsa.

SWEDEN

◆ Base HDA 101

Ericsson's new command/control system is presumably the successor to CCIS. Base HDA 101 was announced in 1989 and is contemporary with the BEAB Base 2000 series. HDA means High-Performance Distributed Architecture. As in the case of Base 2000, proposed applications include ground forces and land-based air defense. The word "base" is intended to suggest a basis or infrastructure upon which command/control systems can be erected. Again, as in Base 2000, the architecture is open to permit easy expansion and modernization. The associated computer is the Ericsson-developed APN 167 (which used the 68020 processor), in single and multiple arrangements. The nodes of the system are connected by an Ethernet LAN, and the nodes share a distributed data base. Unlike CCIS and Base 2000, this system has no separate picture-keeping computer and, therefore, no single- or dual-point failure mode. Programs are written in ADA or in a real-time version of Pascal.

Ericsson emphasizes the flexibility of its concept, to the extent that the software can run on alternative computers. Similarly, there can be many alternative displays. However, a typical system would consist of some combination of 5 types of nodes: a workstation node, a monitoring-and-control node, an I/O node, a data-base node, and a functional node. The data-base node carries large, semipermanent relational data bases and other functions stored in secondary memory; it is not a single repository of the system's dynamic data base. For example, in

a naval system the data-base node might carry maps as well as information on potential threats.

The workstation is the 1- or 2-operator console display. Ericsson envisages a 2-operator console with side-by-side, high-resolution, color, raster-scan screens, plus keypads and roller balls. One screen would normally be fed with scan-converted raw radar video. Ericsson currently offers a modular workstation designated DS 90. In a typical application, up to 4 radars would feed a common radar processor that in turn would feed a radar graphic processor (RGP) in the console. This processor would feed both the display screen and the system data bus. The screen is 1024×1280 pixels, displaying up to 256 colors simultaneously.

Running this sort of monitor (which is increasingly common) requires an enormous amount of data processing, in this case by 4 computers. They exemplify the sheer power involved in current raster-scan display systems. One is a raster converter that transforms incoming radar data from synchronous scanning (e.g., rotating beam) to raster-scan form. It carries out this transformation by feeding radar data into a memory equivalent to 8 bits/pixel/radar (i.e., about 1.25 Mbytes/radar; 4 sources of synchronous video can be accommodated), then stripping the same data out in raster-scan order. The same memory holds graphics that must be displayed with the radar data. Two sets of video can be mixed in a single pixel plane for display and processing together, e.g., when 2 radar pictures are being combined. A second computer generates graphics patterns (including text) for presentation. Its pixel memory provides 16 planes per pixel (i.e., 16 alternative monitor displays, each pixel being assigned both intensity and color). A third is a graphic processor. It is used to transform the video picture (e.g., to change scale or centering), to rotate or shift the picture. The latter alone requires four 25-MHz 68020 processors and up to 4 Mbytes of local RAM (expandable to 12 Mbytes).

The monitoring-and-control mode keeps the system operating.

The I/O node handles external communications. In a ship-board system, such nodes would handle information from ship sensors and from cooperating ships or shore stations.

The data-base node is a separate device handling relational data bases with large amounts of common functions such as recording and playback. It is not clear whether this node is envisaged as a means of maintaining the system data base when the system is not running.

The functional node is a high-performance calculator for special functions such as radar-target detection and tracking.

◆ CCIS/CEPLO/MARIL/MARIS 880

CCIS (Command Control Information System) is a DataSAAB (now Ericsson) tactical system, for frigates, corvettes, and fast attack boats. It was designed for air defense and ATC, as well as for purely naval applications. In the Swedish Navy, CCIS replaced the Signaal M-22, which was used in the original *Spica* class.

The version of CCIS in Royal Swedish Navy service is MARIL; the *Stockholm* class is equipped with an extended version of MARIL 880. This system is based on the Censor 932E computer and can accept targeting data from helicopters and from a shore command center, via a data link, for OTH attacks. The display consoles are designated EPLO (Electronic Plotting System). The Royal Danish Navy's CEPLO (also called DEPLO, for Danish EPLO) is a version of CCIS. The Swedish *Hugin* class, which is generally credited with only a 9LV200 Mk 2, probably has a single (vertical) -console version of CCIS.

CCIS is based on the Censor 900E computer and the DS 86 graphic display system. The computer is used for both displays (picture keeping) and operational calculations (such as those required for fire control). Typically, CCIS is integrated with a 9LV-series weapons control system. For example, in a *Spica II*-class missile boat, MARIL is fed by ship sensors (the air-search and navigational radars, a communications ESM sensor, and an RWR), as well as by data links and by the ship's log and

A MARIL 880 missile-boat installation, showing the horizontal local-operations console and the vertical-screen general-operations plot (GOP) behind, above the 2 alphanumeric plasma displays. The screen in the background is a vertical operations console with a 21-in split-screen phosphor, to display synthetic video (a radar PPI) above alphanumeric. (Ericsson)

gyro. The single horizontal console, which in this version has a 16-in PPI, is manned by the tactical-picture compiler, the weapons officer, and the (antiship) missile-control officer. The weapons officer, in turn, assigns targets to up to 3 separate systems, which are themselves controlled by elements of the PEAB (now BEAB) 9LV200: the gun, the antiship missiles, and the torpedo tubes. Control of guns and torpedoes is exerted through separate single-operator PEAB vertical consoles. Antiship-missile orders are sent directly and automatically to the control panel for the RBS-15 missiles. See the Antiaircraft Warfare section for more details of 9LV200.

In the new *Goteborg*-class coastal corvettes, on the other hand, 3 standard CCIS consoles (2 horizontal LOPs [local-operations plot], 1 GOP [general-operations plot]) are connected to a system bus carrying 9LV Mk 3 operator consoles; the bus is also connected to the ship's weapons and sensors. In this case the combat-control system is described as a variant of 9LV Mk 3, rather than as CCIS controlling weapons, including those fed by 9LV200.

In the *Spica* class, then, the overall system is certainly best described as centralized, the operation suite (consoles and computers) receiving sensor data and designating targets for engagement. Such a system cannot normally survive the destruction of the central processor(s). However, MARIL also incorporates a ship system bus, and the bus can be used to work around individual system failures. Normally, raw radar video is fed directly into the radar plot extractor of the operations suite. The system bus is normally a means by which the operations suite can communicate with the weapons and fire-control devices. However, raw radar video can be fed instead into a plot extractor associated with the fire-control radar tracker, and thus into the combat-system bus. In this way the overall system can continue to operate, albeit with considerably diminished performance. The combat-system bus is largely concerned with the 9LV200 antiaircraft system, so in this degraded mode the ship operates as though 9LV200 is her combat-control system.

HDI 101 (above) and 9LV Mk 3 (below) are the next logical extensions of this idea.

The 16- or 23-in-diameter horizontal PPI display (LOP console) is used for target detection and tracking, 3 operators using their roller balls and keyboards. It includes 2 alphanumeric

plasma displays. There is also a single-operator, 21-in rectangular, LOP (PPI) display, in which the lower part of the screen (coated with a different phosphor) shows alphanumeric information, while the rest of the screen is reserved for raw video. This console also has a roller or joy ball and a keyboard. The 16- or 23-in vertical, command-decision display (GOP) shows only synthetic video. Tracking can be automatic or rate aided. The PPI area shown can be magnified by a factor of up to 128. Magnification is varied either continuously (using the roller ball) or discretely (using the keyboard). There is also a standard data-link terminal (DLT) with an alphanumeric screen and a keyboard.

In a medium ship (a missile attack boat), the 3 displays are typically combined into a 4-operator command center, the GOP standing above the flat LOP, with the 2 alphanumeric displays under it and the keyboard on 1 side. In a larger ship, the command center might consist of paired GOPs, with alphanumeric displays and keyboards between them, and paired LOPs (a total of 4) to either side. A small ship would be equipped with only a single vertical 1-operator console. All announced CCIS installations use either the single horizontal display or the combination of several LOP displays with two GOPs. However, as indicated above, the Swedish *Hugin* class (and others described as having only 9LV series Mk 1 or Mk 2 systems, without associated tactical data systems) probably have single-operator vertical LOPs.

CCIS uses 2 Censor 900 32-bit computers in parallel, each of which is sufficient to run a 2-console system. MARIL 880 substitutes the more powerful Censor 932E for the earlier Censor 900. Target positions are updated cyclically, every 2 min for 24 tracks, or every 30 sec for 6 tracks. In the semiautomatic (rate-aided-tracking) mode, the operator can correct the estimated target position by means of a trackball; the PPI then shows the new position plus a track history. All targets are generally shown with vectors (course and speed). EPLO is designed to accept data from both own-ship sensors and external digital data links. Charts used on the displays are built up of vector lines, typically 1000 of them. Several can be stored on a tape cartridge and called up as needed. In addition, the operators can use their keyboards and roller balls to mark areas of special interest (such as mine fields) onto the electronically stored maps.

Other system computer functions include TEWA, maintenance of a ship data library, weapons coordination and control, EW management, and torpedo fire control (replacing the stand-alone TORCI system of earlier Swedish attack craft). CCIS measures own-ship position by means of both navigational aids (such as Decca and Loran C) and the ship's own gyro and log. It integrates and filters these data to present the ship's position in latitude and longitude, and thus to help drive the tactical display. Other navigational functions are calculation of CPA; calculation of course, speed, and time to take up a designated station; calculation of time of arrival at weapon danger zones (and display of these zones); assistance in various maneuvers (presumably including maneuvering advice when firing chaff); and presentation of navigational patterns.

The ship's ESM system provides CCIS with emitter bearings, as well as with emitter identification data. CCIS sends search orders and bearings to the ESM sensors, jammers, and chaff launchers.

The architecture of the CCIS software reflects Swedish naval tactical concerns. Swedish fast attack craft operate inshore, often among the islands of the Stockholm Archipelago, and they are supported by an extensive shore-based command/control system. Therefore, the attack boat must work in the same coordinate system as the overall shore-based defensive network, rather than in a system of polar coordinates centered on the boat (which might be more natural in an open-ocean environment). In the Swedish case, the situation is simplified because boats operate over relatively short distances, so that a flat rectangular system of coordinates simulates the curved surface of the earth reasonably well. One axis of the system is aligned with a suitable meridian. Geographical features are mapped

using either a Gauss-Hannoverian or a slant stereographical projection.

The Danish CEPLO exists in 2 forms: a single (horizontal)-console version for fast attack craft (bought for the Danish *Willemoes* class in 1972; the ships were completed in 1976-78) and a 4-horizontal-console version (with 2 GOPs). CEPLO was installed on board the 2 *Peder Skram*-class frigates when they were modernized in 1977-79 and was initial equipment for the 3 *Nils Juels* class, completed in 1980-82. In the 4-console version, the horizontal multifunction displays are typically used for local air, surface, and subsurface plots and for weapons coordination and control. CEPLO is now being replaced by the Danish Terma TDS.

◆ 9LV Mk 3 Series/Base System 2000/Sea Viking

Base 2000 is a series of BEAB (formerly PEAB) multipurpose (naval and other defense applications) systems broadly comparable in concept to the new British SSCS. The 9LV designation refers to a fire-control system; the earlier 9LVs are fire-control systems that are part of a larger tactical command system. They are described in the Antiaircraft Warfare section. However, 9LV453 Mk 3, which was selected in 1989 for the new Australian/New Zealand ANZAC frigate is a fully integrated combat-data system, including CIC functions. The 9LV Mk 3 in the new Swedish *Goteborg*-class missile corvettes is an intermediate step between a full system and the earlier combinations of 9LV systems and the Ericsson CCIS. The boundaries between CCIS and Base System 2000 (as implemented in the *Goteborg* class) are not altogether clear, since drawings of the *Goteborg* combat system seem to show elements of CCIS or MARIL (2 standard horizontal displays, connected together, and a vertical command display (GOP), plus a pair of command computers like those typical of CCIS systems). In some cases, a naval version of Base System 2000 may be referred to as FS 2000, the FS being the Swedish acronym for Ship System.

The basis of all of these systems is a ship data bus (a dual Ethernet, each element of which can carry 10 Mbits/sec) which connects all of the sensors, weapons, consoles, and computers. In the *Goteborg* class, a combination of 2 horizontal EPLO consoles and the vertical EPLO GOP lies on the bus, together with the usual 2 CCIS computers. However, the bus also carries 6 standard 9LV Mk 3 workstations. It is connected to the radars (C- and X-band search), to the EW system (both sensors and chaff, with its own subprocessor), to the fire-control tracking system, to the guns (separate from the fire-control trackers; the guns take their orders from the bus), to the surface-attack and ASW system (which is separately fed by the sonar), to auxiliary systems, to a secondary data base, and to a video input. As in the U.S. H930, there is no physical connection between any particular operator station and the sensors and the weapons. Instead, stations produce and receive messages, and the routing of the messages determines which devices receive what. The 2 CCIS computers maintain the overall tactical picture, which is used by all of the consoles.

Each node on the bus has its own processor (CPU), in the form of a single circuit board. The microprocessor is the Motorola 68020, and it is associated with 4 Mbytes of RAM memory (as well as 256 kbytes of read-only EPROM memory carrying instructions for that node). These computers are the functional equivalents of the DCUs of the H930 system. As in the U.S. system, a distinction is made between the architecture of the processor within the node and the separate architecture of the system as a whole, which is presumably buffered from that of the node. As a consequence, the different nodes do not interact tightly, and the system is relatively easy to modify. For example, a great deal of the programming done for the *Goteborg* class could be modified for the Australian project that followed, even though the weapon and sensor fit of the Australian ships was radically different from that of the *Goteborgs*. This simplification reportedly greatly reduced the cost of the Australian system and must have been a major competitive advantage for BEAB.

The standard workstation of the 9LV Mk 3 system. (BEAB)

Programming is all in ADA, for easy transferability to other computers.

Computer functions developed for the *Goteborg* version of the system include the usual tactical-picture compilation, as well as threat assessment of air targets (with display of a threat priority table), and tactical navigation calculation (including intercept and formation calculations). The system is designed for data-link operation.

The modular architecture makes modernization, both within the nodes of the system and by the addition of nodes, relatively easy. The data bus itself can accommodate up to 100 users per segment. BEAB emphasizes the need to accommodate rapid changes in electronic devices, and also the need to modernize ships over their lifetimes. The open architecture of Base System 2000 (which is common to fully modular combat systems) seems comparable in concept to the open architectures of some modern personal computers. Just as in the computers, new devices and new capabilities can be added without major adjustment to the operating-system software, and also without interfering with systems already in place. For example, the *Goteborg*-class corvette is designed to accept later installation of a point-defense missile, such as the vertically launched Sea Sparrow.

The Australian 9LV453 Mk 3, which has been adopted for the ANZAC-frigate project (the Australian version of the MEKO 200), is an enlarged version of the *Goteborg* combat system. In this case there are no horizontal plotting tables at all, only 6 of the new standard 3-screen consoles described below, for the commanding officer/principal warfare officer (equivalent to the U.S. TAO), the surface-warfare coordinator (SWC), the ASW director (ASWD), the helicopter controller, the air-picture controller (APC), and the surface-picture controller (SPC). An additional console can be provided for the EW director (EWD). In addition, there is the usual pair of C2 data-base computers, carrying the tactical picture. The consoles and the computer occupy a command/control data bus, an LAN. It in turn is connected to 2 other buses, the combat-system data bus and a video bus (the latter, through 3 video distribution units). It also runs a plotting table. Compared to the *Goteborg* system, the ANZAC frigate requires 6 or 8 rather than 5 operators/controllers.

In the new units of the Finnish *Helsinki* class, 9LV Mk 3 employs 2 vertical consoles (SPL 85).

In the Danish Standard Flex 300, another application of 9LV Mk 3, the command consoles and their software were developed by Terma, the Danish company. The 9LV Mk 3 elements are the LAN bus and the fire-control system. This system has 3–7 vertical consoles, depending on the assigned role of the boat.

The 9LV Mk 3 family is the first implementation of the Base System 2000 concept, a modular approach broadly analogous to that represented by the U.S. H930 MCS. Computing power is distributed among the nodes of the system, although there are separate command/control data-base (i.e., picture-keeping) computers that represent single (dual) points of potential failure. All versions of Base System 2000 will use a standard single-operator vertical workstation (SPL 85) carrying 3 displays: a high-resolution, 20-in color or monochromatic, random-scan (cursive), display for synthetic video (on its left); a high-resolution, 12-in, raster-scan on its upper right, to display television, radar, graphics, and text; and a second, subsidiary, 12-in, raster-scan display on its lower right for television, A-scan radar data, or text. Operators call up functions by means of 2 touch input screens showing menus, and they also use keyboards and 1 or 2 roller balls. Each console carries its own central processing unit, with a 68020 processor and 4 Mbytes of memory. As a measure of system complexity, BEAB claims that it has produced a software library amounting to 1–2 million lines of code for the *Goteborg* (missile-corvette) installation.

In at least some versions, there may be 2 separate data buses, 1 for the command/control system and 1 for the combat system, the latter carrying sensor video to be distributed to the command/control system consoles.

These systems differ radically from earlier 9LV/MARIL systems, in which all of the computing power was concentrated in separate machines and in which there were special consoles for surface-gunners, air-surveillance, and antisubmarine operations. Moreover, the computers of the earlier systems were far less powerful than those of Base System 2000, carrying only 256 kbyte–1 Mbyte memory.

Sea Viking is a stand-alone subset of Base System 2000, comprising a tracker on a stabilized platform, a tracking-and-ballistic computer, and 1 or more GOCs. It can control surface-to-air missiles or several different weapons sequentially (e.g., SAM, then medium-caliber gun, then CIWS), selecting them in turn on the basis of an optimizing algorithm. The computers are

Cosys 200, as planned for the Turkish MEKO frigates, showing the array of standard Krupp Atlas consoles feeding a data bus, which in turn connects to the weapons system. Krupp Atlas is responsible for tactical data handling; the fire-control system is based on the Contraves Seaguard. MICE is the standard interface developed by Blohm & Voss for its MEKO Mk 3 frigates, and DAIL is the system bus installed in these ships. The main tactical data-handling consoles are in the center of the diagram, for the PWO and for the subordinate warfare officers (ASW, surface, AAW, and EW); the Harpoon-control console is alongside. The consoles above the C₂ bus are the inputs to the tactical system: 2 radar trackers and 2 track supervisors (compilers), the latter being APC (air-picture compiler) and SPC (surface-picture compiler). The hull sonar has its own console, shown to the left. The 2 combat-information units maintain copies of the current tactical picture, as well as archival data. TAICOS is a separate command system (shown at the left). On the right are the 4 consoles of the Seaguard system, 1 system-control console (SCC) and 3 fire-control consoles (TWC), 1 for each fire-control radar. (KAE)

powerful enough, according to BEAB, to evaluate threats (on the basis of ESM and radar inputs) and then choose a mix of hard- and soft-kill counters.

The 9LV Mk 3 series incorporate a variety of new sensors. See the 9LV entry in the Antiaircraft Warfare section for details.

SWITZERLAND

◆ Cosys 200

Cosys 200 is a collaborative effort among Contraves, Plessey, and KAE. The name suggests that Contraves is the lead company, and that the system is an outgrowth of that company's Seaguard ship point-defense system. Thus far the only application is the second series of Turkish MEKO 200 frigates. The

first series had a Seaguard point-defense system linked to a Signal SEWACO-type tactical data system. Seaguard itself has a distributed architecture, and Cosys presumably grows out of the Seaguard system.

KAE (Krupp-Atlas) is the system integrator, providing 8 or 9 standard German Navy consoles. The architecture is fully distributed, using a command bus and separate weapon and sensor buses, all fiber optic (DIAL, a Blohm & Voss shipwide data bus).

The Krupp MPR tactical-data-system consoles, which won a German navy competition in 1988, will appear for the first time in the Type 123 frigate. They are the usual multifunction raster-scan type with a 68020 processor (carrying 4 Mbytes of memory) in the console. Both the console processors and all other computers in the system are 32-bit units, and all software is written in ADA. A 32-bit 68030 can be substituted for the 68020. The Contraves C2003 console used in the Seaguard system itself is very similar and, thus, is broadly compatible with the Krupp main command/control console.

The Plessey part of the system is the search and target-acquisition radar, respectively the Royal Navy Type 996 and the Plessey Dolphin (AWS-6) normally associated with Seaguard.

USSR

◆ Soviet Combat-Direction Practice

A published report (1990) of a visit to the combat information center (CIC) of the *Sovremennyy*-class destroyer *Bezuprechny* provides some insight into Soviet combat-direction practice. The CIC is divided into functional sections that communicate by voice (presumably via headsets); CIC also communicates with the command post by voice. The term "command post" apparently refers to wherever the ship's commanding officer is located, and often that means the bridge. Recent Soviet naval literature includes a lively debate, reminiscent of one in the

U.S. Navy, over the proper place of the commander in battle, be it on the bridge or in CIC. Current Soviet practice is apparently to keep the commander on the bridge, CIC being supervised by a chief combat officer (i.e., a TAO). His tactical summary display is a pair of classical perspex boards in the center of CIC. The ASW module consists of a single passive/active sonar display (PREBOR 6) connected to a separate sonar room. There is also a separate navigational radar console. The AAW module does appear to be automated, with a circular horizontal console (S-170AM), a vertical console (S-170M), and a separate surface-to-air missile-control section (1 OK-10V situation display and 1 OE 3-1/5 target-engagement console). There are also EW and, according to the article, CW modules in CIC (the latter is probably defensive). The commanding officer, when working from CIC, uses an additional air picture console (S-170M), which can be used to direct friendly aircraft. Presumably, the 3 S-170Ms share a common tactical air picture. It is not clear from the published description whether air trackers manually input target data or the single main air-search radar automatically detects and tracks. It is also possible that the air consoles are merely radar repeaters and that tracking is done by grease pencil; the CIC was visited in port. The use of a separate situation-display console suggests that the air picture is automatically transmitted to the AAW controls.

Apart from the SA-N-7 missiles, the ship's weapons are controlled from other compartments. A control station for 4 SS-N-22 antiship missiles is located close to each group of missiles, on each side of the ship. Presumably, targets are selected and fire-control data are generated in CIC. Controls for the guns (130-mm and 30-mm) are local; it appears that their radars are not tied into the air picture in any way. Again presumably, targets are designated in CIC. Such an arrangement would satisfy the supposed Soviet requirement that a ship degrade gracefully in combat. It would correspond to Western World War II and early postwar practice. Similarly, the CIC contains no controls for the torpedoes and the RBUs. If the ship's sonar is indeed their fire control, then presumably they are fired from the sonar room.

There is also a secondary control position containing a ship's wheel and manual (grease-pencil) status boards, used primarily for damage control.

UNITED KINGDOM

In May 1990 the U.K. Ministry of Defence requested bids for the combat-management system (CMS) for the next-generation air-defense destroyers, which are to be bought following British withdrawal from the NATO frigate project.

◆ ADAWS/ADIMP

ADAWS is an Admiralty-designed combat system, based on a central computer and thus broadly analogous to the U.S. NTDS. ADAWS (Action Data Automation Weapons Systems) incorporated automatic radar detection (see below), though that did not generally entail radar data fusion. ADAWS included weapons control. Most installations (except for ADAWS 5) have 2 computers.

ADAWS 1 used a special Camper & Nicholson JGA display; all others use Plessey Mk 8 series vertical and horizontal displays. The standard vertical display is the LPD (labeled plan display), with a 12-in circular, monochrome CRT, for specific sensors and weapons. The JZ horizontal (tactical) display, used to create the merged tactical picture, is a 20-in-diameter, monochrome CRT with an attached 12-in vertical, alphanumeric display. Typically, there are 3 associated keypads and 3 roller balls. The Mk 8-series displays are analog types with digital injection (i.e., analogous to early U.S. NTDS). Most of these systems have 2 horizontal displays (ADAWS 6 and 10 have 4 each). The number of LPDs varies as noted below.

Early British systems differed from NTDS in using only alphanumerics and vectors, where NTDS uses standard symbols to distinguish between friendly, unknown, and enemy (and air, surface, and subsurface). In later versions, which have better

Standard ADAWS 2-operator vertical consoles. Note the use of the light pen for data entry. (Plessey)

symbol generators, ADAWS and other British command/control systems revive the earlier standard symbols (icons) for ship types, which had been used in manual plots at least since the late 1930s. Thus, current British tactical data systems provide the operator with both a vehicle (type) identification (e.g., a triangle for a cruiser) and a letter track identifier alongside it.

Although these systems are always credited with radar-plot extractors, in practice it appears that this option (which the British call plot auto-initiation) was rarely exercised. Instead, a human operator opened a track file by designating a target. The system then applied its automatic plot extractor to the area of the display immediately around this initial plot. This process was called local area extraction (LAX). Typically, an operator initiated a track by identifying a blip of interest (using a roller ball) and was alerted to resolve ambiguities, e.g., 2 tracks that seemed to merge. Once the computer was tracking, it placed a letter at the end of the track: P for track passing through a predicted position, M for a missed target (on that radar sweep), and C for a confused target (the computer followed the plot closest to the predicted position, unless otherwise instructed). The faster the target, and the smaller the probability of detection on a per-scan basis, the larger the local area and the greater the human input. Only in the upgraded systems (particularly those involving Sea Wolf) is there anything comparable to full ADT, as in U.S. systems. Generally, the operator or the system decides which radar to use for tracking; ADAWS does not allow for any form of radar fusion.

Depending upon plot quality, the system may automatically control weapons. Thus, with the advent of ADAWS, ships no longer have separate fire-control systems. Instead, at least in theory, all weapons control is exercised by the integrated control system.

Versions:

ADAWS 1 was for the County-class (second series) missile destroyers *Glamorgan*, *Fife*, *Norfolk*, and *Antrim* (late 1960s), employing 2 Ferranti Poseidon computers. Processed data were fed to the Sea Slug and Sea Cat missiles and to the 4.5-in guns. Computers also tested whether targets could be engaged by the missile system. There was an associated digital data link, so that sensor data and target allocation could be exchanged within a task force. There were 8 twin-display consoles. The digital computer passed target data to the analog fire-control devices, which actually directed fire. The associated plot extractor, SPADE (Special-Purpose Auto-Detection Equipment), was the first British digital device of its type. Earlier automatic detectors (in earlier ADA [Action Data Automation] systems) had been analog devices, comparing analog templates to the growth/decay curves of the radar returns. In these ships the central computer correlated tracks and, in theory, could fuse data from several sensors and also from IFF. The system was probably overly ambitious for its time since descriptions of later versions of ADAWS show substantially less sophistication.

Although the weapons were primarily controlled by ADAWS, all of them retained their older analog controls as backups. Unlike the earlier British ADA system installed on board the old carrier *Eagle*, this system included ASW contacts and was connected to EW receivers.

ADAWS 2, for the next-generation missile destroyer, HMS *Bristol*, employed 2 Ferranti FM 1600 computers (192 kwords). The central computer took over the entire fire-control task, a pattern of centralization followed by later ADAWS variants. In ADAWS 1, weapons control was still carried out by specialized analog machines. From this second version on, ADAWS incorporated 2 types of radar-plot extractors, LFX (limited-area/full extraction) and LAX (limited-area auto-extraction), with or without automatic initiation of radar tracks.

ADAWS 3 was an abortive version intended for the CVA.01 carrier, which was not built.

ADAWS 4, (virtually ADAWS 2 with the Ikara capability deleted) for Type 42 missile destroyers, controls both Sea Dart missiles and the 4.5-in gun. It employs Link 10. Development began in 1967. As modernized in 1988, this system adds a separate captain's console so that the captain no longer has to look over the PWO's shoulder. Software now provides a better threat evaluation in terms of the ratio between rate of approach and range. The ship can now transmit on 3 data links (presumably Links 4, 10, and 11) simultaneously.

ADAWS 5, for *Leander*-class frigates with Ikara ASW missiles, is a subset of ADAWS 2, using a single FM 1600 computer (64k memory, later increased to 128k). This system incorporates 6 LPDs. This version has only LAX with automatic tracking, plus special processing of ASW-helicopter transponder returns. The computer is designated computer outfit DAE-1.

ADAWS 6 is the *Invincible*-class system, using 2 FM 1600 computers. This system incorporates 32 LPDs. ADAWS 6 and 10 incorporate automatic radar detection and tracking.

ADAWS 7 is for Type 42 Batch 2 destroyers; it was developed in parallel with ADAWS 6. Improvements included a shift from Link 10 to Link 11.

ADAWS 8 is a modified ADAWS 7 for Type 42 Batch 3 destroyers; the principal change was to accommodate the Type 2016 sonar.

ADAWS 9 was not used; it had been designed for the abortive Type 43 missile destroyer.

ADAWS 10 is for HMS *Ark Royal*, the last *Invincible*-class light carrier. Presumably, this system will be incorporated in ships as they are rebuilt. This system incorporates 32 LPDs.

ADIMP, the ADAWS Improvement Program, was initiated with a contract to Ferranti in August 1988. Existing FM 1600 computers will be replaced by FM 2420s (for a 6-fold increase in computer power, presumably without major reprogramming). The LPDs will be fitted with raster-type alphanumeric displays in place of the current cursive units (using 68000-series processors and driven by a central Tote Engine), and the horizontal displays will be provided with additional alphanumeric displays. Scan compression will be provided to improve synthetic-video displays. Existing radar-plot extractors apply only to particular radars. However, the ships will be fitted with Thorn-EMI track combiners (comparable to the U.S. SYS series; the contract was let in January 1989). ADIMP applies to *Invincible*-class carriers and Type 42-class destroyers. It includes provisions for Sea Wolf and Goalkeeper and also for the 2050 sonar in Type 42 destroyers.

At the end of September 1989 the Royal Navy issued an invitation to tender (ITT) for captain's combat aid, a computer workstation-based system providing weapons status, target data, and target priorities to a ship's captain, as part of ADIMP. The ITT was originally released in 1988 but was later withdrawn. As of late 1989 the Ministry of Defence was expected

to award an initial development contract in March 1990, with full development following in 1991 and the system completed in 1992. The captain's combat aid seems somewhat analogous to the features promised for the U.S. ACDS, successor to NTDS.

ADIMP also includes a data-link preprocessor (DLPP), which allows a system designed for Link 10 to accept Link 11 and Link 16 messages. An RFP was issued in February 1989, and Thorn-EMI won the competition.

◆ CAAIS

The Computer-Aided Action Information System was conceived as a less expensive alternative to ADAWS. The central computer was retained to help the tactical picture, and processing was distributed as much as possible. The system is described as manually based but computer-assisted, which probably means that it is roughly comparable to the U.S. NTDS: plots are manually entered but are projected ahead by the central computer on a rate-aided basis. The system automatically processes IFF data and vectors an associated helicopter. The consoles do no data processing of their own, so this is not a federated system. The 1966 Naval Staff Requirement called for a unit cost of £100k.

Production began in 1969. Ferranti was prime contractor. Because CAAIS is essentially a computer system, the British designate it a computer outfit, DBA. The first 2 versions to enter service were DBA 1 and DBA 2.

CAAIS (DBA) entered service in 1974. In the first ship so fitted, the Type 21 frigate, the key element of distribution was to retain a separate fire-control system. The first CAAIS system used the FM 1600B computer and commercial Decca displays. FM 1600B was comparable in power to the Poseidon of the original British computer combat system (ADA) but cost about 10% as much. FM 1600B, in turn, has been succeeded by the more powerful but less expensive FM 1600D (which is also used in Nimrod aircraft and in some EW systems).

The main computer occupies a 3-cabinet suite. In the original system, data were presented on 6 Decca CA 1600 horizontal displays, developed from the commercial Deccascan. Each was a 2-operator unit with a 15.75-in, monochrome, analog PPI and 2 alphanumeric displays (16 characters each). It could show raw radar video with graphic overlays and had 8 range scales (1.5–144 nm). A range strobe (used to measure range accurately so that it could be entered into the computer) was adjustable between 100 yd and 60 nm. Each operator had a keyboard with special-purpose keys, as well as the standard alphanumeric set, and with a roller ball. One operator also had keys for synthetic-picture selection and for selection of a particular radar picture. A special console, CA 6001, was used for the search radar and also for primary and secondary IFF data.

Versions:

DBA 1 in *Leander* Batch 1 frigates (32k FM 1600B).

DBA 2 in Type 21 frigates. (DBA 1 and 2 were the initial-production versions). The corresponding weapons-control system is designated in a WSA series.

DBA 3 in HMS *Hermes* (carrier) as modernized (now the Indian *Viraat*).

DBA 4 in "Hunt"-class minehunters.

DBA 5 in *Leander* Batch 3 and Type 22 Batch 1 frigates, to control Sea Wolf missiles (GWS 25) and Type 2016 sonar; the computer is a 48k FM 1600B. As fitted to a Type 22 frigate, CAAIS reportedly can handle 60 tracks.

Ferranti subsequently developed a commercial version, CAAIS 400/450. CAAIS 400 was installed aboard Brazilian *Niteroi*-class frigates. The corresponding WCS is the WSA 400 series. An improved CAAIS 450 corresponds with the WSA 420 series. It provides for data-link operations, can control on-board ECM devices, and performs threat evaluation. CAAIS 450 has a new computer (1600E) and new vertical displays (12-in CRT

for the single console, 16-in for the command console, all monochromatic and incorporating keyboards and roller balls).

CAAIS export installations: *25 de Mayo* (Argentine carrier), *Almirante Williams*-class destroyers (Chile), *Viraat* (Indian carrier: DBA 3 version), *Nyayo* (Kenyan fast patrol boat; CAAIS 450 version), *Inahuma* class (Brazilian frigate: CAAIS 450 version), *Niteroi* (Brazilian frigate: CAAIS 400 version).

◆ CACS

The Computer-Assisted Command System was intended as the ADAWS successor but was rejected for its major planned installation, on board the new Type 23 ("Duke"-class) frigates. CACS was first proposed by Ferranti in 1977 as a replacement for the CAAIS system then installed aboard Type 21 frigates, but the concept was soon extended to the new (and much more demanding) Type 22. The NSR 7933A staff requirement was issued in January 1979. Unlike ADAWS, CACS was contractor developed; indeed, the contractor, Ferranti, was the first to get a full command/control-system contract. The first installation was aboard HMS *Boxer* (1982); the first trials were held in 1985. Development was somewhat delayed by the 1981 defense-spending moratorium.

Ultimately, CACS is probably a good example of the failure of a more or less centralized system under the effects of rapidly changing and growing requirements.

CACS is a partly federated system, its central computer(s) being a pair of FM 1600Es (1 is a running spare). They are linked by an ASWE Serial Highway (data bus) to several Plessey Mk 9 consoles, each containing 2 Argus M700/20 microprocessors. Updated versions have 3 M700/20 per console. In all, CACS 1 has 12 Argus M700 miniprocessors handling displays, sensors, and fire controls. CACS 4, intended for Type 23, included more than 20 M700s. There are also several F100L microprocessors.

There are 2 types of 2-operator consoles, A (command) and B (operator): A has 1 (shared) 16-in, monochrome, cursive main display and 1 Racal 7-in, raster-scan, alphanumeric input display (tote) for each operator. The latter can also be used for video data. The B console has 1 Racal 12-in, monochrome, cursive main display and 2 alphanumeric, 7-in, raster-scan displays per operator. In both, operators can interact with the system via keyboard, roller ball, dedicated keys, and light pens.

What is new, compared to ADAWS, is what Ferranti calls a prompt interface: console operators are presented with a series of prompts (choices) that can be activated by light pen or via the keyboard. This approach is equivalent to menu-driven software in civilian personal computers. As in the civilian case, it becomes practical as computer power increases. Ferranti developed its version as a private venture.

In 1985 CACS was described as capable of tracking over 500 targets simultaneously while conducting threat evaluation. The Type 22 Batch II installation (CACS 1) has 16 displays requiring 26 operators at action stations.

CACS was intended as the first major British system that would integrate passive sonar and ESM data into the action information system. However, that integration proved difficult, and CACS 1 (for Type 22 frigates) could not handle both air and towed-array-sonar pictures simultaneously. CACS 1 was installed in 1984-86, but as of 1989 it is still described officially as "not fully operational." Current forecasts of the date of completion run as late as 1991.

CACS 2 and CACS 3, intended for modernized Type 42 destroyers and their successor Type 43/44 destroyers, were canceled as part of the 1981 defence-review cuts, presumably as consequences of the cancellation of Sea Dart Mk 2.

CACS 4 was the version proposed by Ferranti for the Type 23 frigate and for the new replenishment ship (AOR); both are armed with vertically launched Sea Wolf missiles. Reportedly, CACS 4's development could not keep up with rapidly changing Royal Navy requirements, and ultimately it was dropped altogether in favor of a much more distributed system proposed by Dowty-SEMA. One way to look at the failure would be to note that a hardware producer (Ferranti) was dropped in favor of a

consortium dominated by a software firm (SEMA). MoD requested proposals for the CACS follow-on on 28 November 1986, and bids were due by 15 April 1987. Fifteen-month project-definition-study contracts were awarded on 12 August 1987.

The problem of CACS was probably that its central processor always lacked the capacity to accommodate rapidly changing software.

Ferranti regarded the basic architecture as unworkable and wanted to move instead to the "virtual architecture" of its System 500.

The only surviving new model in the CACS series is CACS 5, for Type 22 Batch 3 frigates (*Cornwall* class). It probably survives mainly because it was always considered a relatively simple modification of CACS 1.

In November 1987 Ferranti announced that it would offer the new FM 2420 computer to update CACS 1 and 5, and a contract to that effect was let in September 1988. A further contract followed on 24 January 1989; the total value of the upgrade is estimated as £30 million.

◆ CANE/DBE/DEA

The Decca (Racal) Computer-Aided Navigational System is a combat system for patrol craft and mincraft. The key is compilation of a current and accurate tactical picture; the system is essentially an automated plotting board. In its simplest form, it is no more than a spot of light projected upward onto the back of a chart to show the movement of a ship, with other lights showing other ships and important fixed points. The spot is controlled by a Decca automatic plotter fed by a Decca navigator and Loran C. Other ships are detected by radar or sonar and are automatically shown by other points of light; these contacts can easily be plotted on the chart. A track-management unit tracks up to 10 surface targets simultaneously, using rate-aided tracking. The operator initiates a track with the usual trackball and assigns a number through a keyboard; detailed track data can be seen on an adjacent display. Later versions have conventional CRT displays.

CANE I (DEA-1) was used on board British "Island"-class offshore-patrol vessels, and a modified version (DEA-2) was installed on board the hydrofoil *Speedy*. It could track 10 targets simultaneously, and it entered service in 1977. DEA-1 consisted of a chart table with an associated Kelvin-Hughes JUD display and an automatic plotter.

CANE II (DEA-3) can track 38 targets simultaneously and was installed on board the "Castle"-class offshore-patrol vessels. It also replaced CANE I on board the "Islands." This version used an automatic chart table, a processor, and 3 consoles. It was a simple central-computer system.

CANE 100/200 are export versions, announced in September 1981. CANE 100 (for fast attack craft) uses an integral Kongsberg KS 590 computer and a table-mounted control-and-display unit. It is a distributed system with a computer in each console. That is a less radical change than might be imagined since the original centralized system was really only the tactical-picture element of the usual combat-data system. The distributed versions add separate consoles for other functions, and the data bus carries the tactical picture among them. Cane 100 incorporates an automatic chart table and an automatic plotter.

CANE 200 is intended for corvettes and larger ships.

As currently (1990) offered, CANE is a distributed system built around a data bus with intelligent I/O nodes. Each tactical control console (TCC) is run by a 16-bit DS500 processor and has 1 Mbyte of internal memory. I/O is controlled by 68000-series chips. The interactive display carries a 12- or 16-in CRT, which can combine raw video with cursive characters (synthetic video); it also uses a 12 line × 40 character data screen. The consoles use resident bubble memory.

A 3-console form of CANE is installed aboard the British flying training ship RFA *Argus*. It is officially designated DBE(1). CANE is also installed on board RFA *Sir Galahad*.

CANE is currently in service or on order for Cameroon, Den-

mark, West Germany, Finland, Hong Kong, Indonesia, Jordan, Korea, Sweden, the United Kingdom, and Yugoslavia. The first CANE 100, for example, was installed on board the Cameroon fast attack craft *Bakassi*. In 1989 installation on board Jordanian "Hawk"-class fast patrol craft was announced. This system is also installed on board 2 new 450-ton Hong Kong police command launches, *Sea Panther* and *Sea Horse*. Racal is currently working on a successor system.

MAINS (Minehunting Information System) is a special-purpose version.

In contrast to the more combat-oriented systems, CANE is basically a surface-ship tracker designed to catch smugglers and poachers. Presumably, it ought to be attractive to small countries interested in protecting their EEZs. In such a role, it would have to be able to accept radar data from a radar-patrol airplane.

CANE exists in both single- and multiconsole versions. In the single-console version, it is very clearly a centralized tactical data system, the single computer feeding both the weapons and the automatic chart table. The multiconsole version shows 2 types of consoles, the control-and-display unit (CDU) and the operations display unit (ODU). The available documentation is somewhat obscure, suggesting both that the data base is replicated through the consoles and that only the CDU carries a processor (in which case the system is entirely centralized about the CDU). The consoles form an LAN that connects to a dual serial data bus. The bus is also connected to an automatic plotter and to an automatic chart table. The manufacturer, Racal, describes the consoles as autonomous, intelligent, tactical command consoles, much like those in, say, NAUTIS. Simple block diagrams suggest that the tactical command consoles occupy an LAN, which communicates with the weapons and sensors via the dual data bus.

The ODU carries a large PPI, either analog or scan-converted (raster-scan); it can also display synthetic video superimposed on raw video. The other standard console, the CDU, contains a processor, intelligent interfaces, data display (televisionlike CRT), and primary operator controls.

◆ RRASL

In August 1990 the Admiralty Research Establishment awarded Ferranti a contract for a demonstration command-decision aid embodying artificial intelligence, RRASL (reactive resource allocation—single ship level). RRASL is to assess a tactical situation and advise the captain and PWO of the consequences of alternative courses of action. It extends the Data Fusion Technology Demonstrator planned for trials in a Type 23 ("Duke"-class) frigate. RRASL is intended to take into account the potential for mutual interference between different defensive measures, both hard- and soft-kill, basing its recommendations on a library reflecting current tactical doctrine and system characteristics. RRASL is typical of several current attempts to apply artificial intelligence to choose between alternative (and interfering) defensive weapons (see the U.S. RAIDS in the Anti-aircraft Warfare section). Much of this problem is presented by the NAAWS program. Because it has to deal with a very rapidly changing situation, RRASL must present a single unambiguous decision, although the user can query its reasons and veto its recommendations. Ferranti claims that RRASL will be based in part on its experience in developing System 500 as the core of 1 of the alternative NAAWS systems.

◆ SSCS (SUCCESSOR)

The Surface-Ship Command System is for the Type 23 and the new replenishment ship (AOR), to replace the failed CACS. SSCS is manufactured by a Dowty-SEMA consortium, the names reflecting a series of industrial takeovers. Initially, the joint venture was described as Gresham-CAP, then Dowty-CAP, then Dowty-SEMA. SSCS is a fully distributed processing system that grew out of a generic distributed system, SUCCESSOR, which used a fiber-optic bus for its LAN. The first application was to a submarine command system; Dowty's proposal actually outperformed the requirement. It became SMCS

The next-generation British standard surface-ship command display, for the Type 23s' SSCS (surface ship command system). The same type of screen displays radar video at the left and sonar tracks on the right. (Racal)

("smacks," the Submarine Command System). There were some minor teething problems, but reportedly, the software proved extremely satisfactory. The next major competition was for the CACS 4 replacement. Plessey (NAUTIS) and Ferranti (System 500) received competitive contracts. Plessey dropped out because NAUTIS (which is fully distributed, without any command-bus LAN) did not correspond to the LAN system architecture that the Royal Navy wanted.

Plessey's place went to Dowty-SEMA, whose SSCS will be used in the Type 23 and the new AOR. It was part of the British proposal for the NATO frigate.

Individual consoles are linked up in an LAN by a fiber-optic bus, and the LAN is itself connected (as a unit) to the ship data bus. Each console contains a 20-in rectangular, high-resolution, raster-scan screen, with 2 plasma screens (totes) for alpha-numerics and a plasma touch panel (and mouse) for interaction between the operator and the system. There is no keyboard as such; the idea is that the operator should not have to take his or her eyes from the screen, except to jab a soft key (i.e., a software-defined key) on the plasma screen. Terminal development entailed design of a series of special processor cards. In theory, the architecture of the system as a whole is simplified by the sheer number of processors available: each processor can be dedicated to a special purpose. The console was originally developed for SMCS.

Two dedicated I/O nodes connecting the fiber-optic LAN to the sensors and weapons via the combat-system highway (bus), 1 to receive and 1 to transmit data. The nodes (with 80386-based microprocessors) do some preprocessing and hold master copies of the data base. They broadcast information into the consoles, which each hold copies of the data base. A hard disk holds permanent or slowly changing data, such as geography.

The Type 23 system employs 12 identical consoles, including separate ones for the captain and the PWO. In contrast, the submarine system uses 5. The surface-ship consoles differ from the submarine system in employing a "joyball" (a trackball with adjustable gearing) instead of a mouse, and an alphanumeric keyboard plus special-function keypads to supplement the plasma soft-key touch panel. A future development will probably have soft keys only, and it will eliminate the keypad altogether. As in other British command/control systems, this display is called an LPD (labeled plan display). Each console contains a full copy of the applications software, so that it can perform any system function.

The Type 23 system as a whole contains nearly 300 processors and over 1500 Mbytes of storage; these figures include the parallel processors (transputers). It appears that the system soft-

ware architecture is similar to that of the Ferranti System 500, programs running within a virtual environment (ADA operating system). Dowty-SEMA claims that the Type 23 command system can handle 1000+ tracks simultaneously.

◆ WSA 4/401/402/403 (GSA 4/GWS 22)

These WCSs are designed to work in conjunction with CAAIS. Typically, CAAIS integrates search-radar and data-link data and passes its tactical picture to the WSA console. The relevant CAAIS console operator can use the tactical picture to assign tracking radar(s) and weapons. Actual computation for gun ballistics or for missile tracking is done in the dedicated WSA console. Different designations apply to progressively more complex systems handling, e.g., ASW as well as surface and air weapons. From this series, Ferranti developed the commercial WSA 420 series. The higher-powered versions can function as full automated combat systems, maintaining track files.

WSA 4 (Weapon System Automation 4) controls the 4.5-in gun and the Sea Cat missile on board Type 21 frigates. WSA 4 is built around a single Ferranti FM 1600B computer, and all functions are centralized in the CIC (AIO in British parlance). There are 2 identical consoles, for gun and Sea Cat control, and both are linked to a 1-operator horizontal console of the CAAIS automated AIO, manned by the missile-and-gun director. This system is sometimes denoted GSA 4/GWS 22 for its separate gun and missile elements.

From the console, the single gun controller can track targets on 2 Type 912 (Orion RTN 10X) radars, see them on television, and fire as many as 20 rounds from the Mk 8 gun. The Sea Cat controller can fire as many as 4 Sea Cats (without reloading). Both are supervised by a missile-and-gun director at a CAAIS display a few feet away. CAAIS compiles the surface and air picture, and the director designates targets to WSA 4 using a tracker ball and marker. CAAIS also assigns the relevant tracking radar. The gun controller initiates the fire-control calculation and orders the gun or missile to aim and fire. Normally, the director receives the WSA 4 track data before fire begins, but in special cases the gun controller can open fire by closing the safety switch and pressing the firing pedal.

There are also emergency control (backup) operating modes for the gun and missile launcher. The 4.5-in gun is then directed by the lookout-and-aiming sight, and the Sea Cat by the pedestal-sight operator. Both would otherwise send their data to the WSA 4 computer rather than to the weapons.

The 2-operator WSA 4 console has 2 main electronic data displays (EDDs) with light pens, each showing data in graphical and alphanumeric form on a page-by-page basis. The correct page is chosen by light pen, using a list running along the bottom (TCD, WCD, NGSA, NGSB, WIND, SEACAT, for target-control display, weapons-control display, naval gunfire-support channel A and B, wind, and Sea Cat, respectively). TCD, for example, shows the status of the 2 trackers, the track number of the target, the weapons mode (e.g., GAA, for gun antiaircraft), and the target's heading, range, speed, and height.

The WSA 4 computer itself stabilizes the tracking radar antennas and also helps reduce tracking errors by predicting future target position. The computer considers all gun ballistics. Because the combination of computer and radars acts like a TWS radar, shifting from target to target while firing at both is relatively easy; and spotting corrections from both targets can be applied. In essence, the computer executes 2 fire-control solutions simultaneously. This technique takes advantage of the shell's 30–50-sec time of flight to provide the equivalent of 2 gunfire channels. Splash spotting is semiautomatic, with the gun controller entering splashes via a trackball applied to a B-scan scope. For indirect fire, the ship's and the target's coordinates are entered into the computer in metric grid form; and the computer automatically tracks the ship, using log and compass data and tidal data. During surface fire, if the director calls for antiaircraft fire, the system can shift over within a few seconds.

The computer permanently holds basic range tables, and in-

The operations room (CIC) of the Brazilian frigate *Liberal* (Vosper Mk 10), showing vertical consoles and a standard 2-operator horizontal display. This ship is equipped with 2 WSA 400-series systems and CAAIS 400. (Ferranti)

formation such as mean sea level pressure, mean equivalent winds, and muzzle velocity (gun wear/ammunition temperature) is entered by light pen.

The WSA 400 series is an expanded version, developed for the ASW version of the Brazilian *Niteroi*-class frigates. WSA 401 controls the Bofors 375-mm rocket launcher and the 4.5-in gun. WSA 402 controls the Ikara and Sea Cat missiles. Similar systems are used in the general-purpose version of the frigate. See also the WSA 420 below.

◆ NAUTIS

Plessey's decentralized command/control system (Naval Autonomous Information System) was based on a standard NAUTIC (Naval Autonomous Intelligent Console). NAUTIS was announced in 1983. Development of the first version, for the single-role minehunter (*Sandown* class) began in 1984. In these ships there are 2 monochrome displays in the CIC, plus a third on the bridge. Their NAUTIS-M version of the system integrates the navigational system, the minehunting sonar, and the control of the minehunting fish. The current U.S. mine-countermeasures ships (*Avenger* class) lack any similar integrator. About 1985–86 the U.S. Navy became interested in the *Sandown* system, which was tested under the Nunn Amendment program. The evaluation was successfully completed early in 1989. In August 1989 the U.S. Navy let a contract for a color version. It is to be integrated with the existing SSN-2 navigational system, in a program designated SSN-2(V) Phase 3.

The console employs iAPX-286 microprocessors, typically dual 80286s in a multibus. Additional iAPX-286s are used for intelligent interfaces to sensors and weapons. RAM is typically 4 Mbytes, expandable to at least 16 Mbytes, with additional nonvolatile memory for program and data-base retention (typically 2 Mbytes, expandable to at least 4 Mbytes). Presumably, the running tactical picture is periodically dumped into the bubble memory. The console can accept video from up to 3 separate radars, as well as up to 8 separate digital inputs, including IFF, helicopter transponder, and data-link plots and tracks. There is an RVP with scan conversion for the raster display. The console also includes a radar-plot extractor with multiple thresholds for constant false-alarm rate, clutter mapping, and windowing. Each console accommodates up to 54 double Eurocards (circuit boards).

Each standard console (workstation) accommodates either a 20-in, 1500 pixel × 1200 line, color raster (announced at RNEE in September 1989) or a 4096 × 4096-pixel, 16-in, cursive monochrome display. The new raster display can show raw radar video, graphics, or alphanumeric tables (totes); the cursive display is limited to synthetic video. The standard console can be supplemented by a separate tote display (alphanumerics) alongside; the enlarged console functions as a command/tacti-

NAUTIS-M tactical display during sonar search, showing the search plan, the history of the ship's track, and sonar coverage with sonar contacts. (Plessey)

cal suite. Each console has 32 software-defined special-function keys, as well as a standard keyboard and a tracker ball.

Consoles are connected to 2 data buses, a combat-system highway and a command-system highway, both 1553Bs or Ethernets.

The data base, replicated within the consoles, covers a 2000 × 2000-nm area (range scales 0.125–1000 nm) and includes radar and sonar tracks, route/search plans, user-designated tactical maps, and synthetic charts. Early system descriptions included a capacity for 6 user-designated tactical maps, 15 synthetic charts, 200 labeled reference points, 5000 underwater contacts, and 32 labeled bearing lines. The system can maintain at least 200 tracks (radar and sonar). In minimum configuration, it can automatically track 20 targets.

NAUTIS-L has been chosen for the refits of the 2 *Fearless*-class large British amphibious ships. They previously had no automated combat systems at all. Presumably, they can now function in part as amphibious flagships, a role that might otherwise have fallen to the British light carriers. This version employs 7 consoles. As of the fall of 1989, installation had been completed aboard HMS *Fearless*.

NAUTIS-P, the patrol-craft system, has been sold to the Royal Thai Navy, both for some new ASW corvettes and for fitting to 4 PRC-built frigates, the latter in 2-console form. The corvette version beat out a rival Signaal system. The Chinese-built frigates are to be stripped and entirely reequipped after delivery. This program is of interest because, once such a conversion has succeeded, many navies possessing similar ships (ex-Chinese or ex-Soviet, or copies) can apply it. A single console can provide radar surveillance, target tracking, target indication to weapons, navigation, and collision avoidance. It can also include optronic and EW control.

In mid-1989 NAUTIS was chosen for refits of 2 New Zealand *Leander*-class frigates, beating out RCA, Ferranti (System 500), Signaal, PEAB (9LV Mk 3), and Thomson-CSF. The system consists of 5 consoles, to control all surface and subsurface weapons and sensors. In all, 3 systems (1 for training) were sold, at a total cost of about £8 million, or about £2.7 million per 5-console system (£500,000 or more per console on this basis, which is much more than the per-console figure given below). These systems are to be installed by 1991.

NAUTIS forms the basis for a Raytheon proposal for an export

surface-ship combat system, and the company may ultimately manufacture it in the United States under license.

Versions:

NAUTIS-A assault ships and auxiliaries.

NAUTIS-D destroyers.

NAUTIS-F frigates. There would be 4 consoles (surface, air, ASW, and command summary). This system is reportedly being considered for the Taiwanese second series (which would be license produced by Raytheon) frigate program, as an alternative to the U.S. Hughes ACS.

NAUTIS-L amphibious warfare and logistics landing ships.

NAUTIS-M minehunters and minesweepers. There are up to 3 consoles (sonar, ship control, mine-disposal vehicle).

NAUTIS-P patrol vessels, strike craft, corvettes. There are 1 or 2 consoles.

NAUTIS-S. This version is a supplement to existing command systems. Typical enhancements include ASW, point-defense-system control, CIWS control, missile/gun-system control, ESM or ECM management, control of containerized systems, aircraft detection and control, command workstations, mine-counter-measures modernization, integrated communications, and data-link operation.

The great advantage of a fully modular system like this one is that it can be installed in a ship that was not designed for a large automated CIC. In the case of the ex-Chinese frigates, for example, Plessey claims that the system will fit in the existing bridge space. That fit is important because (again according to Plessey) adding a new deckhouse (as was done in U.S. NTDS installations) would exceed the strength limits of the existing hull, although it would not impose top-weight problems. Seeing a big derivative market in U.S. sealift ships, amphibious ships, etc., for which NTDS would be much too massive, Plessey has teamed with Raytheon Equipment Division, on a project-by-project basis.

Current cost per console is about £200,000 (about \$320,000).

Although NAUTIS is designed to operate as a modular system, with each console carrying the full tactical picture, at least one buyer has chosen to economize by deleting the full tactical processor from all but 1 console, in which case NAUTIS is effectively a central-computer system with outlying workstations, architecturally equivalent to ADAWS or NTDS. Later installation of the missing processor boards converts this centralized system back into a decentralized one. In this case the deciding factors were the requirements for computing power and reliability; there was no question of combat survivability since in either case all the consoles were concentrated in one restricted space.

NAUTIS can function either as a command data system or as a full combat system including weapons-control consoles; the degree of decentralization can vary radically in this way, as in the question of console content. A drawing of a typical possible NAUTIS-P installation shows that both the central system (2 consoles) and the 2 gun-control consoles would be connected to a common video bus, fed by the navigation and air-search radars and connected to the EW suite. However, the gun-control radar and the optronic director would have their own consoles, connected directly to the gun consoles rather than to the system bus. This arrangement is broadly equivalent to CAAIS.

◆ WAMS/CTC

Racal Marine Radar's Wartime Adaptation of Merchant Ships proposal for ships taken up from trade in an emergency (as in the Falklands) uses a new Command Tactical Console (CTC). CTC, in turn, is based on the Racal-Decca series of ARPA (automatic detection and tracking for surface targets) radars, introduced in 1983 and now mandatory in many merchant applications. CTC was announced in 1985, and at that time the company claimed that it had been installed for, or ordered by,

the Chilean, Chinese (PRC), Dutch, and Norwegian navies. CTC uses the standard Racal ARPA radar target-acquisition and automatic-tracking system, which uses local extraction. The advantage of local, as opposed to global, plot extraction is that radar gain (which determines the criterion by means of which the system decides a target is present) can be optimized separately for each portion of the space the radar sweeps, rather than being set constant for the entire area. The radar can, therefore, make special provisions to extract signals from areas of high clutter. Preprocessing for clutter reduction is by the Racal-Decca Clearscan technique, which is described in the Anti-aircraft Warfare section.

Target data are stored in true- rather than in relative-motion form. In theory, that mode should make it easier for a CTC-equipped ship to coordinate her data with those of other ships.

The system can maintain up to 20 target tracks, acquired either by joystick or automatically (in predesignated guard zones). Such targets can include aircraft at speeds of up to 600 kt. The console displays bearing, range, course, speed, and range and time to CPA in alphanumeric form; the ship's own speed and course can be displayed by designating a known fixed point as a reference. The variable gain in the system makes it possible to detect even small targets (Racal claims it can detect periscopes). Simple electronic maps can be entered into the system memory, superimposed on the radar picture. Targets can be entered into up to 3 separate weapons systems or transferred to other computers.

◆ WSA 420/CAAIS 450 Series

Ferranti's private-venture weapons-control and combat-direction systems are built on CAAIS and WSA 4 experience.

CAAIS 450 is Ferranti's automated AIO (CAAIS), corresponding to the WSA 420 series, providing for data-link operation, for presentation of a unified tactical picture (with indication of the most threatening target), for control of ECM, and for navigational assistance. CAAIS 450 is designed for Link Y operation, with Link 14 as an option. The minimum configuration consists of 2 consoles, each carrying a 16-in CRT, and a third carrying two 12-in CRTs. The first 1-CRT console is run by the command supervisor and the picture supervisor; the second, by the surface-picture supervisor and the EW/data-link supervisor. The 2-CRT console (2 single-operator consoles joined together) is run by the weapons director and the air-picture compiler. This 6-operator configuration can be expanded with 1- and 2-operator units to a total of 8 CRTs and 16 operators. Typical range scales are 4, 5, 8, 10, 16, 20, 32, 40, and 64 nm. The displays are refreshed 16 times/sec, and total system capacity is 120 tracks, 100 of them automatic.

Raw-radar tracking accuracy is improved by software filtering. The figures that follow are based on a search data rate of about 2.5 sec. Given an S-band search radar detecting a 30-kt target at 10 nm, the AIO tracker should maintain an accuracy of 8 min of arc in bearing, 55 m, 4 deg (in course), and 2 kt. Given an X-band navigational-radar detection of a surface target at 5 nm at 20 kt, corresponding figures are 8 min of arc in bearing, 15 m in range, 3 deg in course, and 1 kt in speed. A 350-kt air target at 10 nm should be tracked with an accuracy of 15 min of bearing in arc, 50 m in range, 2 deg in course, and 10 kt. A helicopter (90 kt), tracked by a transponder (RRA) at 7 nm, should be tracked with an accuracy of 10 min in bearing, 20 m in range, 4 deg in course, and 5 kt in speed. In effect, the AIO acts as the tracker of a TWS radar system. Net estimated accuracy is 0.3 deg in bearing and 100 m in range for a surface target (10 nm, 30 kt), or 0.5 deg and 150 m for an air target (5 nm, 600 kt). Both are within necessary target-indication limits for assignment to tracking radar (1 deg, 1000 m).

The simplest WCS, WSA 421, has 2 trackers, a radar (with coaxial television camera) and a visual sight (with laser range-finder) (and as an option a Decca range-only radar). Targets are indicated either by the radar (in search mode), by the visual sight, or by an external target-indication radar. The closed-circuit television monitors a target being tracked by the tracker

WSA 422 console, showing the video screen and the 2 flanking radar scopes.

radar. The computer can slew the visual sight (the optical fire director) onto the target, controlling it either in train or in train and in elevation. Alternatively, the operator can control the sight by joystick, either fully manually (emergency mode) or in stabilized mode. Two guns can be controlled. The system can maintain 2 independent tracks (radar and optical director), and it can also hold a manually indicated point in space at which to aim. A further track provided by the associated AIO can be held in memory; total capacity is 3 simultaneous tracks. One operator can run the system in cruising condition and 2 in action stations (4 for a double version). The system can easily be expanded to provide an extra visual director or an extra radar tracker; the latter requires an additional console.

The system can also fire guns indirectly, for shore bombardment; the grid position of the target is entered into the computer.

The standard weapons-control console carries a 12-in-diameter CRT on its left (TAU: target acquisition unit) side, and a 7-in-diagonal alphanumeric display (tote) and a closed-circuit television monitor on its right (gun controller's position). Displays are run by F-100L microprocessors, for flicker-free operation. They provide 128 stroke-written (cursive) standard characters and 16 programmable characters. The CRT on the left is used as a PPI (for air search), as a B-scan (for surface tracking and splash spotting), and as a split A/R-scope.

Ferranti offered WSA 421 in combination with a Selenia RTN-12X tracking radar with a coaxial television camera; RTN-12X was the monopulse successor to the RTN-10X used in WSA 4, the predecessor system, in Type 21 frigates. The WSA 421 software included special programs to overcome multipath effects in radar tracking of low-flying targets (within 1.5 deg of the horizon). There was also an optical director. Ferranti offered its own Type 901 laser and a Decca range-only radar. Type 901 is a 1.06-micron laser, with a pulse about 25 nanosec long (PRF 10 pps), and a 50% duty cycle. Beamwidth is 0.5 mrad (containing 85–95% of the total energy).

The Decca X-band, range-only radar uses a 17-in dish antenna; beamwidth is about 6 deg, and tracking range is provided in digital form. Peak power is 6 kW (850 pps, pulse width 0.75 microsec).

Typical acquisition time, from target indication with the tracking radar parked, to slew 90 deg to a target 10 deg above the horizon, would be about 4 sec. An initial gun fire-control solution would be available half a second after tracker acquisition, and the gun would be aimed at the target half a second later (albeit not fully accurately). Ferranti claimed significantly better gun accuracy than in earlier systems; a 4.5-in Mk 8 gun made 19 proximity-fuzed bursts out of 19 rounds fired at a Rush-

ton target closing from 7000–1500 yd (speed not given). The 4.5-in gun was the weapon controlled by the 2 predecessor systems, WSA 4 and WSA 400.

Ferranti offered 2 missiles as standard options, Sea Cat (already used in the WSA 4 and WSA 400 systems) and Aspide (in which case WSA 421 would pass target data to the missile subsystem). With additional consoles, the system could control torpedoes and antisubmarine rockets.

WSA 422 extends the 2-operator console, adding a 1-operator surveillance, tracking, and target-indication section, which can provide CIC services. It can accept search- and navigation-radar inputs and can provide manual rate-aided contact tracking. However, WSA 422 can be modified to extract radar data automatically for automatic tracking. The 1-operator surveillance section carries a 16-in-diameter CRT (labeled radar display) and a 7-in-diagonal alphanumeric display (tote). Typical range scales are 1, 2, 4, 5, 8, 10, 16, 20, and 32 nm. Tracks are labeled with a standard NTDS symbol, an indication of data-link status, an identifying letter or numeral, and a 4-digit (octal code) track number. A horizontal line through the NTDS symbol indicates that a weapon has been assigned, and velocity leaders (vectors) and track-history points can be provided. The display is refreshed at a rate of 16 times/sec. It can handle up to 60 tracks, although the weapons director's capacity is 10–12. Typical output accuracy is sufficient for target indication (1 deg in bearing, 1000 m in range).

Like WSA 421, WSA 422 can hold 3 gun-control-quality tracks simultaneously, 2 of them queued. However, because the AIO performs as a TWS radar, sufficient information is available to support surface-to-surface missiles separately.

Both WSA 421 and WSA 422 were built around FM 1600D computers, although later Ferranti offered versions incorporating the more powerful FM 1600E.

WSA 423, built around an FM 1600E computer, is WSA 422 plus a 2-operator CAAIS 450 command console, a more comprehensive CIC than WSA 422 provides. The third position in the WSA-series console is reserved for a separate weapons director. In this case both CRTs of the weapons-control console are 12 in in diameter. Gun-control-quality track capacity matches that of WSA 421 and 422.

As in CAAIS 450, the AIO subsystem can maintain 120 tracks, 100 of them automatic. Accuracy matches that of CAAIS 450, given above.

The command console provides designation directly to surface-to-surface missiles. The other weapons are controlled via interface cabinets fed by both the weapons-control console and the command console.

The standard WSA 423 consists of a 2-operator weapons-control console and a 3-operator AIO; a larger version would have double-headed weapons control (4 operators) and a 7-operator AIO. WSA 423 is designed for optional Link Y and Link 14 operation.

Ferranti also offered MCCS, a Mine-Countermeasures Control System based on CAAIS 450 consoles, singly or in pairs. MCCS was an export version of the "Hunt"-class CAAIS described above.

The new Brazilian *Inhauma*-class frigates have CAAIS 450, almost certainly with a WSA 420-series system; they are equipped with RTN-10X tracker radar. The earlier Brazilian frigates have CAAIS/WSA systems of earlier types, based on FM 1600B computers. The Egyptian *Ramadan* class have CAAIS AIOs and were probably the first ships to get WSA 423 (production began in 1980). Similar systems equip their near sisters, the Kenyan *Nyayo* class and the Omani *Al Sharqiyah* (the other Omani boats have 9LV300-series systems).

WSA 423 is built under license in South Korea by Samsung, to equip newer units of the frigate and corvette classes. In these ships the associated search radar is the Marconi S1810; the fire control radar is the Marconi ST1802, and the electro-optical director is the Radamec HK 409-029. WSA 423 supersedes the Signaal mini-combat systems installed on board earlier ships of these classes.

◆ WS500/CS500/MC500 (System 500)

Ferranti announced these combat systems in 1987, following 3 yr of development: WS500 for weapons control (to supersede the WSA 400 series), CS500 for command, and MC500 for mine countermeasures. All are built around distributed processors using a virtual system environment suite (VSE500).

The great virtue of VSE500 is that programs to run individual weapons and sensors can be inserted relatively easily so that it is unnecessary to build up a single massive program for a ship's command system, a program that is difficult to modify when changes are made in the associated hardware. Much of the effort of development has, therefore, gone into a new method of creating operating software, using the ADA language. The combination of hardware and software modularity should make it relatively easy to assemble a system optimized for any given collection of weapons and sensors. One might see in the modular command program a software parallel to the hardware modularity of the very successful German MEKO frigate, which caters to different navies' great differences in hardware choices.

Moreover, modular programming makes modification much easier and safer since changes in 1 module need not affect the others.

System 500 is designed to employ an FDDI 1 data bus (a fiber-optic LAN) and numerous (typically over 100) Motorola 68020 processors (68030 and 68040 can be substituted as they become available) in standard multirole consoles, each of which carries the full program load of the system, but 500 runs only those processors needed to perform a particular task. As in existing computers ashore, the CRTs of the consoles can be windowed to show several sensor or other device displays simultaneously, and the CRTs can also show closed-circuit television pictures, e.g., from the bridge or from a remotely piloted vehicle. In this sense these CRTs are equivalent to the multipurpose CRT displays of the new "glass cockpits" of aircraft.

In CS500 the track table employed in earlier tactical data systems is replaced by a relational data base catering, in the larger versions of the system, to thousands of tracks. For each track the system carries a long-term history and comprehensive identity data, the latter making it possible to apply artificial intelligence techniques for tactical decision making. Because all the tracks are carried in comparable form, the system can correlate tracks from different sources to avoid duplication and clutter. This correlation is presumably equivalent to current U.S. measures to ensure gridlock (see ACDS and BGAAWC in the Anti-aircraft Warfare section). Moreover, because all radar tracks (taken from ADT sets) are carried together, the system can automatically select the best sensor track for each target; the operator does not shift, for example, between search radars. An associated multilink processor uses correlation techniques to reduce duplication among received tracks before these tracks are correlated with those produced by own-ship sensors.

The main track data base includes sonar and EW data.

Relational data-base techniques were used to achieve very fast reaction time, the Ferranti development team using a new solid-state relational processor (in effect, parallel processor), the first of its kind. Such a processor has the advantage of searching equally quickly through its data base for single or multiple attributes (e.g., looking for all incoming tracks that are at altitudes below 500 ft and at speeds of Mach 1 or more, a combination of 3 attributes that a normal processor would search out 1 by 1).

The program includes sufficient artificial intelligence for TEWA or countermeasures assignment, according to preselected rules. The program also provides maneuvering advice, which is important if the appropriate systems are to bear, and also if the ship is to present a minimum cross section to the approaching threat. Generally, the operator is provided with a veto and does not initiate action. Command-by-negation is necessary for short-range systems facing very high speed or pop-up threats.

The weapons-control applications of System 500 incorporate

Ferranti's System 500 synthetic video display shows the effect of windowing (sonar-performance parameters are shown on the same screen as the tactical situation). (Ferranti)

new types of prediction [software] based on target-profile matching, target-maneuver forecasting, and spread-fire techniques. Earlier systems, based on linear or simple curve prediction, did not have the information capacity to adjust their methods to particular targets, even though intelligence on the characteristic flight or ballistic paths of those targets might well be available in paper form. This type of direct application of intelligence data is possible in systems with really large memories and is likely to become increasingly common in the future.

Although the system is primarily software, Ferranti's favored application employs 20-in full-color CRTs with touch-sensitive screens, capable of rewriting a 1000-track picture within 80 msec; color provides the operator with much more information than a monochrome display. Menus are used to assist the operator in manual inputs. Each console can display both raw and processed video, and resolution is sufficiently good to display navigational charts. The standard console (workstation) carries a large CRT and 2 interchangeable electroluminescent panels, plus a trackball and keyboard. Ferranti also offers a simpler console (e.g., for damage control, hydrography, or a port headquarters) without the 2 electroluminescent panels.

Ferranti has offered a version of CS500 for the Royal Navy Type 23 command-system competition, employing 13 workstations (consoles). A variant, with 6 workstations, has been offered for the new AOR; presumably, both share the software needed to control vertically launched Sea Wolf missiles. Ferranti estimates that 40 workstations would be required for a carrier. As of late 1988, System 500 was being proposed for the Australian ANZAC frigate, for a proposed refit of New Zealand *Leander*-class frigates, and for the West German Type 123 program. Ferranti expects to employ a System 500-type open architecture as its contribution to 1 of the NATO AAW system proposals (see the Anti-aircraft Warfare section).

As of early 1990, 2 versions of System 500 had been sold: a mine-countermeasures variant (MC500, adopted as SATAM for

the new German Type 332 class) and GP 250, a fire-control predictor for the coast-defense batteries of the Royal Danish Navy. In the former case, MBB is the prime system contractor; in the latter, Terma is the prime system contractor.

◆ MINOS

This Marconi small-ship, distributed system uses autonomous multirole consoles connected by a data bus. Development was triggered by the advent of raster-scan displays (which could easily show both raw and processed video), by the appearance of displays suitable for daylight viewing (thus greatly simplifying installation in small ships without special enclosed combat information spaces), and by the availability of proprietary (commercial) computer cards. The last made it much simpler to assemble a tactical data system.

The console is built around a standard VME bus, chosen because cards for about 80% of system functions were already available commercially. Marconi, therefore, could concentrate on the front end, the plot extractor (automatic radar-target detector) and the radar-scan converter necessary to permit display of raw video on the raster-scan screen. Each console incorporates its own processor, and the consoles are connected as an LAN (Ethernet). This LAN, in turn, would be connected (gatewayed) onto the ship's combat-system (weapon/sensor) data bus (highway, in British parlance).

The monitor has 1000-line resolution, and each console can display up to 25 tracks (computing capacity suffices for about 100, but Marconi claims that so high a number would unduly clutter the screen). One Marconi brochure describes capacity per console as up to 20 autotracks and 8 manually controlled, rate-aided tracks, with range selectable from 5 to 160 nm. The existing software can form autotracks on any single plot, and such a track file induces continuous updating of that plot, for full automatic detection and tracking. In theory, the system can do sensor fusion, but that capability probably has not been implemented, as MINOS is intended for the small-ship market. MINOS is designed to support an interface with a data link.

A typical allocation of consoles would be: 1 to support the air-picture compiler, 1 for the surface-picture compiler, and 1 for the tactical position (command position); there could also

be a subsurface console taking sonar data. The track data base is replicated in all the consoles, and thus (as in any distributed system) it is preserved if any console goes out of action. The software is arranged so that lesser functions can be dropped automatically in the event of an overload.

This system was first announced at RNEE 1989 (September 1989). A display there showed two 1802 track consoles and 2 command consoles as typical. The 1802 panel can accommodate an electro-optical (television) display below the main raster-scan screen. It has a joystick. The command console has a keyboard and a roller ball, with an electro-luminescent tabular display under the main screen. The embedded computer is a 68020 on a standard card. Marconi contributed a plot extractor, a scan converter, and track processing software.

As of September 1989 Marconi was suggesting a price of about £100,000–150,000 per console, taking into account the cost of the radar distribution unit, system engineering, etc. That would be roughly similar to the cost of NAUTIS on a per-console basis.

MINOS was initially designated SSCS (Small-Ship Command System); it was, presumably, redesignated when the Dowty-SEMA SSCS was chosen for Type 23 frigates. As of July 1988, Marconi described SSCS as suited to fast attack craft 25–75 m long. A typical installation would comprise 2 or 3 consoles, with more for larger ships. The consoles could be connected to an automated plotting table and also to an event recorder, for recording and playback for later analysis and training.

One peculiarity of the system, at least as described in 1988, was that alongside the usual friend, unknown, and hostile symbols it also carried special symbols for neutrals; and besides the usual air, surface, and subsurface symbols it carried special symbols for hovering craft. In addition, targets would be color coded: unknown in orange, hostile in red, friendly in cyan-blue, and neutral in green. This graphic scheme probably well illustrates the potential inherent in a slight extension of the usual NTDS symbology. In this scheme all targets with speeds greater than 60 kt would generally be classified as aircraft, although such a processing scheme could be changed to cope with helicopters and VTOL aircraft. Targets would generally be identified explicitly as automatically or manually tracked, and they would also be identified with the number of the console responsible for tracking them.

UNITED STATES

◆ Aegis

See Radar Integration in the Antiaircraft Warfare section.

◆ ACDS

Advanced Combat Direction System, the successor to NTDS (see below), uses Link 16 for data transmission and exploits the capabilities of the UYK-43 computer (which replaces the earlier UYK-7). ACDS Block 0, the interim system, covers installation of the new hardware, including the new UYQ-21 display. The associated software is a direct continuation of existing NTDS software, and Block 0, therefore, shows only modest improvements in capability compared to NTDS. ACDS Block 0's software is designated CDS Model 4, and the carrier and cruiser versions are quite different (the carrier is modular, the cruiser restructured). ACDS Block 1 uses CDS Model 5 software.

Block 0 begins a transition from AAW orientation in NTDS toward multiwarfare orientation; Block 1 is structured specifically to support composite warfare commanders (CWCs). This evolution is essential because the threat is no longer easily divisible into the traditional categories. For example, a missile-firing submarine may be tracked by ASW sensors, but it is really an AAW threat. Unless the portion of the combat system that is normally devoted to ASW recognizes a launcher's sound (a transient) as an AAW cue, the AAW part of the system will not be ready to look for a missile emerging from the water near the detected submarine.

Like NTDS, Block 0 is limited in track capacity, range, and "vocabulary" (the ability to describe tracks in greater detail than

ACDS Block 0 and Block 1 pictures of the same tactical situation. Block 0 is equivalent to current NTDS; the diagram shows one hostile submarine (the "v") and two friendly aircraft (the semicircles), plus a ship (the circle) at the bottom. Interpretation is entirely the responsibility of the CIC personnel. Block 1 shows the effect of providing extensive on-line data bases, displaying weapons capabilities and threats. (Hughes)

air/surface/subsurface and friendly/unknown/enemy); Block 0's ability to gridlock is limited to self-correlation, and it has very limited capabilities to integrate ESM and ocean-surveillance data, even though those types of data are becoming much more important. Like NTDS, Block 0 is not designed to automate the decision to engage a target and, thus, does not really greatly reduce a ship's reaction time.

From a maintenance point of view, Block 0 shares the basic problems of NTDS: the program's logic is relatively inflexible, and system updates are difficult because the programming is not sufficiently modular. These problems in turn make it attractive to add stand-alone systems to ships, rather than to integrate the systems with the basic combat system. Such stand-alones, however, tend to be relatively ineffective because they cannot benefit from the ship's main sensors. Quick-reaction ECM systems suffered from that particular problem.

Block 1 marks a departure in system philosophy. NTDS was primarily a display system, the TAO using experience to add the information needed for decisions. In this sense NTDS is semiautomatic. For example, it shows but does not particularly highlight potential threats, and it is not intended to suggest appropriate courses of action. The sole current exception is the command-and-decision (C&D) processor in the Aegis system, which the ship's CO feeds with a series of doctrinal rules (including rules of engagement) and which does indeed suggest courses of action. For Aegis, the weapons-assignment role has

The effect of ACDS Block 1 zone processing. (Hughes)

been melded with the NTDS role to create something new, a combat-direction system (CDS). This change, from pure information coordination to combat direction, is reflected in a change from the existing CIC designation to a new CDC (combat-direction center) designation for the central command/control space of a ship.

Compared to NTDS, ACDS Block 1 offers expanded surveillance coverage, automated sensor processing, and expanded data exchange, both within a battle group and between the battle group and external sources of information.

Block 1 is already planned for all carriers (to enter service beginning in 1992) and may be extended to pre-Aegis cruisers (NTU ships) and to the major amphibious units. The lead ship is USS *Carl Vinson* (CVN 70), which is currently equipped with NTDS Model 4.0. Block 1 (Model 5.1) adds a second UYK-43 computer, plus entirely new software to fully exploit the new hardware. On board a carrier, ACDS Block 1 receives battle-force tactical data from the command/control processor (C2P, a third UYK-43), which receives the tactical data links (and, in the future, the remote satellite links, OTCIXS and TADIXS). ACDS receives all shipboard data directly: ESM data from SLQ-32 and from the Tactical Signals Exploitation System (TSES); SYS-2 radar tracks; beacon video; information from the ASW module; information from the TAS Mk 23 target-acquisition system; and information from the interim afloat correlation system/POST (which receives TADIXS B information from intelligence centers ashore). In the future it should also receive data from the big intelligence-processing systems, such as the Flag Data Display System (FDDS) in the TFCC (see above).

Compared to NTDS, Block 1 operates over 4 times the range (for 16 times the surveillance volume, maximum altitude being fixed). Block 1 can handle 4 times as many track files and adds auto-identification of tracks (7 levels, compared to 3 levels of manual track identification in NTDS). Link 16 provides 10 times the throughput of Link 11. Given much more data, it is possible to correlate tracks automatically and thus to maintain gridlock automatically. The only existing track correlator of this type is SGSAC, a manual system implemented in Aegis ships. On-board and remote ESM can be fully integrated because the system is fed by a highly secure data link (Link 16) that can carry ESM data. In contrast, NTDS ships have to rely on a separate secure data link (Park Hill), and their off-board ESM data are, therefore, processed outside the automated ship's combat system.

In particular, there is now enough information in the system to correlate ESM data for targeting. Such correlation requires special knowledge of individual sensor and emitter characteristics and exchange of data on emitter parameters among several ships, so that the correlator knows which ships are detecting the same emitter. The battle-group command system must, then, associate individual intercepts of what seems to be the same emitter to obtain positions good enough for targeting.

The most visible impact of ACDS Block 1 is in graphics, which are much more detailed than those of NTDS or Block 0. The improved graphics are supported by the second UYK-43, the decision support processor. As in NTDS, the first is primarily a track manager. Graphics are much more than simply a decision aid. Graphic processing, which is already quite common ashore, makes it easy to exploit the position of a point or a track in relation to a preassigned zone of the space in which the system works. For example, it is relatively easy to make the system reaction to a track depend on whether the track is or is not within a zone (say, the 12-mile limit) surrounding some coast. The alternative, to test the track against the entered zone boundary, is time-consuming and is probably outside the power of earlier combat-system computers. Zone processing complements the system architecture designed to accept doctrinal rules ("if . . . then" statements) and to present the operators and the TAO with the immediate operational implications of those rules.

This doctrinal processing can be used to create automatic combat-system checklists (ACSCLs). The CO and staff create the checklists to cover specific situations; each checklist is a series of actions and operating modes that should be optimum for that situation. Each list can also be reviewed and revised at will. All the checklists are carried as computer files, and the CDS automatically implements them when it detects the appropriate conditions. Its action includes display of the checklist itself so that the operator has, in effect, a veto in the event the system has somehow used an inappropriate ACSCL. This type of automation seems essential as threat-warning time shrinks and is an extended equivalent of the auto-engagement capability that is increasingly common.

Block 1 is the first CDS to incorporate an on-line intelligence data base; it can be used for realistic TEWA. In contrast, NTDS had to base its assessments entirely on target speed, course, and range (which, even so, was better than the situation before NTDS). This function seems like what Ferranti is now promising in its System 500 (see above) and will probably be characteristic of future tactical data systems using very powerful computers.

As an indication of the new level of data available on any particular track (i.e., detected target), one can compare data available from Block 0 (i.e., NTDS) and Block 1:

	Block 0	Block 1
Track Identifier	4 values	8 values
Track Category	4 values	8 values
Primary ID Amplifier	16 values	—
ID Amplifier	144 values	—
Platform	—	504 values
Platform Type	—	4095 values
Type Modifier	—	32 values
Nationality	—	country codes
Alliance	—	alliance codes
Unit	—	256 values/type

For example, the same ship might be described as:

Block 0	Block 1
Hostile	Hostile
Surface	Surface
Destroyer	Destroyer
Missile Platform	Krivak-II
	ASW/Targeting
	USSR/Warsaw Pact
	Hull No. 539

Given these specific data, the system evaluates the threat presented by the target (based on its known weapons characteristics, which are stored as a data base), provides alternative methods of engagement, and displays alternative engagement capabilities.

Link 16 is essential for this type of detailed processing because of its precision and its great information capacity. Thus,

the Block 1 program is being paralleled by programs to place Link 16 on board E-2Cs and F-14s.

Unlike NTDS, ACDS will have an integrated ESM interface because Link 16 is secure enough to carry intelligence and ESM data. Bearings can, therefore, be shared rapidly among ships for better targeting. NTDS had to use a separate ESM/intelligence facility using a dedicated, secure signals system, Park Hill. Moreover, because ESM data are integrated with other sensor data, the system as a whole can choose between ESM and weapon responses to particular threats.

One advantage of the much more powerful graphic processing capability is that the format in which information is presented can easily be changed. The data base is object-oriented, so screen data structures are easy to change without recompiling the basic computer code. This capability is important because users have such different desires (and needs) for interface formats. Given flexible formats, individual commanders can choose what they want, and the choice of format does not delay overall system development.

Automated status boards (ASTABs) complement the usual graphic displays, showing threat summary, task organization, and combat-system summary. All ASTABs can be displayed on either the dedicated ASTABs or on CRTs in the CDC, and the system operators can request ASTABs as desired. ASTABs can be defined as multipage electronic documents, 1 page being displayed at a time, but the overall computer system keeps the entire ASTAB up to date, to be called up as desired. There are 60 predefined formats (own-ship and force data) plus 20 user-defined formats. All of this information can be pulled from the full ACDS data base, including the track file and the intelligence data. For example, an operator might define an ASTAB listing ASW threats, giving for each threat platform its track number, its category (submarine, surface, air), its range, its ASW sensor, and its ASW weapon. Another page of the display (which could be called up as desired) might associate each threat with its lethal range. An ASTAB on force status might, for example, list the ships with the status of their ASW systems or their roles (e.g., picket, pouncer).

Hughes Ground Systems is responsible for ACDS Block 1. In contrast to recent modular command/control systems such as the Ferranti Series 500, Block 1 cannot be decentralized, partly because the data base is much too large to fit anything short of a very large central computer. In commercial terms, Block 1 corresponds to a system based on a mainframe with computer terminals, rather than to a decentralized LAN using individual workstations, each embodying the computing power of the system. Presumably, it will take at least a further generation of higher-density computers, and a much more capacious data bus, to permit the U.S. Navy to pass from a centralized NTDS-type system to something decentralized.

The new UYK-43 computer for ACDS supersedes the UYK-7 on which current versions of NTDS are based. The instruction set of the new computer includes the instructions of the UYK-7, so that UYK-43 can run UYK-7 programs: ACDS Block 0 is very similar to NTDS. ACDS Block 1 exploits the full capacity of the new computer. The Block 1 prototype is on board the carrier *Eisenhower*.

There is also a program for conversion of the CICs of existing major units from NTDS to ACDS. New features in a modernized CIC include provisions for Link 16 (JTIDS), the Aegis Tactical Executive System (ATES), Shipboard Gridlock (SGS)/Automatic Correlation (AC), and the Command/Control Processor (C2P). Late in 1988 the *Leahy*- and *Belknap*-class cruisers (CG 16/26 classes) were eliminated from this program.

The Hughes command/control processor (C2P) is intended to meet a requirement that CDSs quadruple their track capacity and effective surveillance range, and also increase their target insertion rate. C2P is a new computer program that mediates between data links and ACDS and the Aegis command-and-decision system. Presumably, C2P makes for faster processing by isolating the central tactical program from data link-handling tasks. C2P extracts information from the links,

forwards these data, and formats appropriate shipboard information for data-link transmission. It runs on a separate UYK-43 computer, outside the main combat-system computer, and uses a USQ-69 display terminal. The C2P operational requirement was issued in March 1982, and the first UYK-43 computers intended for operational evaluation of the Version O system were acquired under the FY88 program. Funding cuts in FY88/89 delayed some tests from FY90 to FY91, others from FY91 to FY92.

◆ FFISTS

Frigate integrated shipboard tactical system, a distributed combat system for *Knox*-class frigates using 4 DTC I computers, is in effect a poor man's NTDS. Like JOTS, this program was run by the Naval Ocean Systems Center (NOSC) at San Diego; it was conceived by a NOSC employee, Mike Pastore. One of the computers acts as a 2-way Link 11 terminal and as the track supervisor. It can accept processed radar data from a SPA-25G radar console. A second computer is responsible for data fusion. A third is responsible for the sonars: it is the interface with the active (SQS-26) and passive (SQR-18) sonars, conducting performance prediction and noise monitoring. The fourth computer conducts TMA for the towed array (the software is called automatic TMA for tactical commanders, ATTAC). The 4 computers are linked by their access to a Shared Resource Monitor (SRM), essentially a large hard disk, via Hewlett-Packard connectors (HP-IB links). The system can accept Link 14, intelligence, and OTCIXS messages, presumably via the data-fusion computer.

FFISTS appeared in the mid-1980s as a rapid-prototyping project; the first ship fitted with it was the USS *Harold E. Holt*. A total of 9 have been installed.

A second-generation FFISTS, using DTC II computers, is planned for 2 *Knox*-class frigates. JOTS will be used as the fusion computer, and the 2 acoustic computers will be replaced by one 2-screen DTC II workstation. The DTC II computers will be arranged in an LAN; they will not need an SRM.

The track supervisor is an expansion of a stand-alone low-cost 2-way Link 11 station, which may ultimately be installed on board the *Pegasus*-class hydrofoils.

◆ HYCATS (SSQ-87(V))

Hydrofoil collision avoidance and tracking system is actually the tactical data system of the *Pegasus*-class hydrofoils. It is used to target their Harpoon missiles. However, there is no provision for receiving Link 11, so they cannot automatically maintain a plot of OTH targets. The system was developed by UNISYS, and the computer is a UYK-44 (however, the lead ship, *Pegasus*, originally had a CP-901B). These ships were originally designed to a German Navy requirement, and the German version would have had the more elaborate AGIS system, with Link 11. Like the British CANE, HYCATS illustrates the convergence of purely navigational systems with combat-control systems, especially when the latter are used to target surface-to-surface missiles.

◆ JPTDS

Junior Participating Tactical Data System was a destroyer version of NTDS developed specifically for the *Adams* class; it was, in effect, equivalent to SATIR and SENIT 2. All of the *Adams* class was to have been fitted, but only 4 ships received JPTDS (DDGs 9, 12, 15, and 21). JPTDS was built around a single UYK-7 computer rather than the 2 (3, if SAMID improvements were incorporated) CP-642Bs of the cruisers. It has 8 UYA-4 consoles: 3 for detection and tracking, 1 for surface/subsurface, 2 for display/decision, 2 for weapons control. There is also a 3D radar console (in 1971, for SPS-39). The existing SPA-33 radar repeaters and WDE Mk 1 Mod 0 were removed. WDS Mk 13 displays target engageability rather than the fire-control solutions displayed by the earlier WDS Mk 11. Computer-aided target scheduling by the Mk 152 missile computer makes for better capability against multiple targets. Mk 13 can feed ship's pa-

rameters (heading, speed, roll, pitch) into JPTDS in the event that the normal sources of parameters fail. JPTDS's functions include radar tracking, weapons-system control, surface navigation, and automatic identification via a beacon video processor. The UYK-7 computer is connected directly to the missile and gun subsystems (the gun system via the missile system), and it is multiplexed to EW, chaff, and the underwater battery. JPTDS also incorporates Link 11. JPTDS's modernization includes the digital update to Tartar (now Standard Missile MR). In the event of a casualty to the UYK-7, and Mk 152 missile computer can be switched to the JPTDS signal generator to drive the FCSC (FCS Coordinator) and EC (Engagement Controller) consoles; the EC is then responsible for target tracking. As initially installed, the JPTDS UYK-7 had only 3 of its 16 available 16k modules. JPTDS was to have been extended to the remainder of the class (and also to the converted DDG 31 class), but that was never done. Installations in the 4 ships were completed early in 1973. The *Adams*-class modernization (including NTDS) was to have resumed under the FY80 program (beginning with DDG 3), but rising unit cost led first to a reduction to 10 units and then to cancellation of the program; 3 ships were modernized using operating funds (DDGs 19, 20, and 22).

◆ NTDS/CDS/MTDS

The U.S. Navy Tactical Data System is the oldest such system still in use, albeit greatly updated. NTDS was the world's first shipboard tactical data system based on programmable solid-state computers and using multiple computers in a distributed tactical data-processing system. It was also the first in the world to use automatic computer-to-computer data exchange, and the first naval implementation of an "expert" computer system in the form of a TEWA system.

NTDS was conceived as a means of automating the World War II-era vertical plot (the grease pencil, i.e., manual display of available radar data from all ship radars) to deal with the increasing number and speed of modern aircraft. After several experimental systems had been designed, a set of technical specifications was written in 1955. NTDS was conceived both as a single-ship system and as a means of exchanging information throughout a task force. NTDS was, therefore, based on standard computers, display terminals, and communications links; and although it was conceived initially for AAW, it was designed so that it could easily be extended to other warfare areas. Each ship would have data links connecting it to other

ships, to aircraft, and to a compatible Marine Corps system on shore. Each ship could control the entire NTDS net, so that on a fleetwide basis the system would degrade gracefully in the event of battle damage. The original NTDS concept also called for the use of programmable solid-state computers, to limit shipboard space requirements and to allow for future change. Some of these decisions were quite farsighted in 1955; for example, at that time it would have been much simpler to hardwire the computers than to make them programmable. Many contemporary systems did use special-purpose computers that, it turned out, froze system design much too early.

The data link chosen was phase-modulated HF (HF was chosen so that ships in the net could be widely dispersed, to minimize losses in the event of a nuclear attack). Message standards and protocols were first set by BuShips in July 1957 and later adopted by a Canadian-British-U.S. Tactical International Data Exchange (TIDE) Committee, and then by NATO as a whole. This message standard became Link 11. An alternative UHF link, Link C, was studied but rejected because of its limited range. The current system does use UHF links to nearby ships and to (and via) some aircraft.

All data had to be converted from analog to digital form. Two standards were imposed: on-line for such essential data as primary radars, gyros, and pit logs; and off-line (keyboard) for other sensors. However, the technology of radar-video extraction was relatively new at the time, and in 1955-57 it was considered impractical to provide RVPs for all the existing fleet radars. Therefore, NTDS was given a manual, rate-aided tracking capability. This manual data insertion was also available as a backup against the failure of those RVPs that were later installed, e.g., for SPS-33 on the nuclear ships *Enterprise* and *Long Beach* and more conventional radars on the carrier *Oriskany*. Only much more recently have RVPs become the rule, sometimes via an integration system such as SYS-1/2.

In the manual system, an operator (detector/tracker) detects a target (i.e., enters it into the computer) by moving a cursor over a blip; the computer acknowledges by superimposing track symbols on the indicated position. The detector/tracker then

⊕ Tentative track	☺ Subsurface friendly
☺ Air friendly	☹ Subsurface unknown
☹ Air unknown	☹ Subsurface hostile
☹ Air hostile	☹ Patrol/ASW aircraft
☹ Surface friendly	☹ Interceptor
☹ Surface unknown	☹ Downed friendly aircraft
☹ Surface hostile	☹ Aircraft carrier

Some standard NTDS symbols; this symbology is now standard throughout much of the West. The goal in symbology is to make the plot as vivid and as immediately meaningful as possible. NTDS seeks this end by using sharp symbols for enemy units and round (soft) ones for friendlies, and by using the upper part of the symbol for an air target, the lower part for a submarine, and the whole symbol (diamond, circle, or square) for a surface unit. Note also the "sea gull" symbol for an ASW airplane. These are warfighting symbols: there is nothing to represent a neutral. On the frigate *Stark*, the neutral Iraqi airplane that actually attacked the ship had to be classified as friendly, and that classification in turn made it impossible to engage automatically (the fire-control system could, however, track a dummy target following the same flight path). These are only a portion of the full NTDS repertoire. For example, the ACDS entry above shows the standard sonobuoy symbol as well as the own-ship symbol. (*Shipboard Weapon Systems* Vol. II, published by the U.S. Naval Academy, no date [late 1970s])

HF discone data-link antenna (AS-2865) for NTDS, USS *Mississippi*, June 1988. (Stefan Terzibaschitsch)

indicates the position associated with the same target on a later (hopefully, on the next) radar scan by moving a "ball tab," a small circle on the PPI, over that location. On each subsequent scan, the operator again corrects target position by ball tabbing the new blip (video) position and pressing a "position correction" button. After 3 such target confirmations, the computer begins to project the target's position, based on the target's course computed from the 3 positions. The operator is then responsible for checking whether the target does indeed follow this steady course and speed.

The action of the operator converts the raw analog video data into digital (position) data suitable for computer operation. In practice, the accuracy of the subsequent track projection is often reduced, as operators hit the "position correction" button 3 times for the same blip position, to be sure that it is entered into the computer as a valid target. Operators are likely to be particularly tempted to do so when targets are approaching at high speed at low altitude, and thus when they are first detected at fairly close range by a radar that may well take 4 sec or more to look again in their direction.

This rate-aided system projected a target's course and speed based entirely on the initial entry, without being able to check (except by operator intervention) whether the target continued at a steady course and speed. In theory, the operator would detect any changes by comparing the target's actual position with the projected position, but verification was not always practical when many targets were present.

Rate-aided projection was not a new idea; it was employed by several earlier systems. However, earlier rate-aided trackers were analog devices, in which a strobe could be positioned over a particular blip and then made to move to match the next appearance of the same target. Strobe position and rate of growth could be extracted from a radar console. In NTDS a digital computer compared successive target positions and generated an estimated target position, which it sent back up to the detector/tracker's screen. Thus, the detector/tracker could insert numerous targets, all of whose positions the computer would project ahead. The earlier analog trackers were limited to a single target.

With manual blip entry, many target detections were missed; and in many cases subsequent blips were missed, so that track files were not constructed or could not be maintained. Hence the importance of RVP (see Radar Integration in the Antiaircraft Warfare section).

Automation of combat data allowed for the passing of these data directly into the ship's combat system. Automation was first realized in the cruiser *Wainwright*, fitted with NTDS and WDS Mk 11 in 1966.

The original NTDS computer was the Univac CP-642, multiple units of which could be assembled in a USQ-20. The CP-642A computer of 1960 was replaced by CP-642B (USQ-20B) in 1963, and in 1971 the current UYK-7 was introduced. It is now being superseded by UYK-43. Early NTDS systems employed multiple CP-642s, 2 in a cruiser and 4 in a carrier (3 in the prototype installation on board USS *Oriskany* in 1961), but UYK-7 was so much more powerful that it could be employed singly, albeit in multibay form. These machines are all described in the separate computer section.

As of mid-1990, the following NTDS computers were in service on board surface combatants:

CP-642A *Belknap* class without NTU, and 1 *Leahy*-class cruiser.

CP-642B *Leahy* class without NTU; *Long Beach*; *Bainbridge*; *Truxtun*; *Mahan* class; and frigates *Koelsch* and *Voge* (now transferred).

UYK-7 *Belknap*; *Virginia* class; *Spruance* class; modernized *Adams* class (including JPTDS ships); *Tarawa* class; and *Perry*-class frigates.

UYK-43 New Threat Upgrade (NTU) ships: CGNs 36-37; CGs 16, 17, 19, 29, 30, 33, 34; DDGs 993-996; and *Wasp* (LHD 1).

NTDS consoles on board the missile cruiser *Wainwright*, 1968. Each console has a trackball that the operator uses to position a cursor over the blip he wants to enter into the system; one such ball is visible on the table in the foreground, and one is being manipulated by the second man from the right. (U.S. Navy)

A single UYK-43 in a *Kidd*-class destroyer replaces a 4-bay UYK-7.

The list does not include Aegis ships, for which the CDS is closely integrated with the weapons system.

The earliest remaining NTDS display is SYA-4; it was superseded by UYA-4 and then by the current UYQ-21. All 3 remain in service. They are described below.

The current version of NTDS is Model 4; model differences correspond to differences in Link 11. Thus the next version, Model 5, corresponds to Link Eleven Model Five (LEMF). Model 5 will also be able to use Link 16. Unfortunately, Link 16 uses the new NATO IFF categories for contacts, which do not match those of Link 11. As a consequence, the 2 systems cannot share quite the same software architecture. Moreover, the C2P, which is intended largely to translate between systems, cannot easily do that.

Typically, NTDS automatically incorporates information from a ship's own sensors and similar information inserted by other ships of a force into a computer data base in the form of a map of the space around the force. Electronic intercept data are collated separately (in special secure spaces), and a sanitized version is entered manually into the data base by keyboard. The basis of the system, then, is the detector/tracker at the CRT. An analogous role is played by a separate beacon video processor tracker, who uses the TACAN air navigation beacon and IFF transponders to track friendly aircraft.

The minimum NTDS installation, then, consists of 4 consoles: 2 for the detector/trackers (1 for air targets, the other for surface/subsurface targets), a summary console for the CIC supervisor, and a console for the weapons-control officer (WCO). The TAO who fights the ship from CIC (under the general orders of the CO) does not operate a console but has access to one, to gain an overview of the tactical situation. This minimum is acceptable only for a highly automated system, employing ADT radars. In most cases there is a considerable degree of track supervision, to ensure that the detector/trackers do not miss targets that deviate from the rate-aided projections the NTDS computer assigns to them. In general, too, there is at least 1 detector/tracker console per search radar. Radar data are merged (in the form of processed video) in the summary consoles, such as those for the WCO and the CIC supervisor.

Generally, the surface tracker/detector is also responsible for inserting sonar data, which are not entered automatically. This split between radar and sonar data reflects the AAW origin of the NTDS system.

The TAO sets target priorities (generally by exception rather than positive direction). The WCO designates assigned targets to the WDS embedded in the NTDS. Ideally, the WDS compares target parameters with preset and entered thresholds and recommends an engagement sequence. The WCO actually selects weapons and fires them. In the *Perry* class the expectation was that some targets, such as pop-up missiles, would arrive too quickly for this sequence to work in time. The ship's NTDS was, therefore, designed for automatic engagement, the WCO having only a veto. However, that level of automation proved less than popular and was rarely, if ever, implemented. It may become more reliable as the frigate's radars are tied together using an SYS system (see the Anti-aircraft Warfare section) in an ongoing current program. One advantage of full integration is that there are many fewer false targets, so a ship's commander can have more confidence in a fully automatic engagement system.

A ship controlling aircraft will often have separate consoles for air controller(s) and for intercept controller(s), and 1 console will be devoted to IFF. There may also be multiple consoles for each of the roles listed. For example, in the minimum installation, the air detector/tracker has to compromise in the choice of range scale. In a larger installation, there may be separate long-range and short-range air detector/trackers.

NTDS development has been evolutionary, probably at least in part so as to avoid major software revision. Consequently, current versions do not take full advantage of the current computers. Hence the shift to ACDS (see above), which Hughes is developing.

Reportedly, NTDS suffers from limited track capacity, range, and vocabulary, the last limiting the system's ability to support decision making on-line. Targets are described as friend/unknown/enemy, which leaves out considerable ambiguity. For example, in the case of the *Stark*, the track of the Iraqi aircraft that actually attacked the ship was initiated by an AWACS aircraft that identified Iraqis as friendly, and the ship carried the track with that identifier. It took an extra effort for the TAO aboard the ship to keep in mind that the airplane was actually not U.S., and not privy to U.S. tactical data (e.g., could attack by mistake). The ship's combat system was so arranged that she

Another view of the standard frigate CIC (in this case, aboard USS *Estocin*) shows the 2-operator weapons-control console (WCC) to the left of the UYA-4 NTDS console. This picture was taken while the ship was fitting out in April 1980. (U.S. Navy)

could not normally attack a target identified as friendly (although that software limitation could be overcome by clever operation).

Limited system vocabulary may also have limited the detail in which the surrounding geography could be presented, and that restriction may explain why the tactical picture in the *Vincennes* showed only a single line rather than an airliner corridor (the single line was the centerline of the corridor). One lesson of the *Vincennes* incident may be that, in combat, decisions are taken on the basis of what the display shows, and that limitations in display tend to be overlooked or ignored.

Advertising for NTDS clones (SENIT, TAVITAC, IPN) tends to emphasize the richness of the tactical display (hundreds of lines, circles, etc.) but not any increase in on-line tactical information to support decision making. ACDS and perhaps System 500 may be the only exceptions.

CDS, the Combat-Direction System, is the successor to NTDS and is currently used onboard Aegis ships. In effect, CDS is the form of NTDS adapted to Aegis.

ACDS is the Advanced Combat-Direction System. Block 0 is a restructured NTDS with new software, entering service in FY87. Block 1 incorporates the Joint Tactical Information Data System (JTIDS) and has improved high-data-rate networking.

MTDS is the analogous Marine Tactical Data System. Its roles include bringing in fire support to protect marines in forward positions.

Perhaps the greatest problem of NTDS operation has been gridlock, the means of assuring that all ships in an NTDS net use the same coordinates to identify the same points in space, i.e., truly share a common grid. If the units do not, then the same target detected by 2 ships may be counted as 2 different targets, and thus assigned 2 (of a limited total number of) tracking and engagement channels. The gridlock problem has now, finally, apparently been solved, initially using Aegis hardware.

◆ H930/MCS

The Modular Combat System is the only U.S.-produced distributed combat system. It was developed by Honeywell and then sold (in 1988) to Hughes. Hughes has continued development and may also be working on a separate small-ship (fast-attack-boat) system, perhaps a mini-NTDS. No information on such a system has been forthcoming. Hughes is currently marketing an advanced version, MCS 2000, based on the H930 concept but using much more powerful processors. Five versions are cur-

The combat information center (CIC) of the newly completed frigate *Curtis* shows 2 standard OJ-194/UYA-4 consoles flanking the TAO (summary) console (OJ-197/UYA-4), with an SPA-25 radar repeater in the background. Not visible between the 2 status boards behind the consoles is a large backup vertical (manual) plot. The trackball of the console in the foreground has not yet been installed, but one is visible on the console on the right. (U.S. Navy)

rently in service: H930 Mods 0, 1, 2, and 3, and MCS (Modular Combat System).

Its developers claim that H930 is the only truly distributed system in current service, that systems described as distributed are really no more than multiprocessor types in which the separate processors are so tightly connected that the failure of any one will disable the system as a whole. The argument is that true distribution is much more a software than a hardware problem. Different combat-system tasks are normally interdependent, whether they are conducted by separate processors or, in sequence, by a single central machine. The key to the H930 architecture is that commands and changes to the tactical picture propagate as messages in a data bus. Any processor assigned to a given role can pick up messages relevant to its operation and can broadcast its own messages freely.

The first system of this type was the Honeywell Experimental Distributed Processing System (HXDP), a land-based system built under U.S. Navy contract, begun in 1972 and completed in 1974. Communications protocols and the data-bus hardware were developed at this stage. Some of the associated hardware was later tested on board the USS *Moosebrugger* (DD 980). As installed at San Diego, HXDP used an LN-66 radar, an E/O sensor/tracker, and a helmet-mounted visual target-acquisition system (VTAS), to control a GAU-8 Gatling gun. There were 3 modules: 1 for surface tracking (STM), 1 for air tracking (ATM), and 1 for weapons control (WCM), the last connected directly to the gun. The STM was fed by the LN-66, and it in turn fed a display/control console. The ATM was fed by the E/O tracker and the helmet sight. All were connected by a bus.

In 1975 Honeywell developed H930 Mod 0 for a fast patrol boat. Five were delivered. This system used 1 air-search radar (SPS-58), 1 surface-search radar (HC 75), 1 tracking radar (a Westinghouse W-120), and 1 Mk 35 optical director, with 2 system operators, to control one 76-mm gun, two 30-mm guns (in an Emerlec mount), and SSMs. The 2 radars were arranged for TWS operation. There were 2 minicomputers (for the 2 operator consoles) and 5 microprocessors. The 2 operator consoles are dedicated, respectively, to air and surface warfare, but either gun can engage any target. The 2 computers are programmed to be mutually supportive. This system became operational in November 1978, probably on board PSMM Mk 5 patrol boats of the South Korean Navy. Honeywell considered Mod 0 an extension of HXDP and thought it important mainly for gaining experience in console design. In this system primary operator switches and status indicators are multifunction, their meaning controlled by the computer program so that the operator's attention would be focused on the immediate task.

In 1976 Honeywell sold its first H930 Mod 1 system to Taiwan. This system was built around 5 UYK-19 minicomputers in 2 multicompartment consoles, connected by a combat-system data bus (LAN). The consoles in turn were connected to such elements of the ship system as guns and missiles. Mod 1 (January 1981) was installed on board 10 destroyers; it employed 1 dedicated air-search radar, 1 air/surface-search radar (SPS-10 and -58 sharing a common antenna), 1 dedicated surface-search radar (SPS-55), 2 tracking radars (HR-76), 1 Mk 35 optical director (with light enhancement), and an ESM intercept receiver. SPS-58 had a digital target extractor, and SPS-55 was a TWS radar. The 2 tracking radars were also programmed to conduct horizon search with automatic detection. At least in this version, the Mk 35 optical director incorporated light enhancement and an embedded television camera. There were 6 system operators to control two 5-in/38 gun mounts, one 76-mm gun, two 40-mm guns, and SAM and SSM (Hsiung Feng I) missiles. Support was provided by 5 UYK-19 minicomputers and 23 microprocessors. There were 2 command/control consoles, their responsibilities split so that the loss of either would not eliminate all capability.

Thus, Console 1 was fed by the ESM sensor, the Mk 35, and 1 of the 2 trackers. In turn, Console 1 was wired directly to the surface-to-surface missiles, to the 76-mm gun, and to 1 each of the two 5-in/38 and 40-mm mounts. Console 2 was fed by the air/surface-search radar and the second tracker, as well as the

heading/azimuth unit; it in turn was directly wired to the other twin 5-in/38 mount and the second 40-mm mount. The 2 consoles were wired together so that they could exchange information.

There were 3 gun-firing stations.

The Mod 1 system was designed so that it could be expanded to accommodate ASW weapons and sensors and so that it could accept a data link. This system was installed on board 13 ex-U.S. destroyers of the Taiwan Navy, rebuilt under Weapon-Improvement Program Phase I (*Wu-Jin I*).

Mod 2 (November 1980) is Mod 1 adapted to a 50-m patrol boat. Two were delivered, presumably for the 2 Taiwanese *Lung Chiang* (PSMM Mk 5) patrol boats. This system employed 1 air-search radar (SPS-58) and 1 surface-search radar (LN-66), 1 tracking radar (HR-76), and 1 Mk 35 optical director. Six operators controlled one 76-mm and one 40-mm gun and SSMs. Unlike Mod 0, Mod 2 employed ESM inputs. Mod 2 used 4 minicomputers and 19 microprocessors.

The associated Mod 3 was a land-based system. Five were delivered to Taiwan, beginning in March 1980, to control Hsiung Feng I SSMs. Mod 3 employed 1 surface-search radar, 1 HR-76 tracking radar, and 1 optical director. Three operators (at 1 tracking-and-control console) used 2 minicomputers and 11 microprocessors. This Mod 3 should not be confused with the Modular Combat System (MCS), which is part of the Taiwanese Weapon-Improvement Program III (see below).

This program forced Honeywell to adopt a modular architecture, because of both the overall complexity of the system and the fact that not all ships of the Taiwanese program had the same suites of sensors and weapons.

Modes 1 and 2 were modular, in the sense that each UYK-19 plus its associated sensors and weapons formed a separate building block (module), functionally independent of the others. However, the computers were physically concentrated and, thus, vulnerable. Moreover, particular computers were tied to particular system modules, so that the failure of any 1 computer would knock out an entire module. Reportedly, too, Mod 1 proved unreliable because its computers tended to overheat despite extensive air conditioning of the computer spaces. Overheating may have been exacerbated because all 5 UYK-19s were packaged in 2 consoles. This problem was cured in later versions of the system.

In the Mod 1 and Mod 2 versions, each module consists of a sensor, served by a distributed computing unit (DCU), and a weapon, similarly served, connected through a control console incorporating another DCU (physically, all the DCUs were concentrated in the 2 control consoles, but some of them were more closely associated with particular weapons or sensors).

Because SPS-58 can be set to detect targets automatically, the system can continuously evaluate air targets, processing highly threatening ones automatically. Given 1 target track, the computer typically takes 4 sec to evaluate a second report. If the second is more threatening, the computer takes 10–18 sec to slew onto that new target.

Typically, operators initiate tracking by marking the blip to be tracked on their PPIs; they can also initiate tracking by entering a target's coordinates, range, and speed (to enter a target visible only from some other platform). The tactical coordinator at the command console then assigns weapons. Four weapons-control positions are available: 1 at the optical director, 2 at the ASW/ASU console, and 1 at the AAW console. All of the guns may be controlled from either console, since commands can be transmitted back via the link between the command console and the 2 weapons consoles.

Against a low-flying target, with the HR-76 director initially centered in a 60-deg sector, reaction time from the arrival of the antenna at the designated position (0.75–2 sec after SPS-58 detection) is 6–12.5 sec (10 sec average).

Honeywell produced a third-generation modular combat system in 1978, using H930 Mod 1 hardware repackaged for better survivability and reduced cabling. This Advanced Development Model (ADM) was tested ashore and afloat by the U.S. Navy. It

consisted of 2 modules (control/sensor and weapon) connected by 3 redundant bus cables 300 m long. Later, a third module carrying a television/laser tracker/ranger was added. This is the system tested on board the USS *Moosebrugger*.

From Honeywell's point of view, the important advances in the ADM were the demonstration that physical separation, which would greatly improve survivability, was practical; the demonstration of multiple (again, survivable) data buses; and some advances in standardized packaging of electronics. As in the earlier H930 versions, controls were programmable.

ADM, in turn, was combined with new software for real-time synchronization, ADT, threat ranking, and engagement recommendation software, to form the basis of a fourth-generation system, the Modular Combat System (MCS). In Taiwanese service, H930 MCS has been applied to FRAM *Gearing*-class destroyers rebuilt under Weapon-Improvement Program Phase III (*Wu-jin III*).

In these ships MCS controls the full range of weapons: a 76-mm gun, 2 single 40-mm L70 guns, ASROC ASW missiles, lightweight ASW torpedoes, and SM-1 surface-to-air missiles. The sensors are the Dutch DA-08 air-search radar (with DA-05 antenna), the U.S.-supplied SPS-10/58A, the Westinghouse W-160 tracker radar, the Signaal STIR, a Honeywell-developed electro-optical sensor, a data link, ESM (derived from the Hughes SLQ-31), and a Krupp-Atlas DSQS-21 sonar. The ship

The standard console of the Modular Combat System. (Hughes Ground Systems)

carries a Phalanx close-in gun and supports a torpedo-carrying MD 500 helicopter. The tactical data system may also be adapted to control surface-to-surface missiles. ASW weapons are controlled through a Mk 114 (analog) fire-control system, which was supplied when the ships were transferred by the U.S. Navy.

In this system the control consoles were made physically independent of the weapons and sensors they served. Each console could, in theory, receive data from any sensor, limited only by the software for its own task. Each sensor or weapon had its own associated distributed computing unit (DCU), communicating with the system data bus. Some, but not all, of the DCUs are mounted in the operator consoles.

In such a system the DCUs must be able to function independently yet respond to commands from anywhere in the system. There can be no single controlling element, the failure of which would destroy the system. For example, there can be no single data-bus controller providing synchronizing pulses since it would represent a potential for single-point failure. From a programming or operational point of view, such an architecture permits the easy addition or deletion (e.g., because of battle damage or electronic failure) of any module. It also makes relatively simple the assembly of a system to meet a particular user's requirements. Moreover, since the consoles and sensors and weapons need not be cabled together, some of the consoles can be located relatively far from the others. This possibility was not realized in H930 MCS. However, in its second-flight (modified *Perry*-class) frigates, the Taiwan Navy is providing a secondary CIC in the form of a damage-control central. The damage-control space will be equipped with standard consoles and can, in theory, function as an alternative CIC in the event that the primary CIC is disabled. Presumably, this requirement was formulated as a result of satisfactory experience with H930 Mod 3.

In H930 MCS there are 4 operator consoles (EO/weapons control, AAW/surveillance/weapons control, surface surveillance/weapons control, and track radar/weapons control), plus a horizontal command/control console and a computer-driven plotter. In some cases data are passed through the console into the global bus, but each console can execute any function. Thus, the air-search-radar data and the IFF data pass through the AAW console; EW, surface-search-radar, and data-link data pass through the surface console.

The architectural details that follow apply to all 3 main versions, but particularly to H930 MCS.

Each DCU contains both a resource computer (a UYK-19) and a separate I/O controller (IOC), a microcomputer. The IOC controls communication both with the devices (e.g., sensors or weapons) and with the system (global) bus that connects the DCUs. It periodically moves device data into the resource processor and retrieves computation results from it for processing into messages for the other DCUs. Because the IOC can access the resource computer's memory without the latter's intervention, the resource computer can be programmed with little or no concern for overall system operation. Its program is truly modular; thus, changes in the program have no effects on other parts of the overall system.

This feature had some attractive consequences. Software written for any application can be modified freely for another because such changes do not affect other portions of the system. For example, a standard ballistic program was written using a different set of coefficients for each gun. Such standardization greatly reduces the labor of programming, and it also makes programming errors much less likely. Moreover, changes to adapt to a new gun or a new type of ammunition require only revision of the table of coefficients. The tabular technique also makes it possible for operators to modify system operation relatively simply. For example, threat ranking can be modified by changing a table that weights various parameters describing a particular target. Such modification has no effect on the operation of other programs within the overall system, yet it can greatly change the way the ship reacts to a particular situation.

On a larger scale, modular design makes it easy for the system

Two versions of the H930 system illustrate the transition from distributed to fully modular operation: Mod 1 at top, Mod 4 at bottom. (Hughes Ground Systems)

as a whole to reject particular sources of data or decision. A controlling officer can always decide to vary the degree of automation with which the ship engages targets by affecting such decision-making programs as the threat ranker, whose features can be selectively enabled or disabled. This feature is broadly equivalent to the battle doctrine that the commander of an Aegis ship can insert into the computer system, yet it is probably much easier to change.

The IOC can be programmed in a fully standardized way, subject only to whatever special formats the device data arrive in. The main role of the IOC is to shuttle data within the DCU without overloading the resource computer. The IOC does this in part by maintaining a table of the names, addresses, data requirements, and status of all tasks and interfaces within the DCU. In some cases the IOC itself is used for application, as opposed to communication, tasks. Typically, it extrapolates gun orders to smooth ballistic-computer results into a form suitable for the gun servos. An IOC can also take over tasks from an overloaded resource computer.

Two separate buses, a parallel local bus inside the DCU and a series of serial global buses between DCUs, are used. The local bus is an extension of the internal data bus of the IOC itself. The effect of this architecture is that the IOC has, in effect, a dual-port memory connected simultaneously to the IOC processor and to the global bus. Messages awaiting transmission are stored in fixed positions in IOC memory, whence they can be read by the global-bus interface. Once a message has been read into the global bus, a flag in the message position is reset so that the IOC can enter a new message. Similarly, when the global bus interface senses a message addressed to the DCU, it can interrupt IOC operation. The IOC saves its present data and checks the special message location for a new message.

The designers accepted this degree of complexity to avoid overloading the resource computer. They sought to avoid direct computer-to-computer data transmission so as to avoid locking the DCUs into a rigid pattern susceptible to single-point failure. Hence the importance of the bus, into which each computer sends messages addressed to other computers, either for command or for weapons-control functions. The effect of the architecture is to isolate in each DCU those features particular to, say, a given sensor or weapon, so that what comes out is in a standard message format.

The system architecture avoided the use of any master data-bus controller, which would have represented a potential single point of system failure. Some degree of bus control is, however, essential because messages broadcast simultaneously would collide and become garbled. As in other bus systems, time is divided into slots, and the system has to be designed to provide only 1 message/time slot. However, division has to be done without providing any single master time standard.

In the case of the H930, each DCU is allowed a sequence number. Each message carries a sequence number. Each global-bus interface through which the message passes reads this number and adds to it; the interface has a table showing whether it is allowed to transmit in the next time slot. This arrangement is still not sufficient since a bus interface that fails will fail to increase the sequence number and, thus, will prevent another interface from transmitting. Each bus interface is, therefore, assigned a time-out period, the interval it waits before transmitting in the event the bus is quiet. Since the intervals are staggered, the unit with the shortest time-out period will automatically transmit (and restart the cycle) if several bus units cease to operate, or if the system is shut down and then restarted.

Each DCU is also provided with a real-time clock. Timing signals are important for many calculations, e.g., of target motion. Data sent to other DCUs must be timed because the purpose of the system is to provide useful dynamic data. The system clocks should, therefore, be synchronized. Again, no master clock can be provided. The solution adopted in the H930 is to include a clock time of transmission in each message. Upon receiving the message, a DCU resets its own clock to match.

Distances within the system are so short that transmission can be considered instantaneous.

Each message contains start and stop markers, a functional address (so a particular DCU can decide whether it wants to read the message, which is broadcast throughout the bus), an access vector, a word count, the data itself, a real-time clock value, and a cycle redundancy code. Message length is variable (hence the start and stop markers), up to 128 16-bit words.

Typically, 2 modules (a tracker and a missile launcher, plus 2 DCUs) can be connected to a third DCU in a common control console. In a more elaborate system, a surface-search radar, a Mk 35 optical director, and a hull-mounted sonar might all feed 1 control console, which might use their data to control antiship guns, torpedo tubes, and an antiship missile. Such a network would, in turn, be connected to a command/control console, which would be used for battle command. That console might simultaneously control another network, consisting of an air-search radar, a weapons-assignment console, an antiaircraft gun, and an antiaircraft missile. In principle, because all of the sensors feed data into all of the control consoles, any weapon can engage any target detected by any sensor. In theory, too, because much of the data generated by any sensor is processed at that sensor (by a DCU), reaction time should be very short.

Throughout, the driving philosophy was that the system should exploit the falling cost of computing, going from centralized to distributed architecture. Honeywell argued that, because the resource computers did not have to handle communications (bus) processing, overall system computing power increased in proportion to the number of the resource processors. A more tightly linked system devotes an increasing percentage of the power of each main computer to communication as it grows. In the H930 the bottleneck on system power is bus capacity. The system has 2 redundant global buses, each of which has a capacity of about 2.5 Mbits/sec. Special measures were taken to reduce message traffic, so as to remain inside this limit. Data on the bus are, in effect, filtered because much of the processing occurs in the DCUs located between sensors and bus. Typically, the global bus handles 20 messages/sec, and it is shielded from more than 100 messages/sec.

For example, radars deal with an enormous mass of information. However, an ADT radar reduces that mass of echoes to quite simple messages about the position and course of a given target. Tracking radars present special problems because in theory they generate data at about their PRF, which may be several thousand Hz. In this case radar data are transmitted directly into the appropriate resource processor, which generates the appropriate tracker-control signals digitally. The processor also smooths the corresponding pointing data, transmitting smoothed data to the system as a whole at the rate of 10–20 points/sec, a rate adequate for ballistic or missile-guidance calculation. The computations in turn are extrapolated (to a rate of 100/sec) to keep guns and missiles smoothly pointed. Admittedly, this smoothing adds complexity since the radar's processing computer could connect directly to the servos and provide quite sufficient data without any intermediate computation. However, the advantage of the modularity is so great, and the price of the additional computation so low, that it is acceptable. Presumably, it would become less acceptable were the system faced with much faster (and much more violently maneuvering) targets.

Mod 3 was designed to accommodate upgrades. Honeywell (and then Hughes) tested a 4-DCU system. The operating system as a whole has been rewritten to accommodate ADA software (it was originally written in ALGOL), and 1 ADA DCU was incorporated into the test system. In addition, 1 of the 4 DCUs had its processor replaced by the processor of the more powerful ROLM 1666 (the new processor is designated ROLM 1822). The new processor is about 5 times faster than the existing unit and has 16 times the memory capacity. Yet it occupies a circuit board compatible with those of the earlier Mod 3 system and, thus, can be used to upgrade existing ships.

As of late 1987 Honeywell planned to continue development

of MCS, to include several functions previously not completely integrated into the system:

- real-time data-link processing, for multiship operations
- separate operator stations for warfare area controllers, sensor supervisor, and emergency CIC backup
- integrated ASW capability with aircraft control, sonobuoy processing, complete underwater-situation display, and control of on-board ASW weapons (which at present are still controlled through the Mk 114)
- interactive automatic operation with IFF and ESM
- expanded capabilities for triangulation, navigation, and collision avoidance.

The current ACS (Advanced Combat System) or MCS 2000 effort goes further. It includes a new and much more powerful data bus, with a capacity of about 100 Mbit/sec, compared to the 10 Mbit/sec Ethernet standard in most systems.

◆ Litton System for Korea

In July 1989 Korea awarded the Litton Data Systems Division a contract for a naval tactical command/control system to provide automated contact between a shore command facility and a deployed patrol craft. The Korean subcontractor is Samsung, which already manufactures the Ferranti WAS 423 system. No details of the system are available, but it is apparently similar to a land-based command/control system, TYQ-23, which is used to control tactical aircraft. The marines will use it to replace the Marine Tactical Data System (MTDS), which in turn is compatible with NTDS. The current TYQ-23 computer is the 16-bit AYK-14 (2 are used in parallel), although Litton hopes to replace it with a 32-bit computer programmed in ADA, with 6 times the AYK-14 performance. Litton has an in-house project to add raster-scan (rather than cursive) displays.

The shipboard terminal of the Korean system is probably the Litton Tactical Display Console (TDC), which the company advertises for air, land, and sea applications. Because it was originally designed for applications such as the MTDS replacement, the TDC is designed to receive information on 1 link and transmit it on a different type of link (the marines must use both NTDS and land-oriented data). Thus, it can act as a gateway between link nets. The TDC achieves this type of performance by providing multiple track-reporting interfaces, the track picture itself being carried by the console computer (global memory).

The TDC has a 19-in color display incorporating a transparent touch panel (TTP). Such construction entirely eliminates the need for trackballs, joysticks, or light pens. Internally, the global memory and graphics controller feed into a VME bus, which in turn feeds the system-control and situation-control (i.e., data-filtering) processors and the interface- and link-control processors. Range scales are 2–2000 nm, and the console can carry 1024 tracks. The console is designed to grow to accept a 25-in color monitor.

The TYQ-23 contract was awarded in May 1987.

The first installations will be on board Korean frigates. The same Litton TDC, with its 19-in (1028 × 1028-pixel) display, is a TADIL-A (Link 11) receive-only terminal on board the battleship *Iowa*, where it also drives a large-screen display and 2 remote monitors.

DISPLAYS

◆ NTDS Displays

The current standard is the Hughes UYA-4, which replaced the earlier SYA-4; the UYA-4, in turn, is being superseded by the Hughes UYQ-21. UYQ-21 is also the standard display for several other systems.

SYA-4 was the first production NTDS console, designed about 1960. It employed discrete semiconductor technology. The first NTDS systems had switchboards that could address 15 SYA-4 terminals. The single-CRT console has a rotary switch for 22 operating modes. The basic console function is radar-target de-

tection. SYA-4 as a whole consists of the display consoles, special-purpose readouts, radar-azimuth-conversion equipment (the SYA-4 system converts ship-centered polar coordinates, in which radar targets are detected, into NTDS-oriented rectangular coordinates), a radar-data switchboard, a pulse amplifier, and a symbol generator. Each CRT console is accompanied by a separate console to display alphanumeric data (see below). System control (weapons coordination) requires a second type of console.

UYA-4 (designed about 1965) introduced integrated circuitry; only 1 type of console was required. The single console is designated OJ-194/UYA-4. Each console has 18 variable-action buttons (VABs) but also 6 fixed-action buttons, so that each VAB can adopt up to 48 labels. Similar variety on an SYA-4 console required entry of a function code by dialing. The OA-7079(V)10/UYA-4 console that immediately preceded OJ-194 has a roller mechanism, for 30 operating modes. OJ-194 has 45 operating modes. The system as a whole has 16 radio channels, compared to the 10 of the earlier SYA-4.

UYA-4 includes a large-screen (20-in) horizontal summary console, originally OA-7981 and then OJ-195/197. OA-7981 has an internal memory (4k 30-bit words). OJ-195 has an improved display, and OJ-197 has 18 VABs (48 labels) and 6 fixed-function buttons in place of the action entry panel and rollerball of the earlier console.

The system also employs an OA-7980 height-finding console, with 3 × 5-in CRTs (2 for height, 1 for raid size estimation). One CRT shows targets within selectable bearing gates (3, 6, 11, 22 deg), the other targets within selectable range gates of 4, 16, 32, and 64 nm. Each can call up a track by number and can show either full altitude scale (100,000 ft) or low altitude (30,000 ft). The raid-count CRT has selectable range gates (4, 8, 16 nm), azimuth lines (7, 15, 31, 63 deg), and bearing gates (3, 6, 11, 22 deg). Multiple CRTs are needed because the associated radar operates in 3 dimensions, not the 2 of a single CRT.

With the CIGARS (Console Internal Generation and Refresh System) field change, OJ-194 can create 1000 separate graphic symbols and also has much better ability to generate circles. The CRT is 12 in in diameter, and its minimum range scale is 1 nm.

Pre-CIGARS consoles have no internal memory capacity. In their case the UYA-4 system includes a refresh memory unit (RMU), which actually produces the successive screen images at a refresh rate of 15/sec, for flicker-free presentation, via a central pulse amplifier/symbol generator (CPA/SG). All UYA-4s include the CPA, which has 2 input and 2 output channels. Each channel can drive 15 consoles. Thus, 2 computers can drive 2 groups of up to 15 consoles each, and they can switch between the 2.

UYA-4 also includes a radar azimuth converter, CV-2095/UYA-4, for each radar, converting analog range and bearing data to digital form suitable for display on the digitally controlled consoles; the converters also produce the range marks used by the consoles.

A version of the OJ-194 console with CIGARS serves as the display of the SPS-48 and -52C radars. The display is computer driven, and it provides the operator with descriptions, such as land clutter or jamming, automatically selecting the best possible fix.

A full NTDS/WDS installation incorporates 2 separate types of operator console, 1 (with a single CRT) for data input or data utilization, and 1 (with 3 smaller CRTs in parallel) for height/size display. The latter, OA-7890/UYA-4, is used to evaluate and supply target height and raid size; 2 CRTs are range-height indicators, and the third is a size-analysis indicator. The main CRTs are PPIs with a maximum range of 512 nm. In early versions of UYA-4, as in SYA-4, each is associated with a separate readout console, carrying a square CRT and providing alphanumeric data on track number, IFF (SIF) code, track bearing and height, track range and speed, threat evaluation, interceptor data, and weapons recommendations. The OJ-194 console combines the 2 CRTs in 1.

Each single-CRT console can function in several data input modes:

Air Detector/Tracker (DET/TK) Each operator is assigned a specific sector, e.g., 60-deg wide, out to 128 nm; the operator detects (inputs into NTDS) all observed contacts and tracks them (monitors NTDS tracking). The number of consoles assigned to this role varies with the level of air activity. Friendly aircraft are automatically tracked by a Beacon Video Processor (BVP) using their Mode II IFF responses. In principle, a detector/tracker first enters a contact as a tentative plot (not transmitted to other ships via Link 11); the ID operator checks to see whether it is friendly. On a second radar sweep, the plot is refreshed, and the computer uses the 2 points to establish target course and speed. On the third update, the computer begins to carry the contact as an unknown; the track supervisor is responsible for ensuring that it is not a contact already carried by another ship in the group.

Surface Tracker (SURF) This tracker also sees the low-altitude air picture. The PPI is set on a shorter-range scale.

Identification Operator (ID) This operator assigns the identification symbol (friendly, unknown, enemy) to a track. The NTDS symbology makes no allowance for neutral targets.

ECM Supervisor (EC) This supervisor evaluates ECM raid reports, enters this information into the computer, and sends it via the data links.

Special Tracker (SPL-TK) This tracker provides high-precision data on a limited number of tracks for insertion into the associated WDS; the PPI is set on a 4-mile-range scale.

Track Supervisor (TK Sup) This supervisor monitors the system operators. The TK Sup assigns sectors to the detector trackers, supervises the height/size operator, corrects confused track situations, removes tracks when appropriate, supervises the communication keyset, ensures the accuracy of geographical position data, and can assist the ID operator. This role is equivalent to the "picture editor" in some Israeli systems.

Similarly, there are several data-utilization modes:

Ship's Weapons Coordinator (SWC) The SWC is the primary assistant to the Ship's Evaluator (the supervising officer in CIC). The SWC interrogates the NTDS computer to choose an optimum weapon, orders and initiates engagements, and orders hold-fire or cease-fire.

Intercept Controller (IC)

Air-Traffic Controller (ATC) The ATC is on carriers only.

Flag Mode on flagships This mode provides the embarked unit commander with a summary tactical plot.

Fire-Control Systems Coordinator (FCSC) The FCSC is for ships with embedded WDSs. The FCSC, the ship's fire-control officer, receives missile assignments from the SWC, decides which missile fire-control system to employ against a specific target, initiates interdirector designation, coordinates optical designation, and enters fire-control and weapons status into the NTDS computer. If a target is in the blind zone of a fire-control radar, the FCSC recommends a course to clear the director.

Engagement Controller (EC) The EC is for ships with embedded WDSs. The EC, the ship's missile officer, is under the FCSC and sends orders to the missile system (e.g., type of missile), ensuring that the target is not in the launcher's blind zone.

The full NTDS system also includes 4 keysets to input information into the computer: navigation (own-ship position), aircraft data (CAP data: e.g., type of aircraft, weapon load out, fuel state), ECCM (characteristics of intercepted transmissions, including bearings), and communications (identifies other ships in the Link nets, allows the TK Sup to send transmitting instructions to the NTDS computer).

A full NTDS/WDS includes a separate weapons-control panel, generally flanked by the FCS and EC consoles, providing the

means to observe and manually control data flow between the computer and the fire-control launching systems. There is also a casualty weapons-direction panel (CWDP) in the missile-director control room, providing backup in the event that the NTDS computer fails. The CWDP can select missile mode (AA or surface), can designate from director to director, and can warm up and fire missiles.

These modes of operation are typical of any pre-Aegis NTDS system.

UYQ-21 is the current multipurpose display system. Hughes consoles within the system are OJ-451/452 and OJ-535; see also the AVP (OJ-653), below. The system also includes the PT-525 liquid crystal projector described below, with an OJ-471 controller. UYQ-21 can display 256 unique shapes (64 alphanumeric, 128 tactical symbols, and 32 symbol modifiers, plus 32 computer-programmable symbols). Symbols can appear in multiple sizes and intensities, and they can be made to blink to emphasize them. Lines are point to point, velocity vectors, and connected segments. The system can also generate circles, ellipses, and arcs in any size or orientation.

OJ-451 is a high-resolution stroke-writing (cursive) console. It is used to display synthetic video in systems employing a central data buffer. The console can also display raw video. An OJ-451 basic display unit (BDU) has a 13 × 11-in CRT (1024 × 800 or 1024 × 1024 pixels). Spot size is 0.010 in. Contrast ratio is 5:1 (3 bits/pixel).

OJ-451 is used in Aegis systems and in recent NTDS installations.

OJ-452 is a 2-screen acoustic console, displaying both synthetic video and raster-format video. Each CRT has its own acoustic display generator (ADG: CV-3550). The ADG can accommodate up to 2 Mbits of memory/CRT to refresh the acoustic data display. Contrast ratio is 12:1 (4 bits/pixel). Among

OJ-451 console with auxiliary monitor on top. Versions of this console can be used with either the UYA-4 or the UYQ-21 NTDS display systems. (Hughes Ground Systems)

OJ-452 acoustic console. (Hughes Ground Systems)

other ASW applications, OJ-452 is used in shipboard LAMPS installations.

OJ-535 is an alternative monitor, for systems employing digital-television (DTV) technology, which includes raster-scan radars. It is the high-resolution raster-scan (1280×1024 or 1024×1024 pixels, selectable on the front panel) display of the system, measuring 13×11 in. Minimum range scale is $\frac{1}{2}$ nm. Current consoles are monochrome, but 3-color units are replacing them. Up to 4000 characters can be displayed. The console has 5 input channels, 3 for composite video and 2 for composite or noncomposite video.

OJ-535 is used in cruiser and carrier CDSs (non-Aegis).

OJ-451 and OJ-535 exist both in single-screen versions and in versions with auxiliary CRTs (IP-1357) above the main screen. OJ-535 also exists in a dual-CRT version (the CRTs are stacked vertically). In this case the upper CRT is rotated 180° to provide the operator with an optimum viewing angle.

The 12-in auxiliary CRT is used for alphanumeric readout (2048 characters in a 64-character font); it can also display 525-line video.

The consoles are all equipped with keyboards, with trackballs, with a computer-controlled action entry panel (3×6 switches), with 20 variable function keys, and with a separate 6×7 array alongside the keyboard.

Aegis ships and some others now have large-screen projection displays, PT-525/UYQ-21, as part of their UYQ-21 display systems. Aegis cruisers have 4 projection displays; Aegis destroyers (Arleigh Burke class) each have 2. Large-screen displays are also being installed on board carriers, as part of their TFCCs (2 each), and on board some classes of NTDS ships: 1 each on board Leahy- and Belknap-class cruisers (but 2 on board the flagship, Belknap, for installation in FY93), 2 each on board the Virginia-

OJ-535(V)3 double-monitor console. (Hughes Ground Systems)

and California-class nuclear cruisers; 2 each on board Kidd-class missile destroyers (for installation in FY97-98); and 4 each on board Wasp-class amphibious carriers (LHDs). As of early 1990, installation had been completed on board the carriers Saratoga, Independence, Kitty Hawk, America, Nimitz, Dwight D.

OJ-535(V) single-monitor version. (Hughes Ground Systems)

Eisenhower, Theodore Roosevelt, and Abraham Lincoln and on board the cruiser *Richmond K. Turner*. The FY90 program calls for installation on board the cruisers *Gridley* and *Fox*. FY91 includes the cruisers *Reeves*, *Wainwright*, *William H. Standley*, and *California* and the carriers *Constellation* and *Carl Vinson*. FY92 installations are the cruisers *Josephus Daniels*, *Sterett*, and *South Carolina*.

Installation was scheduled for the battleships *Iowa* and *New Jersey* (for FY92), prior to the decision to lay them up, their screens will presumably go on board their sister ships.

The PT-525 liquid-crystal projector is driven by a digital television-signal generator, CV-3582, which processes computer output. One generator drawer suffices for 4 channels, as in Aegis cruisers. The generator provides 1024 × 1024 pixel resolution. Projection can be vertical or horizontal; in a CIC, the projector is generally located behind the large display screen. The typical image size is a 42-in square.

◆ Advanced Video Processor (AVP)(OJ-653/UYQ-21)

Developed by Diagnostic/Retrieval Systems, AVP is an addition to a UYQ-21 display system. The initial application is to the SQQ-89, but the manufacturer expects the AVP to become the standard U.S. Navy color display. Future versions may have single CRTs. The CRT is a 1280 pixel × 1024 line, color, raster display (30 frames/sec in interlaced mode, 60 frames/sec in a noninterlaced mode), expandable to over 2000 lines. Video bandwidth, which determines display information content, is 120 MHz. The current production version, for SQQ-89, has 2

CRTs mounted vertically. AVP can emulate the current UYQ-21 NTDS display but can also display specialized graphics.

The AVP is built around a standard VME bus. The embedded host processor uses a 32-bit 68020 chip with a 68881 coprocessor; memory is 1 Mbyte of ROM/PROM (for program software), 32 kbytes of fast read/write memory, and 4 Mbytes of data memory. The separate graphics processor has 256 preset characters, plus 512 software-defined characters, with 4 sizes/font. The graphic acoustics processor has a throughput of 5 Mflops (expandable), with a pipelined architecture; it provides 110,000 10-pixel vectors/sec/screen. The associated image memory is 8M pixels, in 256 colors and 256 shades of gray (24-bit planes). Claimed MTBF is 3000 hrs (15-min MTTR).

Full-scale engineering development of the AVP began under the FY88 program, with a production decision due in FY90.

◆ CWS (Color Workstation)(OJ-666(V)/USQ-88(V))

The Raytheon CWS is a "smart" display and, thus, halfway between an adjunct to a command/control system and a stand-alone data processor. CWS was the first high-performance color graphics workstation bought by the U.S. Navy, and its first planned application was to the Flag Display Data System (FDDS), part of the TFCC described above. However, the CWS contract for FDDS was canceled, and DTC 2 computers were bought instead. CWS is derived from Raytheon's experience with UYQ-31.

As of the spring of 1989, 108 units were on order, with options for another 159. Current applications include ATACMS and the JSIPS (Joint Services Imagery Processing System). CWS was ordered for TFCC but was rejected in favor of DTCs.

The standard CWS cabinet accommodates 2 color, 19-in, 1280 pixel × 1024 line, raster-scan monitors, driven by a Silicon Graphics IRIS geometry engine and a new variable-line-rate display controller. The same hardware can accommodate several alternative monitors: 20 × 20 in (2048 × 2048 pixels, used by the FAA for ATC), 13-in (diagonal: 1280 × 1024 pixels, a smaller version of the standard 19-in color display), 17-in diagonal monochrome (1280 × 1024 pixels, standard in the UYQ-21 series), and 10 × 10 in monochrome (1024 × 1024 pixels). Computer capacity suffices to drive a 2048 × 2048-pixel monitor at 60 frames/sec, i.e., more than 240M pixels/sec. Special software avoids the usual jagged edges of monitor images by modulating adjacent pixels, at a rate of up to 40M pixels/sec.

A 16-bit, local-display, processor bus provides intermodule command and diagnostic communications. A parallel high-speed data path connects the display processor, the geometry engine, the image-memory-update processor (IMUP), and the refresh-memory/video generators (RM/VG). The display processor, built around a 68020 chip, translates functions written in high-level language into data and control words for the remainder of the hardware. The display processor makes it possible for application programs to be written in terms of user-defined world coordinates. It also stores the external data display list and accommodates serial I/O ports.

The graphics engine translates and scales the user-defined "world" boundaries and coordinates into a form suitable for display in the pixels of the monitor(s); it also preprocesses data for the IMUP. The IMUP converts graphics instructions and data into address and data patterns required to plot every pixel into memory. For example, it fills in pixels between boundaries and between vector end points. Finally, the RM/VG stores 2 frames of video data (1 display, 1 refresh) for each monitor. It feeds directly into the display monitor, converting digital pixel data into analog data suitable for display and monitoring screen refreshment and synchronization. One RM/VG drives 1 monitor; the CWS can accommodate up to 8 of them, all on a high-capacity (30-Mbyte/sec), 64-bit, image-processing bus fed by the image generators (the IMUP and the geometry engine). Thus, the CWS can drive up to 8 monitors. Five RM/VGs can be fitted into the CWS backplane.

There are 3 types. A 2K RM/VG drives the highest-resolution display (2048 × 2048 pixels). The 1K version drives a 1280 ×

The Advanced Video Processor (AVP), OJ-653/UYQ-21. This example contains an acoustic video processor (behind the cooling vents) in its bottom. (Diagnostic Retrieval)

1240-pixel color monitor or two 1024 × 1024-pixel color monitors; the 0.5K version drives a 640 × 480-pixel display. The RM/VGs use 256k-image memory chips and store 8 bits/pixel. The video-generator portion of the RM/VG contains a 256 × 24-bit color look-up table and either three 8-bit 360-MHz (2K-version), three 8-bit 125-MHz (1K-version), or four 8-bit 64-MHz (0.5K-version) digital-to-analog converters. A total of 256 colors can be selected from a palette of 16 million.

The graphics engine has a large number of special-purpose VLSI chips to perform 2/3D geometric transformations, with a throughput of more than 80,000 floating-point coordinates/sec.

The display processor itself is fed by a 32-bit, 10-Mbyte/sec bus, to which are connected I/O modules, up to 3 separate (and parallel) application processors, a video formatter, and a digital scan converter. Each I/O module has its own 68020 local processor. As of 1990, CWS can accommodate NTDS E, MIL-STD-1553B, and ESDI disk I/O; the design can accommodate the new Safenet (see the entry on the NGCR computer system) and Mil-188C. The video formatter is used to receive and process digital raster-oriented radar or sonar data. It scrolls and waterfalls A-scan data and preprocesses A-scan data for display. The digital scan converter performs analogous processing of analog PPI radar signals; it offers variable range scales, offsets, target aging (i.e., it can store subsequent target positions), sweep correlation, and scan integration. Because analog radar video is converted into pixel form, graphics/texts can be superimposed on it.

The video formatter and the digital scan converter also connect directly to the image bus.

The application processor is built around a 68020 running at 16 MHz; it also contains 0.5 Mbytes of PROM, 12 Mbytes of read/write memory (RAM), 3 timers, a DMA controller, a floating-point math coprocessor, and 5 serial interfaces for external inputs.

Thus, the basic CWS accommodates four 68020 processors, 1 in the display processor and 3 in separate application processors. They run at a throughput of 2 MIPS. Each has 12 Mbytes of memory. An enhanced configuration uses dual 32-bit 68020s, each with 24 Mbytes of memory, with dual 160-Mbyte hard-disk drives. The 3 applications processors can be replaced by 15-MIPS RISC-based devices (using Motorola 88000 chips).

CWS was initially developed for the Federal Aviation Administration's Advanced Automation System, using a 2048 × 2048-pixel, high-resolution, color display (1984-85); meanwhile, Silicon Graphics developed a high-speed graphics processor and related software. Mil-spec packaging and display firmware were developed in 1986-88.

◆ ACWS/AMW/BSY-2 Console

Librascope's Advanced Color Work Station (ACWS) and Advanced Multifunction Workstation (AMW) were displayed at the U.S. Navy League show in April 1990. ACWS is the display of the Kollmorgen nonpenetrating periscope now under development. The 2 workstations are very similar; AMW is a growth version of ACWS. The periscope console has 2 CRTs and 2 image processors (forming 2 image channels for the 2 cameras of the periscope). The console includes image postprocessing. For example, the image produced by a FLIR in fog can be intensified using a pixel-by-pixel processor.

ACWS is available in both single- and dual-screen (vertically stacked) versions, in each case with 19-in (1280 × 1024 pixel, refreshed at 60 Hz) CRTs. It is built around a 32-bit VME bus, which normally carries a display processor (a Motorola 68020), a display memory, and a graphics engine feeding the screen(s). The bus can also carry a hard or optical disk, an applications processor (another 68020, which can be supplemented by an array processor), and a man-machine interface processor (a third 68020 handles input devices: keyboard, joystick, trackballs, electroluminescent touch screen, digitizing tablet, and audio inputs). The ACWS can digitize up to 3 separate analog video inputs, which enter via its graphics engine.

Each display/applications processor carries 4 Mbytes of memory and operates at 2 MIPS (100 kFLOPS).

The Librascope Advanced Color Workstation (ACWS). (Librascope)

The graphics engine uses a 68020 I/O processor, a 12-MIPS display list processor, and a 20-MFLOPS array processor; its image generator is a separate high-speed ASIC processor. It can calculate 1M (10 pixel) vectors/sec, 27M pixels/sec, 50,000 flat shaded polygons/sec, or 60,000 5 × 7 characters/sec. It can erase a full screen in 150 microsec, and it can support pan, zoom, and scroll functions on the screen at a rate of 24 frames/sec. There are 2 color (red-green-blue) output channels, each of which can have up to 12 bit planes (for overlays) and each of which can be drawn using a 4096-color palette (i.e., 12 bits/pixel). The engine can accommodate an optional shading processor. Radar and sonar sweep converters are available.

AMW is a growth version with an array processor, a real-time relational data-base manager, and an image processor (ACWS has only the image processor); the chassis can accommodate 3 processors. The array processor will provide sufficient capacity to display active sonar and radar data; to enhance active sonar, radar, and optronic data; and to generate 3D presentations of the acoustic environment (e.g., ray traces), mine fields, navigational aids, and weapons trajectories. AMW is also somewhat more application- (or engineering-) oriented than ACWS.

Like ACWS, AMW is built around a VME bus with 34 slots. Typically, it accommodates relational processor(s) with associated 28-Mbyte RAM, plus array processor(s) with their associated RAM, plus 150 Mbytes of hard disks. The relational processor can store and sort its 28 Mbytes 1000 times faster than a 68020-based software system. The array processor operates at 25 MFLOPS, for parallel processing of sonar, radar, or optronic data. These are in addition to application processor(s), each with 4 Mbytes of RAM, and a graphics processor.

The graphics processor is much more powerful than that of the ACWS. It consists of up to 6 types of elements, each of them connected both to the VME bus and to a separate picture element bus: frame grabber(s), a display list processor, a display list memory, hardware vector generator(s), and bit-map (frame-refresh) memories/display output processors. The latter interact with the two 1280 × 1024-pixel (60 frames/sec) touch-interactive (using IR with 1/8 the resolution of the monitor) color CRTs, which also connect with the applications processor. The optional frame grabbers convert standard composite video to 640 × 480 (8-bit monochrome or 12-bit color)-element images

for input to the display-refresh memories, which actually feed the monitors. Images are processed at 30 frames/sec. The bit maps have 4–16 planes/monitor, which can be overlaid with 4-bit plane/16 color transparent annotations.

CRT graphics capability is similar to that in the ACWS.

The operator panel provides fixed function keys, programmable keys, a typewriter keyboard, track marbles (trackballs), and a 512×256 -element electroluminescent touch screen.

The BSY-2 submarine combat system uses a simplified version of ACWS with only a single graphics engine. However, the chassis allows for later growth.

◆ MRCS

UNISYS's Militarized Reconfigurable Console System is its VME-based intelligent console, presumably based in part on experience gained with the *Kanaris* project (see the Antisubmarine Warfare section). The console has 12 slots for 68020/68881-based processors (up to 4 on the bus) and can accommodate 4–24 Mbytes of RAM. Processing speeds can be up to 6 MIPS. The bus can also accommodate up to four 68020-based I/O processors and up to 12 interfaces. The embedded graphics generator supports 2 independent monitor drivers (4 graphics planes, expandable to 8, per driver) with 16 colors (expandable to 256). It can generate 50,000 vectors and 5000 characters/sec, and the hardware incorporates a cursor generator. Resolutions: 768×1024 , 1024×1024 , and 1024×1280 . Dimensions (single monitor): $53 \times 26 \times 55$ in, 725 lb.

◆ Multifunction Workstation

The Rockwell (Autonetics Marine Division) workstation, announced in 1990, is an offshoot of the OJ-564 console used in the SOSUS system. It is included here (rather than under ASW) because it seems to fit the same basic requirement as the Raytheon CWS and the Librascope ACWS. The French Navy has ordered a half-height version and the associated cabinet. Like the other workstations described here, the Rockwell unit is built around a VME bus (backplane), which can accommodate standard cards for functions such as analog-to-digital conversion and video processing boards. The basic workstation contains a 1-channel processor but can accommodate a beam-former.

Although the workstation has 2 monitors, it can display 4 video channels simultaneously by windowing; it accommodates 2 separate video buses, each of which can be fed by 2 video channels. The graphics engines are Sun Windows with enhanced throughput (a polygon can be filled at the rate of about 25M pixels/sec, and 200,000+ vectors/sec can be generated). The video channels can accommodate 256 colors and have a bandwidth of more than 100 MHz; they produce 60 frames/sec without interlacing. Displays are 16 or 19 in (diagonal) or 20×20 in, with resolution of 1280×1024 , 2048×2048 , or 2048×1536 . They can be color or monochrome. Each monitor has 4, 8, or 24 memory planes.

A diagram of workstation architecture shows 4 main buses feeding the VME bus: a CPU bus, an array processor bus, and 2 video buses; the VME bus also carries RAM, an operator interface, and a controller with its own disk memory. The CPU (a 68020 with a 68881 coprocessor) carries 4 Mbytes of RAM, and the system can accommodate a 12-Mbyte RAM card. Available operator interfaces include a keyboard, a trackball, track marbles, a joystick, a stiff stick, a light pen, a mouse, hard and soft (programmable) function keys, and a flat touch panel. The console accepts up to 18 channels of RS-232 I/O, and it can accommodate a 344-Mbyte hard disk.

Dimensions: $75 \times 22 \times 48$ in (fits a 24-in hatch); weight is less than 500 lbs.

Rockwell offers a related single-monitor acoustic processor. One application is a specialized torpedo alert processor (TAS), which is fed by existing acoustic sensors and which provides an audible alarm as well as a CRT display. TAS shares unique software and special hardware (acoustic display, spectrum analyzer, and beam-former) with other Rockwell acoustic processors.

◆ SPA-25, SPA-50, and Other Radar Displays

SPA-25 and SPA-50 are the standard U.S. raw-video radar repeaters, superseding the earlier SPA-4. The earliest version dates from the mid-1960s. The chief current version is SPA-25F, a horizontal or vertical 10-in, digital, solid-state PPI. SPA-25G (see below) is a very different and much more capable replacement and, thus, merits separate treatment.

In SPA-25F displayed range is $\frac{1}{2}$ –300 nm, with $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 5, 10, 20, and 50 nm range rings. The range strobe can be used to read off ranges within 0.03%, and resolution is 10 yd below 50 nm and 0.1 nm above 50 nm. LED readouts show bearing and range of strobed targets (range in nm and yd). The display can accept radar signals at 10–5000 pps, with widths of 0.3–25 microsec and a scan rate of up to 60 rpm. This display can function either as a conventional PPI or as a range-height indicator for 3D radars. SPA-25 can be connected to a dead-reckoning unit that offsets its sweep (so that the radar shows something approximating true rather than relative motion). MTBF is 4000 hr (MTTR 20 min).

SPA-25 is often used alongside SPA-50, which is generally similar except that its CRT is about twice as large (22 in in diameter). SPA-25 accepts PRFs between 15 and 5000 pps. There is also a smaller-diameter PPI, SPA-18 (7-in screen, range scale 2–30 nm, PRFs 57–3000).

SPA-18, -25, and -50 were generally used with surface-search radars. They succeeded an earlier SPA-4 (10-in PPI, 140–3000 pps, range scale 1–300 nm). The contemporary air-search repeaters were SPA-8, -33, -34, -40, -41, -43, -59, and -66.

SPA-8 can show an off-centered display and can be used to display information. The electronic cursor and range sweeps or strobe and range sweeps can be time-shared. Range scale is continuously variable from 4 to 300 nm. Tracking cranks position the strobe or electronic cursor origin, and any target within 250 nm may be centered on the scope. The origin of the off-centered cursor and strobe may be controlled separately from the sweep itself. SPA-8A, -8B, and -8C are trackers. These PPIs have provision for DRT input.

SPA-33 and -59 are off-centered PPIs that can operate either as general-purpose PPIs or as part of an AEW system. They are similar to -8A, -8B, and -8C but have 2 joysticks in place of the range and bearing cranks, 1 for cursor origin and 1 for strobe and cursor bearing line. They have no provision for DRT input. Range limits are 300 and 400 nm, respectively.

SPA-34 combines -8 and -33 features and can function as a general-purpose off-centering PPI, an AEW-tracker indicator, or as an AEW repeater. It is too large for any ship smaller than a destroyer.

SPA-40 is a range-height indicator, with a maximum altitude of 150,000 ft and a maximum range of 300 nm. A joystick controls a height-line cursor or an angle-line cursor. Height is calculated by an analog computer and is accurate to within 200 ft. Errors due to earth curvature and refraction of radar signals are automatically corrected. The operator may select a delayed sweep to show a 30-nm segment between 0 and 150,000 ft, between 50,000 and 150,000 ft, or between 0 and 70,000 ft. The center of the range segment may be between 15 and 285 nm.

SPA-41 replaces SPA-40; it can display both height and angle simultaneously. The CRT is rectangular rather than circular.

SPA-43 is an intercept tracking-and-control computer.

SPA-66 is a more accurate replacement for SPA-34. In addition to the SPA-34 functions, SPA-66 can accept rectangular coordinate voltages to function as a range-height indicator for use with electronically scanned 3D radars, such as SPS-39/52. In the tracking mode, the operator sets the tracking strobe or the cursor origin to follow the position of any selected point on the display (e.g., own-ship or a selected target). The tracking information is displayed on counters, and it can be transmitted by synchro (i.e., by analog link). In the AEW-tracking mode, the reference point is own-ship position. In the AEW-repeat-indicator mode, the center of the display is displaced by an amount equal to, and opposite from, the offset provided by the tracking

An SPA-66 precision radar scope in use in the CIC of the frigate *T. C. Hart*, 1986. Note the fade chart under the sailor's right elbow: it shows the fading and reinforcement of the radar beam, probably that of an SPS-49, at different elevation angles, because of interference between the direct path and the path of a signal reflected off the sea. Such a fading chart can be used for a rough estimate of aircraft altitude; frigates like this one have no long-range 3D radar. (U.S. Navy)

set. The point of reference selected on the tracking set becomes the point of origin for the repeater. If own-ship is selected as the tracking point (i.e., if own-ship position is tracked on the radar picture provided by the airborne radar), then the repeater reads off ranges and bearings relative to own-ship; it provides a radar picture as though the AEW radar were part of the ship's fixed radar suite. As in other repeaters, SPA-66 shows fixed range rings and incorporates a variable-range strobe (to measure range accurately) and a movable cursor (to measure bearing). The cursor and range strobe can be centered on the sweep or unlocked and moved independently to set up air intercepts. The range strobe can also be used as a variable range ring, adjustable between 4 and 400 nm.

SPA-25G replaces virtually all of this equipment. It has a raster-scan display, uses radar digital scan conversion, and incorporates a 5-Mbit digital memory. SPA-25G can function as an electronic plotter and, thus, can form the basis of a very simple tactical data system on board a ship without such a system (or as a system backup). Although it is nominally a radar display, SPA-25G has some of the attributes of a simple tactical system such as CANE; it exemplifies the blending of display and data-system technology.

The 17-in rectangular screen shows both raw and processed video; the radar processor accepts 100–3600 pps, antenna rates of 0–60 rpm, and signals as short as 50 nanosec. Radar data are stored in digital form in three 1024×1024 -bit memory planes (to provide a gray-scale level of 8 shades, corresponding to 3 bits). The display itself is 1280×1024 pixels, the central 1024×1024 elements of which are dedicated to radar video (the rest are tabular). The CRT is raster scanned in 1125-line format (80 frames/sec, interlaced 2:1, i.e., a full 40 frames/sec). Resolution: 92 vertical lines/in.

Memory suffices to store, plot, and label 99 targets, 64 of which are target tracks. The system automatically calculates range, bearing, speed, and CPA and displays these data in a track-data-file block on the CRT; the data are also automatically made available to the data bus connected to the SPA-25G. Graphic images using up to 128 display lines can be created to show traffic lanes, harbors, marshaling areas, restricted zones, etc. Because radar data are held in a digital memory, the display need not fade (decay time is adjustable between 250 msec to no decay). Range scales are $\frac{1}{4}$ –250 nm or $\frac{1}{2}$ –500 nm; range rings are set at $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 5, 10, 20, and 50 nm (with 0.25% accuracy).

There is a special air-intercept mode, in which the processor calculates an intercept solution and displays alternatives for near-collision intercept and forward-quarter intercept. Outputs can be synchro or digital.

The associated executive controller is a 68000 16-bit chip, assisted by 8-bit microprocessors.

MTBF is 3000 hr (MTTR less than 30 min).

Both versions of SPA-25 are manufactured by ISC Cardion.

The new (1990) SPA-50G (made by Cardion) is intended to supplement SPA-25G. SPA-50G is intended as a tactical display, as a means of multisource data correlation and display, and as a real-time tactical decision aid. Because it incorporates considerable memory and computing power, it adds to the overall reliability of the CDS it serves. It can also be used for data link access, and it can be connected to a shipboard data bus network. For example, it can perform an electronic mailbox function.

SPA-50G uses scan-conversion techniques (i.e., raster scan) to display data from several sensors as well as graphic overlays. The cabinet is tied together by a VME bus. It incorporates 5 microprocessors (a 68020 system processor, a 68020 application processor, a 6809 operator-control processor, a 6809 for 1553 bus control, and a bit-slice graphics generator) with over 7 Mbits of digital bit-mapped memory for graphics, to accommodate 3 radar memory planes (i.e., video from 3 radars simultaneously) and 4 graphics memory planes (typically a status and designator plane, an own-ship plane, a graphics plane, and a map plane, each of which can be switched in and out of the display). There is also a radar-video integrator. The display is 1280×1024 pixels, refreshed at 40 or 80 Hz.

System processor memory capacity is 64 kwords of PROM and 64 kwords of RAM (expandable to 126k and 256k, respectively). The application processor memory is up to 8 Mbytes of RAM and 512 bytes of PROM, with further expansion capability. The application processor board can accommodate a 68020 (16.67-MHz clock rate), a 68881 math coprocessor, 4 Mbytes of dual-port dynamic RAM, up to 512 kbytes of EPROM, and up to 32 kbytes of static RAM. The graphics generator board uses

SPA-50G, a new-generation console, parallel in concept to SPA-25G. Such consoles include automatic radar target detectors and, thus, can be used to feed combat data systems such as FFISTS. (ISC Cardion)

a 125-nanosec instruction cycle and a 16-kword display list buffer. It has 2 standard character sets, large and small. The system runs at 16 MHz.

Further internal circuit boards can be added to expand SPA-50G capability.

As in the case of SPA-25G, this is another example of a display merging with combat system computers.

◆ UYQ-23

Motorola's smart interactive terminal is used for intelligence systems such as NIPS (SYQ-9) and BGPHEs (SLQ-50). It fits a standard 19-in rack; it incorporates a stroker display and can also display real-time or time-compressed video. The (V)3 and later versions have a split-screen display, and its keyboard includes a trackball. The (V)5 version has 2 trackballs. The (V)6 version has 3 split-screen displays. Internal memory varies with the version: 8k, 16k, 32k, or 128k 16-bit words. The digital interface is NTDS fast or RS-232C, depending on the version. The (V)1 version (8k memory) is part of OK-324/SYQ (NIPS terminal). (V)6 is part of OJ-557(V)/USQ-88(V) (TFCC).

Aircraft Tactical Data Systems

Just as with ships, aircraft can benefit from the integration of their sensors to form a coherent tactical picture. Large patrol aircraft are analogous to ships, with separate sensors served by individual operators. The tactical data system forms a single coherent picture out of the various pieces of data available on board to different operators. The first example of such integration was probably the Airborne Tactical Data System (ATDS) of the Grumman E-2, which is analogous to NTDS. Another very early example was the Lockheed P-3C (A-NEW). The integration of the E-2 is very similar to that of a shipboard CIC.

Single- or 2-seat aircraft are integrated on a very different level: the mechanism of integration has been the HUD, the single integrated tactical picture that a computer can form and superimpose over the pilot's view of the outside world. The first operational HUD, and the first tactical airborne digital computer, appeared together in the U.S. Navy Vigilante attack bomber of the 1960s. In such cases time pressure is probably a stronger driver than the sheer mass of information. As a consequence, the development of tactical aircraft data systems has gone more into display technology (i.e., into getting the information into the pilot's head in usable form) than into data handling per se, as in a maritime-patrol airplane.

The amount of data a pilot can process is inherently limited, and the computer can help by filtering (integrating) some of the relevant data, or by combining them in more usable form. By presenting them on the HUD, the system as a whole saves time since the pilot need not glance down periodically at the instruments (air data readouts) and tactical displays (e.g., radar, FLIR).

HUDs appeared at about the same time as aircraft data buses, including bus connections to the weapons pylons and bomb bays. In the past, aircraft were specifically wired to carry particular weapons. A pylon might be stressed for, say, 1000 lb, but its wiring, and the wiring of the aircraft fire-control system, determined just which 1000-lb stores it might accommodate. In addition, specific wiring carried specific arming and release messages (which might not be any more complicated than the release of a magnet) to the pylons. A bus, connected to a stores-control computer, can, in theory, accommodate a very wide variety of different weapons, perhaps the entire variety that a navy or air force uses. The only real remaining limit is aerodynamic; some shapes may not separate cleanly from particular aircraft. Moreover, the behavior of a particular shape, once it has separated, will depend in part on the aerodynamics of the dropping airplane. A ballistics (weapons-aiming) program will, therefore, have to be arranged for each combination of airplane and weapon. Hence the continuing need for integration testing; software and computers do not solve the problem completely, but they do greatly simplify it.

An airplane carries numerous air and tactical data sensors, and to display all of them would be to cover the HUD in symbols. HUDs are, therefore, designed to show only a fraction of the available data, the pilot selecting alternate programs (e.g., for cruise, for air-to-air combat, for particular bombing tactics).

The pilot must still look almost directly ahead to see the HUD superimposed on the sky. That must be distracting during violent maneuvers, as in close air-to-air combat. The ultimate HUD displays its data, not on a fixed screen in the cockpit, but on the pilot's helmet.

Pilot reactions still impose a time lag. The pilot sees a target and must move to react, e.g., to fire a weapon. No matter how perfectly coordinated the pilot is, hand movement will lag head and eye movements. One solution is to place sensors in the cockpit to pick up the pilot's head movement. The AH-64 ground-attack helicopter uses a simple form of this system. The concept would seem to have an important potential shipboard application by allowing quicker defensive reactions to lookout sightings, e.g., of incoming aircraft or missiles.

Besides the helmet HUD and the head sensor, it seems inevitable that the extent of integration, i.e., the extent to which the central tactical system combines different sensor outputs, will expand. Current aircraft generally still segregate ESM data from other tactical data; they are fitted with separate RWRs, for example. It seems likely that future tactical aircraft will have integrated EW suites (warning, identification, reaction).

The other likely future development is in the combination of information, which is now presented to the pilot via a HUD and displays, and the actual motion of the airplane. Many current tactical aircraft, such as the F/A-18, are flown by a computer, which provides the pilot with an artificially generated feel of the controls. However, the control circuit and the sensor circuit are entirely separate, just as, on board a ship, steering and engine orders are not controlled by the tactical data system. For an airplane, maneuver is intimately connected with air combat; the airplane itself is used to aim many of the weapons. Violent evasion triggered by ESM warnings is often necessary for survival. The next step, then, would seem to be to integrate existing fly-by-wire systems and existing computer-based air-combat systems. The pilot would still decide what to do, but the aircraft system would make many more of the implementing decisions. A pilot might, in theory, look at a distant enemy aircraft (indicated by radar on the helmet display) and order the airplane to engage. The airplane would then maneuver itself into an attacking position, and it would indicate to the pilot when to release weapons. A current U.S. DARPA program, the Pilot's Associate, makes much of this promise. One justification for more computer control is that a pilot may be unable to control an airplane through the really violent maneuvers that should be practicable in the near future.

This sort of integration already exists, in a limited way, in terrain-avoiding or ground-following systems, in which the aircraft radar directly instructs the flight-control system. Instruction may involve particular hydraulic actuators, or it may involve direct input into a fly-by-wire flight controller.

Helicopters are intermediate between the large multioperator aircraft and the tactical fighter or bomber. Typically, integration means that there are no longer any displays unique to any 1 sensor. Instead, the multifunction displays can be switched to any sensor, using an internal data bus.

CANADA

◆ HINPADS (AYW-501(V))

The Helicopter Integrated Processing and Display System for the Canadian version of the EH-101 (the New Shipboard Aircraft) is being developed by the NSA Mission Systems Consortium, led by CDC. The other members are Canadian Marconi and Litton Systems Canada. A published photograph of the mockup shows two 2-screen consoles side by side, each with 2 keyboards and a joystick.

FRANCE

◆ Atlantique Nouvelle Génération

The key difference between this version and the original Atlantic is the presence of an integrating computer, a 15M/125X (512 kwords). The associated acoustic processor is SADANG (*Système Acoustique d'Atlantique Nouvelle Génération*), the 2-position Thomson Sintra TSM 8200 (DSAX 1), sufficient to process 16 LOFAR or 4 directional active buoys. There are 2 identical stations, each with its own processor and display (a CRT with a 2-page refreshing memory, 8 channel displays, and 1 paper chart recorder with 4-channel display). SADANG processes omnidirectional LOFAR buoys in integrated ALI, HY-FIX, DEMON, and CODAR modes; DIFARS and VLAD in ALI-BFI and ABI modes; and also active buoys (omni and DICASS).

The architecture is semicentralized, with the central processor in charge of system management, communicating with peripheral computers running the signal processors and the data bus. The central computers carry the main tactical operational software. Each subsystem-management computer has its own tactical-and-management program so that its operator can process and filter incoming data and operate autonomously if the central computer fails.

The system is designed to function equally well against surface and submarine targets. Radar, ESM, and FLIR are the primary surface sensors, and the sonobuoys and MAD are the primary ASW sensors. The interior of the airplane is arranged so that the tactical operator (TACCO) can occupy either of 2 positions suited to these 2 roles, with 2 identical stations for the TACCO and the radar operator, each with a multipurpose display. A third multipurpose display is provided for the pilot. In the antiship role, the TACCO sits forward, near the ESM operator; in the ASW role, aft, near the acoustics processors. Each of the 2 identical TACCO/radar-operator stations has a bicolor multipurpose display to show raw video and the tactical situation, plus an alphanumeric display, a display selection panel, programmed action keyboards, and a trackball. These stations include the FLIR display. There are also alphanumeric displays for the navigator/communications operator and for the acoustic operator. An automatic plotting station (the aircraft's position is marked by a point of light) at the navigator/communications

station functions as a backup to the computer-driven tactical plot.

The basic combat-system crew (other than 2 pilots and a flight engineer) consists of the TACCO, the navigator/communications operator, the ESM-ECM-MAD operator, the radar operator, 2 acoustic operators, and a front observer; the airplane can carry 2 more observers as reliefs.

The normal load is 100 sonobuoys and 4 torpedoes or 2 Exocets, for an 8-hr mission on station at low altitude 600 nm from base. The buoys are carried in 4 reloadable launchers, plus four 18-buoy launchers; there is internal storage for 30 buoys. There are 4 hard points under the wings (two 750 kg, two 1000 kg). The bomb bay carries either 8 Mk 46 torpedoes, 12 depth charges, 9 mines, 2 AM 39, or 3 Mk 46 and 1 AM 39.

The earlier Atlantic was chosen in 1958 to meet a NATO specification; the last was delivered in July 1974. Design of the second-generation aircraft began in 1978, the prototype appearing in 1985. The first production airplane was handed over to the French Navy in October 1988. At that time the Atlantique Nouvelle Génération was described as the most complex aircraft yet developed in France.

The earlier Atlantic 1 is operated by France, Italy, Pakistan, and West Germany. It lacks any integrating computer system. The sonobuoy processor is the U.S. AQA-5; the radar is DRAA-2B; the MAD is DHAX-1; and the standard ESM set is ARAR-10B. French aircraft were later equipped with a Sparton demultiplexer and display for DIFAR buoys, TD-1135/A. The Dutch Atlantics have already been retired in favor of P-3Cs. The Italian aircraft are being upgraded by Dassault, with IGUANE radars, AQS-902 processors, and a U.S. tactical data system, probably ASN-150. The West German aircraft were modernized by Dornier and will probably be replaced by P-7As. These aircraft have Loral EW-1017 ESM sets.

◆ Super Étendard

Remanufactured Étendard strike fighters were fitted with a Thomson-CSF VE-120 HUD fed by a Kearfott UAT 40 central tactical computer built under license by SAGEM. The computer receives both radar (Agave) and inertial-navigation (a Kearfott UNI 40, built under license by SAGEM) data. Functions: navigation to a point stored in memory; bomb delivery, including automatic or manual release; and direction to a missile-firing point in space.

This program dates from 1974–77.

UNITED KINGDOM

◆ Central Tactical System

The tactical data system of the Nimrod MR.2 is built around a GEC 920 ATC computer; a separate Ferranti FM 1600D computer processes the data from the Searchwater radar. The associated acoustic processor is AQS-901, which uses twin 920

The Lynx cockpit illustrates the impact of computerization. The left photograph shows a Royal Navy Lynx, with its radar or electro-optics screen at the left. The right photo shows a similar cockpit with the central tactical system (CTS) installed. Numerous dials and switches are replaced by a pair of CDUs, and the space released has been filled by a tactical situation display. In the earlier cockpit, the integrating function of the display had to be carried out either in the heads of the pilot and copilot or on a manual plotting board. The situation display shows synthetic video, not the raw video of the radar or electro-optical sensor, which is still carried by the separate screen on the left. (Racal)

ATC computers; another 920 ATC serves the ESM system. The primary display for the tactical navigator (analogous to the U.S. TACCO) is a 24-in-circular CRT (summary plot). There is a separate navigational (track-keeping) plot.

The original Air Staff Requirement (ASR 381) for what became the Nimrod MR.1 was issued on 4 June 1964. The Comet airframe had been under consideration for the maritime-reconnaissance role as early as 1958, when it competed with the Breguet Atlantic for a NATO program. However, the system envisaged in 1964 was very different from the unintegrated systems of the 1950s. The first true Nimrod prototype flew in June 1968, and the first aircraft entered service on 2 October 1969. It used a 920B computer.

The MR.2 program began in 1975, and the first aircraft modified to this standard were delivered in 1979. New avionics included a better search radar (Searchwater in place of ASV.21D) and Loral ESM pods (in place of Thomson-CSF units). During the Falklands War, Nimrods were modified to carry Sidewinders, bombs, and Harpoon missiles. Modification was probably simplified because it involved software changes rather than re-wiring, the aircraft already having digital tactical data systems.

A Nimrod upgrade is now being considered; it includes Staff Requirement (Air) 909 for a new acoustic processor, SR(A) 910 for the central tactical system, and SR(A) 911 for systems integration. As of late 1989, RFPs were expected in the late spring or summer of 1990, but it was possible that they would be canceled in favor of British acquisition of U.S. P-7As. In the event RFPs were issued, project definition was expected to be quite short, suggesting an urgent need to replace the existing Nimrod avionics with existing, rather than future, equipment. The acoustics upgrade specification was written by GEC Avionics and RAE Farnborough; proposed system architecture is similar to that of the GEC Avionics AQS-903, already selected for the British Merlin (EH-101) helicopter. However, it uses more modern microprocessors (Motorola 68000 series) and will incorporate transputers and custom-designed integrated circuits (which suggests some application of Curtis-like processing; see the ASW section). Software will be written in ADA rather than in Coral 66.

As of early 1990, the series of avionics-update staff targets was being deferred, pending completion of an MoD study to determine whether it would be better to modify the existing airframes or to buy new ones (presumably P-7s with British equipment). There had been a report that severe corrosion problems would force the retirement of the existing Nimrods and, therefore, that no mid-life update would be worthwhile. Current plans call for the RAF to continue to operate its 36 Nimrod MR.2 and its 3 Nimrod R.1 ELINT aircraft through the year 2003. Eleven short-time airframes intended for the abortive Nimrod AEW program are in storage and could presumably be used either to replace badly corroded aircraft or for cannibalization.

◆ Escorter

MEL announced this small maritime-patrol-airplane tactical data system, which uses distributed processing, in 1989. Escorter has a series of identical consoles, each with a color raster display, a stiff-stick controller, a multifunction (i.e., software-configured) keyboard, and a tactical display processor. All are tied together by a 1553B bus. In the core configuration an additional video bus connects the search radar and the 2 consoles (TACCO and SENSO), feeding each with radar video. The main bus carries synthetic-radar-video, MAD, ESM, and processed acoustic data (the acoustic processor receives sonobuoy data directly, but these data are also fed into the bus). The acoustic processor is run from a separate acoustic operator (ACO) console, incorporating a display and a touch-sensitive keyboard. MEL offers 2 other options, an expanded (increased-performance) version and a reconfigurable system.

The expanded system adds a FLIR, a data link, and a capability for stores management (for attack as compared with surveillance alone). The stand-alone MAD and on-top position indicator (OTPI) of the core system are replaced by subsystems in-

tegrated with the 1553B bus, and the acoustic processor is expanded by the addition of a Barra side processor. The acoustic operator can control active buoys (DICASS). The consoles are provided with an auxiliary video channel so that they can be switched between FLIR, radar, tactical display, and acoustic display. Either operator can slew the FLIR using a stiff stick.

The reconfigurable version uses 3 identical consoles, any 1 of which can function as SENSO, TACCO, or ACO. This surveillance system uses a radar as its main sensor, lacking the expanded acoustic processor of the expanded version. Nor is there any MAD for a final preattack fix. However, there is an acoustic processor.

MEL describes Escorter as an ASV (surface-search) or ASW system and indicates the market it seeks by illustrating its brochure with a Dornier 228 and a Grumman S-2 Tracker. The brochure shows a variety of applications: synthetic radar video, raw radar video with ESM data and strobes, and ASW (sonobuoys and target track). In each case, the screen is divided into a graphic display on the left and a tabular display on the right.

The processor used in the system is not identified.

◆ RAMS

The Racial Avionics-Management System is the central tactical system (CTS) of Royal Navy Lynx (HAS 3 and later) helicopters, and the tactical data system for Royal Danish Navy Lynx helicopters. It is a partial glass cockpit, the main displays being 2 alphanumeric screens (control display units, or CDUs). RAMS 4000, the military version, employs 2 processor interface units (PIUs) containing up to 3 microprocessors, a data transfer device (DTD) to load initial data, and the 2 CDUs. The CDUs and PIUs are all connected to a dual 1553B bus, and the PIUs and DTD are also connected to a non-1553B internal aircraft equipment bus, for equipment not compatible with a 1553B. The Royal Navy version includes a 12-in programmable color tactical situation display (TSD). Further CDUs and PIUs can be added to the basic system, which can accommodate more than 1 TSD. RAMS uses nonvolatile mass memory (presumably bubble memory).

◆ Sea Harrier

The Sea Harrier FRS.1 has a Smiths Industries 6-50-series HUD served by a 20-kword Smiths Industries digital weapon-aiming computer (WAC) and an Ericsson SDS 80 air-data computer. The associated Ferranti inertial platform is controlled by an 8-kword computer. The HUD displays aircraft altitude and heading; other flight information selected by the pilot (IAS or Mach number, barometric or radar altitude, angle of attack, side force, vertical speed); navigational aids such as beacons; air-to-surface aiming data including a continuously computed impact-point (CCIP) or manually depressed line-of-sight (DSL) mode; air-to-air aiming solutions; air-to-air symbols; and an independent standby sight.

The HUD produced for the AV-8B, which is presumably similar to that of the Sea Harrier, has a 22-deg field of view. Presumably, the Sea Harrier system is not too different from that of the Tornado (5-50 series). The latter has a 9-kword memory; its inputs are 8 digital data channels and up to 32 discrete commands (e.g., ordering up an air-to-air rather than an air-to-surface program). Computer speed: add/subtract time, 3.75 microsec; multiply time, 8.63 microsec; divide time, 9.13 microsec. Accuracy: boresight, 0.05 mrad; symbol positioning, 0.22 mrad within 5 deg of dead ahead (0.32 mrad within 10 deg). Presumably, the Sea Harrier version has a larger memory because the Sea Harrier lacks the Tornado's 64k central computer.

Sea Harrier FRS.2 has a more integrated combat system tied together by a dual 1553B bus. As in other recent aircraft, an objective of the system is to permit the pilot to fly with little recourse to heads-down instruments or displays. In this version an eye-level up-front control panel (UFCP), just under the HUD, carries whatever critical weapons-system controls are not on the stick and the throttle. The earlier analog displays are replaced by a pair of multifunction displays (1 for the radar), leav-

ing only a few heads-down instruments. There is still a separate RWR, but its information is passed into the bus and, thus, should be available on the multifunction displays driven by the central computer. When the display shows raw radar video, it will be driven directly by the radar. Otherwise, synthetic video will be taken from the bus via a control-and-interface unit that is directly linked to the HUD/WAC. For example, a display can show threat data, target priority, and navigational information.

The bus does have some limitations. For example, the radar processor is too large to fit directly next to the radar transmitter-receiver, so it is located in the after avionics bay, near the tail. It is connected to the radar transmitter-receiver by a special fiber-optic link, whose bandwidth is needed to carry the raw radar data.

◆ TATTIX (ASN-902)

The GEC-Marconi tactical data system for a maritime-patrol aircraft incorporates the company's AQS-902 acoustic processor. TATTIX has been installed on board at least some Fokker Enforcers. The data bus is an ARINC 429 or a 1553B. The tactical plot (625 lines, 50-Hz frame rate) can accommodate up to 256 data entries and can show up to 64 tracks, up to 16 operator-defined circles or areas, and up to 16 annotated vectors. Range scales are 8, 16, 32, 64, 128, 256, and 512 nm. The same display can be used for ESM/radar to show a sonobuoy field, for localization within a sonobuoy field, and as a sonobuoy tote. The display can be monochrome or color.

Weights: tactical processing unit, 16.0 kg; tactical control unit, 4.5 kg; tactical display unit, 14.5 kg; cursor control device, 0.5 kg.

◆ TMS

GEC Avionics Tactical Mission System for Sea King 42B ASW helicopters for the Indian Navy, and also for modified British ASW Sea Kings. TMS incorporates the AQS-902B/C acoustic processor but can employ the Super Searcher radar, TANS navigation system, Hermes ESM, HS 12 dipping sonar (in the Indian helicopters), and Sea Eagle missiles. The microprocessors are 17 Z8000 and Z80 8-bit chips in 2 LRUs. Indian Sea Kings have 2 CRTs, each with its own keyboard.

UNITED STATES

◆ ASN-123

ASN-123 is the Teledyne Systems tactical data system for SH-3H Sea King (carrier inner-zone ASW) helicopters, operational in 1978. ASN-123 provides accurate automatic navigation, tactical situation displays, and flight-management and tactical aids, including multiple torpedo-attack solutions. The system was later upgraded with expanded computer memory and air-to-air and ship-to-air data links.

ASN-123 is also the tactical navigation/data system of the SH-2F LAMPS I helicopter; presumably, the SH-3H installation is an expanded version of the earlier LAMPS version.

ASN-123 is nominally a tactical navigation system. However, in the SH-3H it includes a panel on the sensor operator's console for entering sonar and sonobuoy data into the central TACNAV (ASN-123) computer. The main system display is in the cockpit, and the TACCO there has the main system-control panel. The dipping sonar (AQS-13E) incorporates a signal processor, which is also used to process sonobuoys the helicopter may lay; their data are displayed on the sonar CRT. The sonar processor is also used to send MAD data into the tactical data system.

In the SH-2F the system consists of a processor, a TACCO panel, a SENSOP panel, and a tactical navigation display. The automatic inputs are from a tactical navigation radar (ASN-182, to measure speed over the surface), a compass (ASN-50), a true-airspeed indicator, the sonobuoy receiver (ARR-75, to indicate which channels are active), and the sonobuoy launcher (to indicate which buoys were dropped). The on-board sensors monitored by the crew are the LN-66 surface-search radar, the ESM (ALR-66), and the MAD; sonobuoy data are processed exter-

nally, on the ship controlling the helicopter. MAD and radar data are entered manually through the SENSOP control panel; the radar has a separate display. Up to 20 radar contacts can be inserted into the system in this way. The TACCO monitors the ESM system and enters contacts manually into the central computer. The main system outputs are navigational: for example, true helicopter position and speed, navigational error (bias), base ship predicted position, course, and speed. Sonobuoy and torpedo splash points are predicted based on ballistics, using a manually entered aircraft altitude and manually entered or computed winds.

The computer holds data on a 512 × 512-nm area, with grid center specified by coordinates when the system is initialized before takeoff. Only a portion of the full area can be represented at any one time, but grid center is always the same (unless the computer is reset). There are 7 range scales.

◆ ASN-150

The Teledyne Systems ASW tactical data system is used in the modernized LAMPS I helicopter (SH-2G) and the SH-60F carrier inner-zone helicopter and is offered for export. The associated acoustic processor in the LAMPS I is UYS-503. ASN-150 was derived from the earlier ASN-123 described above.

The first version of ASN-150 was TDMS, the tactical data-management system of the SH-60F, the successor to the SH-3H; it is an outgrowth of ASN-123. The SH-60F has a crew of 4: pilot, copilot/TACCO, tactical (radar) -sensor operator (TSO), and acoustic-sensor operator (ASO). The TACCO and TSO each have a multifunction display; the pilot and ASO have horizontal situation displays. The system is tied together by a dual-redundant 1553B bus, and it is driven by dual tactical computers. TDMS also includes an armament-system controller (ASC).

The helicopter operates both a sonar (AQS-13F) and sonobuoys; the same sonar-data computer (embedded in the AQS-13F) processes signals from both (4 sonobuoy channels) and displays the results on the multifunction displays.

The dual data processors are CP-1820/ASN-150, a military version of the Teledyne MECA 43 computer (described below).

A variant of the same data system, ASN-150(V), has been specified for the Fokker Maritime Enforcer Mk 2, currently in the proposal stage. Details below refer to this version, but they are probably not too far from the characteristics of the U.S. helicopter versions. The original Enforcer (17 of which were sold) had a GEC-Marconi ASN-902 as an option.

A typical ASN-150 display. The aircraft has dropped a mixture of LOFAR (L), DIFAR (D), and active (A) sonobuoys, and the computer is used to correlate the data they produce. The 2 circles are the ranges produced by the active buoys, on channels (RF) 15 and 17. The DIFAR buoys give bearings that place the target very close to one of the intersections of the range buoys. (Teledyne)

This type of ASN-150 display would be used to fire a Harpoon missile. A series of ESM bearings, all on C/D-band, is used to localize the target approximately. The missile is set to follow a dogleg path (with a left turn) to attack target 01. The arcs show the Harpoon's launch envelope. (Teledyne)

The Enforcer 2 sonobuoy processor is UYS-503; the radar is APS-140(V); the MAD is ASQ-504; and the ESM set is ALR-606(V)2; this system would also include a GEC-Avionics TICM II thermal imager. The Maritime Enforcer would have a 10-sonobuoy launcher, and it would use a BEAB BOP 300 chaff launcher. ASN-150 includes 2 stores-interface units (SIUs), each of which can control 4 weapons stations, for a total of 8. The system design includes provision for Link 11. The system is tied together by a 1553B bus. It employs 2 redundant tactical processors (CP-1820/ASN-150), driving 4 monochrome 15-in multifunction displays (MFD), 1 color 15-in multifunction display (MFD*), 1 color 6-in multifunction display (MFD), 7 control display units (CDU), and 4 display control panels (DCP). The principal operators are the TACCO, the ASO, and the NASO (nonacoustic-sensor operator); each has the following displays:

	ASO Station	TACCO	NASO	Cockpit
MFD	2	1*	2	6-in MFD (1)
CDU	1	2	1	2
DCP	1	1	1	1
Data Loader	—	1	—	—

Each MFD can display radar, FLIR, acoustics raster video, or stroke-written tactical-situation display. The CDUs are the primary operator interfaces with the system. The DCPs are extensions of the CDUs, providing extra display-oriented keys and a cursor control stick. The data loader is a small cartridge with 512 kbytes of RAM, which initializes the tactical data processors, and carries additional mission data.

System functions include navigation; automatic weapon pre-setting; target tracking; tactical aids, including assistance in 4 attack modes (intercept point, circle mode, snake mode, and vectored attack [vectac]); antiship surveillance and targetting; search and rescue; and fly-to points. Plotting aids are 15 vectors, 15 circles (fixed or expanding), an aircraft track history (10 dots), and a hook cursor. Scale is selectable between 0.5 and 128 nm/in. The system can carry 1 aircraft location, 1 datum, 30 sonobuoys, 30 DIFAR contacts, 15 range-only contacts, 30 DICASS contacts, 15 sonar contacts (entered through the data link), 15 target tracks, 15 surface ships, 30 radar tracks, 30 ESM contacts, 15 visual/manual contacts, 30 reference marks, 15 survivor locations (for search and rescue), 15 TACAN beacons, 30 fly-to points (fixed or moving), 1 intercept point, 1 weapons-release point, 1 snake-mode display, and 1 Harpoon launch envelope.

The data processor is the Teledyne MECA 43. Its arithmetic is arranged for 8-bit slices so that it can work with 16-, 24-, or 32-bit words. Memory options are magnetic core (18-mil cores, 16k 16-bit words, cycle time 1.0 microsec, or 13-mil cores, 16k 16- or 24-bit words, cycle time 0.8 microsec); CMOS RAM (2k or 4k 16-bit words, cycle time 0.2 microsec); bipolar RAM (2k 16-bit words, cycle time 0.05 microsec); or PROM (8k 16-bit words, cycle time 0.2 microsec). The central processor can address up to 64 kwords, expandable to 1M. Speed: fixed-point add/subtract, 1.625 microsec (floating-point, 7.531); fixed-point multiply, 4.375 microsec (floating-point, 12.531); fixed-point divide, 7.125 microsec (floating-point, 19.781). Floating-point numbers are represented by 16 or 32 (or 24 or 48) bits. This computer differs from most others in using only 2 parity bits for 24-bit words. There are 103 instructions (88 basic instructions).

The high-order language is JOVIAL J73/1.

In the version now advertised, the tactical processor contains 448k 16-bit words (384k of EEPROM program memory, 32k of core, and 32k of semiconductor RAM).

◆ A-6E/DIANE

The Grumman A-6 Intruder was the first U.S. naval airplane designed as an integrated weapons system. System architecture, laid down in 1957, has remained constant from the original A-6A through the current A-6E, although the original name, DIANE (Digital Integrated Attack and Navigation Equipment), has been dropped. The central computer, originally a Litton ASQ-61, communicates with the pilot via an 8-in Kaiser AVA-1 vertical display unit (VDI), whose synthetic video shows the route to fly. The computer does not fly the airplane during combat: in 1957 no one would have trusted a computer to do that. For example, no version of the A-6 has an automatic terrain-avoidance mode: the pilot flies to avoid the terrain displayed on the VDI. However, the computer can release bombs at a point it calculates, as the pilot flies the indicated path. There is no HUD. The computer does fly the airplane when it is not maneuvering, through an autopilot (automatic flight-control system, AFCS, designated ASW-16).

The second crew member, the bombardier-navigator (BN), designates targets to the computer via the main radar display (the AVA-2 direct-view radar indicator, DRVI). The pilot can designate targets via a bombsight. The BN selects weapons and chooses between salvo and train (sequenced) drop, the latter using an intervalometer adjusted either directly or via the computer.

The cockpit of an A-6E shows, on the left, the pilot's "road in the sky" display; on the right is the FLIR. The flat glass above the display is the pilot's optical sight. The missile panel is between the seats, showing what missiles the airplane is carrying (in this case, 2 HARMs). (Grumman History Center)

The VDI shows a synthetic-video "road map" called a contact-analog display (since it is analogous to what might be seen outside the cockpit) with artificial perspective. Aircraft attitude is shown by a ground-stabilized artificial horizon line, and "ground texture" and "cloud texture" symbols give the pilot a sense of motion toward the horizon. Horizontal lines above and below the horizon indicate pitch in units of 10 deg. A road on the ground indicates the desired flight path, and cloud symbols move to indicate changes in aircraft pitch and bearing. Numbers on the sky display are a heading "tape," giving the airplane's bearing. The tactical data system can superimpose attack information, including target symbol, steering symbol, release, and pull-up. The same CRT indicates the appropriate flight path during a carrier landing, based on ACLS signals.

Kaiser developed a solid-state radar-data scan converter, which allowed the VDI to show terrain elevations at 10 different ranges, out to 10 nm ahead, over a 60-deg sector. Each range contour is colored a different shade of gray to provide contrast, and terrain above the flight altitude is shown as above the horizon. A pilot can select 1 of 4 different ranges and code the terrain there with black vertical highlight bands. The pilot avoids this terrain by flying the (bomb) impact bar to the marked contour. Flight path and attack symbols can be superimposed over the converted radar data for low-level attacks.

The third stage in VDI development was provision to display FLIR and LLLTV images, for the A-6C (TRIM) and then for the A-6E (using TRAM).

The BN can enter up to 4 targets (or waypoints) into the computer. The VDI shows a target symbol for each in sequence, and the pilot flies toward it by keeping the symbol centered on the VDI. The symbol lights up when the airplane is 10 sec from the computed drop point. The VDI shows the effect of any evasive maneuver as a computed miss distance. Further targets are called up by pressing 1 of 3 buttons under the VDI. If they are outside the VDI field of view, it shows the appropriate road to take. Limits on the computer-VDI combination show in the requirement that the pilot bank into the new heading at exactly 30 deg.

The principal system sensors are a radar (originally a combination of APQ-88 and APQ-92, now APQ-148 or -156), a doppler navigational radar (APN-153, to measure speed over the ground), a radar altimeter (APN-141), an inertial navigation set (ASN-31, now ASN-92), and an electro-optical sensor (TRAM, introduced in the A-6E version; see below). Because the A-6 was designed largely for close air support, it had to be able to bomb targets with indistinct radar images, either designated from the ground or described in terms of offset aim points (the aim points being bright radar reflectors or the marines' TPQ-10 radar bombing beacon).

DIANE's development in service exemplifies the flexibility inherent in a digital computer. System capability was extended more through changes in software than in hardware aboard the airplane, as Programs P-1-P-8 appeared through the 1960s. The program originally supported straight-path weapons delivery (including straight dive or climb), dive toss, and high loft (for nuclear delivery). In 1967 an assisted automatic visual-bore sight mode was added: the pilot centered the target in the sight and pressed the bomb release to designate it. The radar measured the range, and the computer worked out the release point.

The computer was particularly useful in Shrike (ARM) delivery. Without a computer, an airplane pointed Shrike at the target radar after the missile seeker locked on. However, the computer made indirect attacks possible. Shrike could acquire (but not lock onto) a radar 40 nm away. Because the seeker had a narrow field of view, such acquisition indicated that the target was dead ahead, within a narrow cone. DIANE could store this indication as a datum. Once the datum had been entered, the pilot could make a long, slow turn to a different position, then again point at the emitter for another bearing; DIANE could triangulate since it continuously kept track of the airplane's position. Using that information, it could compute the appro-

priate airplane path to loft Shrike toward the target, the missile's seeker acquiring the target as it approached. The missile seeker had a large enough footprint to make up for the inaccuracy inherent in such an attack. The missile gained considerably in range. This approach was later applied to the AGM-78 (Standard ARM) missile under the designation passive angle tracking (PAT/ARM: 6 aircraft were modified). Six aircraft were fitted in 1970 with the APS-118 target identification and acquisition system (TIAS), in effect an extension of PAT/ARM. Although these particular systems are no longer in service, the tactical ideas they represent remain in the A-6E software. About 1980, 12 A-6Es were fitted with AWG-21, which could control Standard ARM missiles. Many aircraft now carry HARMs.

Avionics represented 43% of the cost of an A-6A (compared to 20% for the contemporary F-4B, which was considered highly automated). Available technology was not reliable enough: in 1968 the radars were credited with 40% attack reliability, and the total system with only 26%. Limitations in the electronics probably also limited performance when the system worked as designed. In 1968 it was estimated that an A-6A bombing a well-defined target from 1000-ft altitude could achieve a CEP of 900 ft (1500 ft from 3000 ft). Against a difficult radar target, however, CEP might easily grow to 4800 ft. These large CEPs were attributed largely to the sheer size of the radar beam, which could easily pick up the wrong aim point.

The solution (the A-6E system, proposed in 1967) was threefold: a more reliable radar (APQ-148, later upgraded to APQ-156), a faster and more capacious computer (ASQ-133), and ultimately a laser range-finder with a very narrow beam (working with the TRAM electro-optical sensor). Many A-6Es were reworked A-6As, initially fitted with the new radar and computer, for 21% improvement in operational readiness and 76% improvement in full systems capability. The A-6E itself was improved in stages. A-6E CAINS introduced a new standard inertial navigator (CAINS, ASN-92). The TRAM (AAS-33) electro-optical sensor was tested in 1974, and the first production A-6E TRAM flew in December 1978. The upgraded TRAM/DRS entered production in 1979. TRAM video appears on an 8-in CRT above the BN's DRVI. The FLIR can be slaved to the radar or to a stored aim point, and the laser is used for final ranging (reportedly it has 10 times the range accuracy of the radar, measuring target position to within 5 ft). The initial effect of the new computer and radar was to reduce radar CEP by 49% and visual CEP by 53%; CAINS reduced navigational CEP by 28%. TRAM made for further improvement, achieving 66% of the A-6E radar CEP (i.e., about 33% of the original A-6A radar CEP, or about 300 ft) and 71% of the A-6E visual CEP.

A fully digital ("glass") cockpit was planned for the abortive A-6F.

◆ A-7E

The A-7E system is a single-pilot equivalent of the A-6 system intended for day rather than night attack. The pilot designates the target and flies the airplane, using a HUD (through which the target can be seen) rather than a heads-down road-map display (and a separate designation display for the BN). The pilot designates a target defined by the HUD reticle, either aiming the airplane itself or slewing the reticle onto the target. The system radar (APQ-126) is slewed to the reticle. In an alternative radar bombing mode, the target is identified on the radar, and the reticle is slaved to the radar. The addition of a FLIR projected onto the HUD provides all-weather performance since the system can be used in what amounts to its visual mode. In each case, as in the A-6, the system radar (an APQ-126) measures range to the target. The system senses airplane motion and continuously computes the appropriate release point. The pilot follows HUD steering and solution cues. A pull-up symbol on the HUD warns the pilot that the plane has reached minimum safe pull-up distance. The system automatically releases weapons at the appropriate moment.

The continuous release-point calculation makes for flexibility: the pilot can change from tactic to tactic during an attack

without changing switches. There are 9 computed attack modes: normal, normal offset, radar, radar offset, navigation bombing (i.e., with reference to stored coordinates), gun mode, rocket mode, re-attack mode (second pass), and toss mode (presumably for nuclear delivery). In each case the pilot can choose to attack from a dive, level flight, climb, or over-the-shoulder. Analog systems allowed for only a limited repertoire of maneuvers; earlier A-7s had to approach their targets at a preset altitude and speed and perform a prescribed pull-up maneuver.

Data from sensors are refreshed about 25 times/sec; the computer refreshes the HUD 50 times/sec to avoid blurring and jitter. At this rate the display can follow aircraft maneuvers at rates as great as 200 deg/sec. The system measures winds (a major factor in bomb ballistics) by comparing doppler/inertial velocities with measured air data. As originally delivered, the system computer carried ballistics for more than 100 weapons. The computer (ASN-91) solves the trajectory equations (trajectories as such are not stored because the range of initial conditions is too great) to display bombing instructions on the HUD.

LTV, the aircraft manufacturer, claims that the computer-driven system makes for twice the accuracy of the earlier analog type, so A-7Es should require half as many sorties per target. Claimed accuracy: CEP 150–200 ft for level bombing, 8.1–9.6 mils for dive-toss delivery (15 mils for the previous analog system), 8.2–9.5 mils for strafing (rockets or 20-mm cannon).

IBM was system integrator, using a pair of 7094 computers to simulate the flight dynamics of an A-7.

◆ A-NEW (P-3C)

The P-3C was one of the first maritime-patrol aircraft to have a computerized tactical data system. It is analogous to a surface ship whose sensors and weapons are tied together by a central NTDS computer. Communication and coordination became much more efficient since information is transferred directly from console to console. Even in the initial version (Mod 1), the tactical coordinator (TACCO) could devote 85% of the time in the target area to tactical decisions, spending only 15% on coordination with the pilot and the sensor operators (SENSOs) and on mechanical manipulation, a reversal of the usual ratio.

The computer maintains a consistent tactical picture on board the airplane, using dual inertial navigators and a doppler radar. Automated navigation eliminates errors due to low-altitude high-G maneuvers, and its accuracy helps an airplane chasing fast submarines. Automated navigation eliminates the lengthy and mechanical calculations needed to determine relative sonobuoy positions. Navigation also includes prediction of the splash points of all the stores the airplane drops, including sonobuoys and torpedoes. However, unlike the later S-3, A-NEW did not track sonobuoys drifting in the water, so the airplane had to overfly their positions periodically to verify them. The TACCO can use the computer to estimate the likely results of alternative tactics. Such estimates were impractical in noncomputerized systems because each entailed so much computation, particularly of navigational data.

The automated navigation system is combined with a flight director (which replaces the 2-axis attitude indicator of the P-3B), providing the pilot with point-to-point steering commands calculated by the computer for, for example, greater precision in dropping sonobuoys or in executing a MAD search.

All information in the airplane was centralized, so it could be recorded (for later playback and analysis) and also transmitted (via Link 11) either to a surface ship or to an airplane relieving the one on station. Playback is important because targets missed in flight may be detected after an airplane lands, to be prosecuted on a later flight. Parallel with A-NEW, specialized ground or shipboard centers (ASWOCs, ASW operation centers) were developed for real-time or playback analysis. Typically, they have computers and gram printers equivalent to those on the airplane.

A-NEW meant, literally, a new ASW weapons system. It was conceived in July 1960 at the Naval Air Development Center

P-3B

P-3C

These drawings of the P-3B and -3C show 1 of the major effects of computerization. In the P-3B, all of the sensor operators are lined up facing 1 side of the airplane, so that the TACCO can look over their shoulders and integrate the data they produce. The airplane is far too narrow to allow for side-by-side seating facing forward or aft, which would be much more comfortable. In the P-3C, only the 2 acoustic operators face to the side, since only they use consoles too wide to be mounted athwartships, and the TACCO normally need not look over their shoulders, seeing what is needed on the TACCO display. In the P-3C, the TACCO seat is the one facing forward, on the right-hand side of the fuselage, just forward of the wing. (U.S. Navy)

(NADC) at Johnsville, Pennsylvania (the contract for P-3A production was not let until that October). Contracts for feasibility studies for computerization of airborne ASW were awarded in mid-1961 to North American (Autonetics), Hughes, Librascope, and Loral. A-NEW was approved in December 1962; the program was managed by NADC rather than by any single outside contractor. At that time the principal contractors were Dunlap & Associates, General Dynamics/Electronics, Grumman, Lockheed California, Loral, and Univac (Sperry), the last for the computer. As the manufacturer of the P-3C, Lockheed ultimately became system integrator (the company was displaced only with the advent of the Update IV version).

The first Mod 1 version was flight-tested on board a P-3A early in 1964. It was reportedly so successful that the fleet tried hard to bring this interim version into production. The next version, Mod 3, was flight-tested in 1966 (Mods 0 and 2 were ground versions). The final prototype system was Mod 3.2. The P-3C was approved for production in August 1967, and the first production prototype flew on 18 September 1968, roughly contemporary with the Nimrod, which also has a computerized tactical system. The P-3C entered service in 1969. By 1965 work on a second generation (Mod 4 ground prototype), compact enough to fit on board a carrier airplane, was beginning, with first contracts awarded during FY66. Mod 5 was the airborne

prototype. The result was the S-3A system described separately below.

Mod 1 doubled the rate at which a P-3 could prosecute a fast submarine, partly because the TACCO could handle twice as many sonobuoys. For the first time, too, the TACCO could use a variety of sonobuoy types simultaneously. Tactical navigational accuracy improved by an order of magnitude. Mod 3 introduced an improved TACCO console (50% more functions with about 30% fewer buttons, using VABs) and standardized multipurpose sensor displays to replace the earlier electro-mechanical ones (so that acoustic operators could, for example, monitor such nonacoustic sensors as the MAD). This version also introduced the Univac 1830 computer (CP-823/U), which had a maximum capacity of 32 kwords (in 4k increments), replacing an adapted air force missile-guidance computer. The P-3C entered service equipped with the more powerful Univac 1830A (CP-901), which was about twice as fast (1830 microsec cycle time was 4 microsec, and add/subtract time was 8 microsec) and had a 64k memory (plans originally called for 48k). In 1967 it was officially estimated that a P-3C would be 2-3 times as effective as a P-3B, essentially because of automation.

Automation also brought complexity: it was said that the electronics part count in 1 P-3C equalled that in all 144 P-3Bs. However, reliability did not suffer badly because the new electronics was generally solid-state.

The following description applies to the original P-3C (A-NEW) system; see the ASW section for details of improved versions (Updates).

The tactical coordinator (TACCO) is equivalent to a ship's TAO, supervising 2 acoustic sensor operators (SENSOs 1 and 2) and a nonacoustic operator (SENSO 3). Typically, a P-3C also carries 2 observers aft, plus a navigator-communicator and a flight-deck crew of 3. Compared to a P-3A or -3B, there are 2 fewer acoustic operators. However, a P-3C can continuously monitor 16 sonobuoys, compared to 8 for a P-3B or 4 for a P-3A, and the frequency spectrum covered is 10 times wider. These improvements all result from electronic, rather than electro-mechanical, data collection. A single operator can monitor 1 buoy or 1 narrow band visually while the system collects data from other buoys and other bands, then shift to those other data at will. Physically, the great change from past practice is to supplement the usual paper LOFAR recorders with CRTs. However, the expectation (in Mod 3) that all the SENSOs would have multifunction consoles has not been realized.

Compared to a P-3C, a P-3B has more specialized crew members. Navigation is a full-time job, so there is a separate radio operator. Sensor stations are specialized, so there are separate MAD/radar (equivalent to SENSO 1), Julie-ECM, and Jezebel stations. There are 3 observers, rather than the 2 on the P-3C, but the P-3C gains enormously in this respect by adding an LLLTV or FLIR (which SENSO 1 observes).

The central processor was conceived as part of a computer-aided human decision system. The tacit assumption was that the computer could not be expected to detect passive sonobuoy targets automatically. A SENSO decides that a LOFARgram indicates the presence of a submarine and passes that processed information (in the form of bearing lines or likely detection circles around particular buoys) into the central tactical computer by means of keysets on the SENSO 1 and 2 consoles.

The TACCO and SENSO 3 have ASA-70 summary tactical displays, whose 16-in CRTs can show synthetic-video symbols, scan-converted raw radar video, and LLLTV (later FLIR) video. A second CRT shows alphanumeric, such as radio channels and remaining sonobuoys. The TACCO calls up information from the SENSOs and from the central computer via a trackball and keyboards.

The pilot and copilot have ASA-66 tactical-data displays (with 7.5-in CRTs) showing sonobuoy positions, fly-to points, aircraft position and track, and predicted submarine track and position. These data are also available to the TACCO. The pilot can enter visual contacts directly into the display (and thence into the central computer).

An AQA-7 sensor station on board a P-3C shows both the CRT and the multichannel hard-copy recorder below it. The CRT is fed by a computer memory; operators can switch among buoys or among narrow bands without losing the data on the other buoys or the other bands. The hard-copy recorder, however, has no memory beyond what is on the paper, so it is very limited in the number of channels it can handle. (U.S. Navy)

In the computer-controlled mode, the airplane detects a submarine using passive LOFAR buoys, then drops command-activated buoys (e.g., SSQ-62), whose pinging is controlled directly by the central system computer, to localize the target. Then the plane flies directly over the predicted target position, using MAD for final confirmation before dropping a weapon.

Because buoys are selected through the computer (which is aware of the mix on board), the primary launchers on a P-3C are external: 48 unpressurized A-size preloaded chutes. They are supplemented by 3 reloadable A-size chutes (with 36 buoys stowed in launch containers) and 1 B-size chute. Earlier P-3s stowed all their buoys internally because they were manually selected: they used 9 chutes (and the airplane had to be depressurized to launch buoys through them).

Aside from the new acoustic processors, the P-3C introduced the APS-115 radar for full 360-deg sea-surface coverage and an LLLTV instead of a searchlight. The 43rd production P-3C introduced the ASQ-81 MAD. There was also a new automated ESM suite.

◆ ATDS

The Airborne Tactical Data System, the airborne equivalent of NTDS, is carried on board E-2 aircraft. Its air-to-air link to fighters is Link 4 (now Link 4A). ATDS was conceived roughly simultaneously with NTDS. The then Bureau of Aeronautics began to develop requirements for a carrier-based AEW/CIC airplane in 1955, but as yet there was no computer small enough to serve it. An interim contract was, therefore, given to Grumman for an interim nonautomated alternative, the E-1B (WF-2). The ATDS specification was issued in November 1955. Grumman received a contract for the E-2 on 5 March 1957, and the first fully equipped airplane flew in April 1961.

The E-1B carried 2 radar operators who could maintain 4-6 tracks and could control no more than 2 simultaneous intercepts using voice control. In 1960 it was estimated that an E-2A (not yet in service) could maintain 250 tracks and control 30 interceptions (via automatic data link). Newer versions have greater capacity. The crew consisted of 1 radar operator (instead of 2), an air controller, and a CIC operator. Each has an APA-172 console with a 10-in PPI and a 5-in alphanumeric display; targets are designated by light pen. The air-search radar automatically detects targets.

The system (picture-keeping) computer, a dual L-304, OL-77/ASQ, replaced an earlier hard-wired unit beginning in 1972. Originally, it had 8 kwords/module, but that capacity was doubled within a decade. A current project to buy a new computer had not been funded at the time of writing (mid-1990).

◆ LAMPS (SH-2 and SH-60B)

See the ASW section.

◆ S-3A

The S-3A tactical system was conceived as a smaller version of that of the P-3C, with some of the reduction in size balanced by better automation and a faster computer (AYK-10). There are only 3 crew members, in addition to the pilot: the copilot, responsible for nonacoustic sensors (radar and MAD) and communications; the sensor (acoustics) operator; and the tactical coordinator, who directs the weapons system as a whole.

Each has an ASA-82 multipurpose display (MPD). The pilot's smaller display is limited to the tactical plot; it guides the pilot during submarine-contact prosecution. The auxiliary readout unit, at the SENSO station, presents acoustic data only: the SENSO can simultaneously observe processed signals from 16 sonobuoys and monitor the tactical situation. Each MPD can display all mission data: acoustic (e.g., LOFAR) data, raw and scan-converted radar, FLIR pictures, ESM data, MAD data, and a tactical plot. The MPDs also present computer-generated cues (operational directions and suggestions) at the TACCO, COTAC/copilot, and SENSO stations, as well as alerts (system condition or failure messages).

FLIR and radar video are sent directly to the tactical displays; the acoustic-data processor (OL-82) feeds directly into the TACCO and SENSO displays and into the ARU. ESM, sonobuoy, and MAD signals are fed into the AYK-10 computer and thence into the displays. The computer (under TACCO control) normally controls sonobuoy dropping, although there is an alternative manual mode. Of the 60 sonobuoy chutes, 1 (chute P-2) is reserved for search and rescue.

The central computer automatically computes a splash point for each sonobuoy. It monitors sonobuoy drift through the water by locating all the buoys in the field. Passive buoys transmit radio signals continuously, and the sonobuoy reference system (SRS, designated ARS-2) locates them by passive interferometry, using 13-blade aerials distributed over the airplane's fuselage (i.e., by measuring phase differences between signals from the same buoy received at different aerials). Active buoys, which do not transmit continuously, are located by sending a modulated signal on their UHF command links and then measuring the same modulation as received on their VHF up-link. ARS-4 is a modified ARS-2 for the S-3B version of the Viking. The sonobuoy reference system was a major change from past practice, eliminating the requirement to overfly the buoys periodically, and permitting an airplane to remain at high altitude. A version of the S-3 sonobuoy reference system (ARS-3) was later incorporated into the Update II version of the P-3C.

The main (AYK-10) computer compares sonobuoy signatures with a library of stored signatures. The acoustic processor calculates target position when the airplane switches from passive detection to active localization, using active buoys. The acoustic processor was credited with a capability for automatic detection, though this may have been overstated. It integrates LOFAR signals over time to detect lines automatically, but in some cases such integration will not bring up a discontinuous

or changing line that might be evident from visual examination. The computer memory retains a record of the rise of different buoy signals; in theory, the sensor operator can use these data to trace the movement of a submarine through a buoy field.

The acoustic processor continuously records 28 channels of analog data, including 16 sonobuoy channels, raw and filtered digital MAD data, time codes, MAD cues, and commands from the AYK-10 computer. The SENSO and TACCO can listen directly to the signals heard by any particular buoy, e.g., in a directional audio mode.

Proposals for what became the S-3 were submitted in April 1968, and in August 1968 Lockheed and General Dynamics were asked to submit final versions. Lockheed was chosen in 1969. The S-3A first flew on 21 January 1972, and it formally entered service in February 1974.

The Canadian CP-140 Aurora has a modified version of the S-3A suite. Compared to a P-3C, it has a larger multipurpose display (MPD). The tactical compartment contains three 2-operator consoles, each with 2 MPDs and keysets to communicate with the AYK-502 (Univac 1832, i.e., AYK-10) central computer. The acoustic processor is OL-5004, similar to the OL-82 of the S-3A but with added vernier displays and ambient sea-noise measurement.

◆ TDS (RAN/RAWS)

The Collins Tactical Data System for helicopters was originally developed for the coast guard HU-65A and then modified for the RAN S70B Seahawk. The RAN version is called RAWS (Role Adaptable Weapon System). RAWS is quite different from the U.S. LAMPS; the RAN wanted the helicopter to be effectively independent of the frigate from which it flies. The model for RAWS, then, is the U.S. S-3 Viking.

TDS differs radically from earlier computer-based tactical data systems in its emphasis on the interaction between operator and display; it is designed so that the operator need not take his or her eyes from the display to use a keyboard. In a conventional system, the entry buttons must change function during operation, so touch-typing is impossible; the operator must be able to see what the buttons represent. The operator runs the TDS system by manipulating icons on the tactical display with a cursor driven by a joystick (a slew controller). The effect is much that of the Apple Macintosh computer. The manufacturer, Collins, emphasizes this view by calling the system computers Display Control Units.

Using RAWS, 3 operators can conduct a full ASW mission: a pilot, a TACCO, and a SENSO. The U.S. LAMPS III, which has much the same airframe, has 4 more crew members, aboard the parent ship, in the ship's operational cell (SOC).

The pilot and TACCO sit side by side facing forward, each with a navigational CRT (horizontal situation video display), with a larger (8 × 8-in) raster-scan tactical display between them. The navigational displays can show synthetic-video dial faces, radar video, synthetic-map data, map information overlaid on radar video, a hover display, and FLIR (when installed). The big raster-scan display shows the overall tactical situation in terms of NTDS and special symbols. The console between the pilot and TACCO carries dual keyboards and a slew controller.

The SENSO console in the rear of the helicopter contains a second tactical display, a third keyboard, and a second slew controller.

The central computer is provided with a data-loader cartridge carrying navigational data, sonobuoy loadout, initial search-pattern placement and orientation, contact/target information, and communications parameters (frequency selection and tuning). This form of initialization, data going directly into the controlling computer, makes for much quicker launch after contact, as little manual prelaunch setting is required. It also provides a natural pathway for in-flight updates via a data link. Data-loader capacity is 32 kwords.

The system is tied together by a dual-redundant 1553B bus, which has 22 terminals, 3 of which are reserved for future

The cockpit of an RAN Seahawk helicopter shows elements of the Rockwell Collins tactical data system. The cockpit panel is dominated by the 8 × 8-in tactical display unit (TDU). The smaller screens are MFD-80 navigational displays (horizontal situation displays), and the pilot and copilot each have CCD-810 control display units (on either side of the central console). The slew stick controller for the main display is visible on the left, at the lower edge of the CCD-810. (Rockwell)

growth (ESM, FLIR, and a dipping sonar); the current system uses 46% of bus capacity. The acoustic processor is a UYS-503 sonobuoy processor (which can handle 8 DIFAR buoys simultaneously). The helicopter carries 30 sonobuoys and 2 torpedoes or missiles. The SENSO chooses and launches sonobuoys via the tactical system, and the tactical display provides the necessary displays and alerts of contact. The system computes CPAs, doppler fixes, and hyperbolic fixes.

In the antiship role, the displays can show radar video, and the same navigational programs can set up a missile launch.

Each of 2 DGUs contains 3 advanced-architecture microprocessors (AAMPs): a system processor, a display processor, and an I/O processor. The AAMP is a single-chip 16-bit VLSI CMOS microprocessor, development of which began in 1979; it has been incorporated into numerous Rockwell projects, including the GPS satellite. The chip can execute double (32-bit) and triple (48-bit) -precision floating-point arithmetic and 16- and 32-bit fractional arithmetic. There are 3 versions. AAMP1, in production since 1986, has a peak performance of 1.7 MIPS (sustained 0.8 MIPS) at a clock rate of 20 MHz. It has also run at 30 MHz (2.4 MIPS) over a limited temperature range, and a

version using 1.6- and 1.2-micron rather than 2.0-micron technology has run at over 50 MHz. This chip contains about 74,000 devices. There is also a version fabricated using CMOS/SOS (silicon on sapphire) technology, for better resistance to radia-

Text (an acoustic set-up page) used by the Seahawk sensor operator (SENSO) to set up the acoustic processor and sonobuoy receivers. (Rockwell)

TACCO display of a sonobuoy operation on board an Australian Seahawk. The operator uses the slew stick controller to select from among a menu of icons shown at the left. The 3 buoys marked "B" are bathy-thermal, measuring the temperature (and, therefore, the sound velocity) profile. A line of passive buoys has been laid; the crossed symbol at the lower right indicates own aircraft (the triangle laid atop the left-most buoy indicates a fly-to point). The small triangles pointing to the left indicate visual contacts (stylized eyes). A hostile submarine contact, with course and speed (indicated by vector length) appears with its contact number, 2341, heading toward the buoy barrier. The small circle superimposed on the large one is the cursor; the circle at the bottom (above the word "fixed") is the active icon, with its meaning given. The letters "TACP" indicate the current display mode, with the display range scale, current time, display center point, alerts and annunciations, and bearing/range spread out along the lower border of the display. The hooked-item designator and strobe range/bearing from cursor can be displayed above the lower right-hand border. At the left, the upper left symbol indicates display mode selection. Modes are: TACP (tactical plot), R/TACP (radar tactical plot, i.e., radar display with tactical-plot symbology), R/TGT (radar display with radar tracked target symbology), Radar (video), and ACOUS (acoustic processor display video). Next to it is scale selection. Below are query (calls up an associated alphanumeric page) and move (repositions template and active selection display area to the other side of the display screen). The third line is the recenter command (selects display screen center) and suppression/restoration/deletion of designated targets. Fourth line: vector and strobe commands, the former displaying associated bearing and range. Fifth line: pointer (displays the pointer symbol) and circles (creates and modifies circles). Sixth line: create a track and track aid (update, reposition, modify, split, merge, sequence existing tracks; displays variable-length leaders and creates a target area of probability). Seventh line: tac aids (establishes and displays solutions for tactical and attack display aids) and fly-to (creates a fly-to point). Eighth line: transfer (displays designated targets on the horizontal situation displays) and data link (provides for designation of targets for data link transmission). Ninth line: special tactical markers (SPL) and fix designate (displays a tentative target symbol at the operator-designated location). Tenth line: patterns (creates manual-flight and sonobuoy-drop patterns) and stab (stabilizes sonobuoy plot and establishes data link gridlock). Eleventh line: hold (temporarily suppresses the display of all new [unacknowledged] PDIs) and radar center/scale (changes radar center/scale to that currently selected for the tactical plot display). (Rockwell)

tion. AAMP2 has 48-bit internal data paths for better performance and adds some instructions to the AAMP1 set. Performance: 2.3 MIPS peak, 1.6 MIPS sustained. Production began late in 1988. This chip contains about 117,000 devices. An SOS variant is planned. The current TDS uses the AAMP1 chip.

The current TDS uses 70% of the installed memory and 50% of the ultimate maximum memory capacity. There is a current reserve of about 40% of processor throughput.

◆ UDACS

Boeing's Universal Display and Control System is the basis of the P-3C Update IV. The UDACS console was originally devel-

The horizontal (4 × 4-in) display of an Australian Seahawk shows, at the same time, navigational data and the tactical plot (at the center), with a fly-to point. (Rockwell)

UDACS is the next-generation U.S. maritime-patrol-aircraft system, replacing the centralized A-NEW of the P-3C and its 3 Updates with a distributed architecture using 68020 processors tied together by a 32-bit maxibus; burst mode throughput is 192 Mbytes/sec. In keeping with the distributed architecture, all the operators (including the TACCO) have identical workstations, whose screens can display any sensor's output, and which can combine sensor outputs using windowing. Conventional keyboards are replaced by plasma touch screens, which can change configuration in accordance with changes in workstation function. The upper picture shows windowing: a tactical plot is superimposed on LOFARGrams. The lower photo shows a sonobuoy tactical plot with a FLIR image windowed into its upper left corner. Note the keyboard in the console next to this one; recent UDACS photographs show only the plasma panel. (Boeing)

Update IV (UDACS) installed on board a P-3C. All 4 sensor-operator consoles are identical and lined up together. The TACCO console is forward, facing forward. (Boeing)

oped for the RNZAF P-3B update, and it is now offered for installation in a possible maritime-patrol version of the Boeing (Canada) Dash-8 airliner.

UDACS is a fully distributed system, without any central computer. The microprocessors are 68000-series chips.

NAVIGATIONAL SYSTEMS

FRANCE

◆ Syledis

Syledis is a precision hyperbolic navigation system used by French Tripartite Minehunters, operating at VHF frequency. See Decca (below) for an explanation of hyperbolic navigation. Syledis was developed specially for the Tripartite program. The minehunters were also fitted with Thomson-CSF TSM 5700 doppler sonars to measure velocity (both fore and aft and lateral) over the ground.

◆ Toran

Toran is a precision circular navigation system used by French Tripartite Minehunters, operating at HF frequency. Distances to 2 transponder beacons are compared, and position is found by triangulation. The Toran shore system is operated by the French lighthouse and navigational beacon authority.

◆ Trident III

Trident III is a 3-beacon position-fixing system developed by Thomson-CSF and installed on board some export mine-countermeasures craft.

USSR

There are 2 major satellite navigational systems, 1 comparable to the U.S. Transit and the other to the U.S. Global Position Satellite (GPS). The Transit equivalent consists of 6 satellites in 60-deg orbits and 6 in 30-deg orbits. GLONASS is reportedly comparable to GPS, the first 3 satellites having been orbited in October 1982.

There are also several surface systems. One of them, ALPHA, is similar to the U.S. Omega. It is not clear whether the designation is Soviet.

UNITED KINGDOM

◆ Decca

This navigational system was developed by the Admiralty Signals Establishment from 1937 on; Decca was first used to guide small craft and minesweepers during the Normandy Invasion in 1944. The Decca Navigator Company was founded to further

develop the system after the war, and to operate the associated system of transmitters. Although not as accurate as such higher-frequency systems as Hi-Fix/6, it is still used as a backup in mine countermeasures and would be available in wartime to guide merchant ships through cleared mine fields. Decca is effective at short and medium ranges; Loran and Omega are long-range systems.

Like Loran, Decca uses master and slave stations and measures position by forming a hyperbolic grid. All such systems are based on the geometric fact that all points for which the difference between the distances to 2 fixed points is the same form a hyperbola between them. A series of differences defines a series of hyperbolas, and in theory one can determine on which hyperbola one lies. A second pair of stations provides a second series of hyperbolas, and position is determined by the intersections between the 2 series.

Decca operates at low frequency, 70–130 kHz, with a nominal maximum range of 240 nm. Average maximum position errors at this range are 150 yd by day and 1200 yd by night; at 100 nm from the master station, the average errors are 30 and 100 yd, respectively. Typically, a chain consists of a master and 3 slave stations. The signals are all CW, distances being measured by comparison in phase between master and slave signals. Because phase changes are cyclic, position can be measured only within one 360-deg cycle, which is called a lane. Special supplementary signals are transmitted so that a receiver can determine in which lane it is located.

◆ Hi-Fix/6

Hi-Fix/6 is a Racal Marine Systems (formerly Decca) precise navigation system, operating at 2 MHz, essentially a higher-frequency equivalent of Decca. Hi-Fix/6 and the earlier Hi-Fix are used by some mine-countermeasures craft (such as Belgian and Dutch Tripartite Minehunters and by British craft). Hi-Fix/6 is now being superseded by Hyperfix (see below).

◆ Hyperfix

Hyperfix is a Racal Marine Systems precise navigation system, superseding the earlier Hi-Fix/6. Like Decca and Hi-Fix, Hyperfix uses phase comparison. The system operates at 2 MHz (actually the 1.5–3.5-MHz band), with a repeatable accuracy of 5 m at 250 km at night (500 km in daytime), described as 20 times better than earlier 2-MHz systems. Ranges as great as 700 km are available much of the time, depending on ionospheric conditions. Accuracy is often between 1 and 2 m.

Each station in the chain transmits signals at 2 frequencies about 1% apart. As in Decca and Hi-Fix, phase comparison is used to determine position within a lane. The lane is determined (within a group of about 100) by comparison between the phases of the 2 signals. At the frequency used, a lane is about 75 m wide at the baseline. Resolution is 0.001 lanes (but the display is not fine enough to fully exploit this accuracy).

Hyperfix has been deployed in chains of remotely controlled stations around Britain. The system has been adopted by Canada and at present is being supplied under contract to the U.S. Navy.

Twenty-four stations are being supplied in the Persian Gulf under Japanese contract.

◆ Micro-Fix

Micro-Fix is a new Racal 5-GHz line-of-sight system with an accuracy about 1 m out to 80 km. The ship transmits a signal that is returned from 2 or more portable shore stations for triangulation. Racal claims that this system is unique in being continuously self-compensating. The company is now developing a nonradiating hyperbolic variant.

UNITED STATES

◆ GPS (Navstar)

Global Positioning System will be completed by 1990. It will fix position within about 16 m (spherical accuracy), and velocity within 0.1 m/sec. With such accuracy, GPS becomes a means of guiding weapons against fixed targets, and several recent weapons, such as SLAM, are to incorporate GPS receivers.

A user automatically chooses the 4 most suitably located satellites and locks onto their navigation signals, obtaining a pseudorange (time difference) to each. These 4 pseudoranges in turn figure in 4 simultaneous equations, which the specialized Navstar computer solves for user position.

The first series, whose launchings began in February 1978, cover the continental United States and are intended primarily for test and validation. Ultimately, an 18-satellite constellation will provide global coverage. Satellites orbit at 10,898 nm, with a 12-hour period. Each weighs 1020 lb and is expected to last 5 yr (carrying 7 yr' worth of consumables, primarily booster fuel).

Including in-orbit spares, the total system consists of 28 satellites.

◆ Loran/Omega

Long Range Navigation system was originally devised during World War II and is now quite common on a worldwide scale. Omega is a variation. The basic unit consists of a "master" emitting timed pulses and a transponder ("slave") some distance (usually about 500 nm) away. A ship equipped with Loran listens for both master and slave pulses. The time difference between the 2 indicates the difference in path between the 2 stations, since the slave emits only after the master pulse has traveled the distance between master and slave stations. This time difference in turn defines a hyperbola on which the listener must be located. By listening to 2 pairs, the ship can locate itself on 2 intersecting hyperbolas (the system is often called hyperbolic navigation or hyperbolic fixing). Accuracy depends on the ratio of ship's distance from the baseline to baseline length; the longer the baseline, the better. Therefore, the tendency in Loran has been toward lower frequencies that propagate better over greater distances.

The original Loran-A operated at 1850–1950 kHz with a range of about 450–800 nm by day and 1400 nm by night, using ground-wave transmission. Loran-A was very widely deployed in the North Atlantic and North Pacific between 1955 and 1970. Loran-B was an abortive attempt to achieve greater range by reducing frequency. Stations proved difficult to synchronize, and the ground and sky waves interfered. Loran-C solved these problems by using synchronized pulses for both time-difference and phase comparison, and -C became operational in 1957. As coverage expanded, -C superseded Loran-A, which was largely abandoned in 1977. Loran-C operates at 90–110 kHz. Ground wave range is 1200 nm, but signals can also propagate by sky wave (range with 1 reflection from the ionosphere is about 2300 nm, and with 2 reflections about 4000 nm; the latter can be received only at night).

The purpose of the master/slave combination is to synchronize signals from the 2 stations of the hyperbolic pair. During the late 1960s, atomic time standards that made for simpler operation were developed. Pulses were synchronized by time standard. The secondary (formerly slave) station transmitted

upon receiving the master pulse but did not have to retransmit the original pulse. The system uses a form of pulse compression to achieve very long range and compares details of the pulse to avoid confusing ground and sky waves.

Omega operates at 10–14 kHz. At such very low frequencies, signals penetrate the sea surface and can be used by submarines operating at periscope depth. By using atomic time standards to synchronize very distant stations, Omega can exploit baselines as long as 5000–6000 nm; a total of 8 stations (the last of which, in Australia, entered service in 1982) cover the entire globe, 3 and usually 4 stations being usable from any position. As in Decca, phase difference is used for positioning, each lane being 8 nm wide on the baseline. Lane identification is by phase comparison of 3 auxiliary signals multiplexed with the basic 10.2-kHz signal. A ship finds her approximate position by some other means, to within about 50 nm, and then uses Omega to obtain a better fix. Once an initial fix is obtained, a receiver can count lanes crossed to maintain an accurate fix. Positions can be obtained within 1 or 2 nm.

◆ PINS (SSN-2)

The Magnavox PINS (Precise Integrated Navigation System) is installed on board the new U.S. *Avenger*-class minesweeper/hunters, following tests on board the older minesweeper *Pluck*. PINS was designed to operate with or without the assistance of shore-based fixed reference systems, and also in very deep water, integrating all available references: Loran-C, Raydist, Transit (and then GPS) navigational satellites, and a doppler bottom log effective to depths as great as 20,000 ft. The bottom log measures true ship's speed, so that position can be measured accurately between satellite passes. PINS is also used to record mine contacts and the ship's track through an area.

◆ Raydist

The Hastings Raydist "T" is a commercial hyperbolic (phase comparison) navigational system broadly comparable to Decca and its successors, originally adopted for the sweeping of Hanoi-Haiphong in 1973 and still in use as a U.S. alternative to other fixed systems. In 1972 the United States had no such system, and navigational accuracy was no better than 100–250 yd; a more precise system had been sought for a quarter century. Two ground networks and 33 receivers were purchased in October 1972 and installed on board the sweeping helicopters, the mine-clearance ship MSS 2, and 2 ocean sweepers. Each ground network consisted of 2 CW and 2 single-side-band (SSB) transmitters. During the 1973 clearance operation, average navigational error was reduced to 10–20 yd.

◆ SINS

SINS stands for Ship's Inertial Navigation System; it is presumed that the Soviets have an analog. SINS is the basic sensor of the U.S. Navy's ballistic-missile program (Polaris, Poseidon, Trident) since SINS is the nonemitting submarine position-and-motion indicator. In practice, SINS data are updated every so often by using Transit or some alternative navigational satellite, but any such update requires the submarine to put a detectable radio antenna through the surface. SINS's performance is measured in terms of the required reset interval to determine position to within a given error. Perhaps the major source of error is drag exerted on the main SINS gyro by its supporting structures.

Compared to the inertial sensor of a missile, SINS must function over much longer periods at much lower velocities. Otherwise, it is identical in concept: measured submarine acceleration is integrated to provide submarine velocity and then integrated again to provide submarine position. The missile's fire-control system requires not only the absolute position of the submarine (latitude and longitude) but also its heading, speed (north and east components), roll, pitch, and vertical velocity (heave), a total of 8 parameters.

Work on SINS began in 1954, based on the research done for the inertial navigation system of the air force's Navaho cruise

missile. The first unit, installed in the USS *Compass Island* and *Nautilus*, was a modified missile N6A, with a gas spin gyro bearing. Mk 2 Mod 0 was introduced in the *George Washington*-class ballistic-missile submarines, with a total of 56 being built (3 per submarine). Installation of a new stable platform housing with fewer temperature gradients and airflow variations converted these units to Mod 4. A new SINS, Mod 2, was introduced to support the longer-range Polaris A-3. It incorporated a new gyro with greater angular momentum (i.e., less affected by unwanted torques). Mod 2 was installed in the *James Madison* class. Mod 3 introduced an additional monitor gyro, identical to the main gyro, that compensated for drift in the 2 leveling gyros. Mod 3 was installed in all ballistic-missile submarines but the *George Washington* class. For Poseidon, with its greater range (2600 nm), Mod 3 was modified to a new Mod 6 configuration.

A new electrostatic-gyro-support technology was developed for Trident submarines, although early units have the earlier Mk 2 SINS.

SINS is installed on board carriers, where it provides initial data to aircraft navigation systems (CAINS).

◆ TACAN

Tactical Air Navigation system is a transponder that provides aircraft with accurate distance and heading information. The antenna rotates within a radome, producing a series of coded pulses: bearing relative to magnetic north, beacon identification, and beacon distance. Equipment on board the aircraft processes these pulses to provide location data. Because

TACAN is a transponder, it is somewhat more discreet than the earlier beacons, which emitted whether or not they were required. Current U.S. TACANs operate on 252 channels (evenly divided for reception and transmission) in L-band (1025–1150 MHz for reception, 962–1024 and 1151–1213 MHz for transmission). TACANs can communicate with up to 100 aircraft within a 300-mile radius. Ships generally carry a single TACAN antenna, mounted at the masthead. There are 4 standard antennas, URN-20, URN-25, SRN-6, and SRN-15, all of which provide the same type of pulse train.

The Soviet equivalents are Top Knot, in the *Kiev*-class carriers, and various versions of Round House, which are always mounted in pairs, either fore and aft or athwartships.

◆ Transit

Transit was the first U.S. satellite navigation system, developed by the Applied Physics Laboratory (APL) to exploit the doppler effects of passing emitting satellites like the first Soviet Sputnik. APL used doppler data to measure the Sputnik's orbit but then realized that, given a known orbit, doppler data could be used to measure position on the ground. Transit was proposed in 1958, primarily to support the Polaris submarine program, and was placed in full-time service in 1964, becoming the first U.S. operational satellite system. It was made available for commercial use in 1967.

The current Transit system consists of six 100-lb solar-powered satellites in 600-nm orbits, each carrying a precise crystal clock and emitting orbital signals. Accuracy at a fixed site is about 100 ft.

STRATEGIC STRIKE SYSTEMS

CHINA (PRC)

◆ C-SS-N-3

Dimensions: approx 1.5 × 10 m [60 in × 33 ft]

Weight: approx 14,000 kg [30,000 lb]

Warhead: 1 (reports vary on yield)

Range: est 2700–3600 km [1750–2300 nm]

A C-SS-N-3 missile being loaded on board a Chinese Xia-class submarine. (*Ships of the World*)

C-SS-N-3 missiles. (*Ships of the World*)

A Xia-class missile submarine. (*Ships of the World*)

The first submerged launch was carried out on 12 October 1982 by the single Golf-class trials submarine, at a range of 1600 km. The missile has 2 solid-propellant stages. Twelve missiles can be carried by Xia-class submarines; in 1988, 2 such submarines had been completed and 2 were under construction. Reportedly this weapon was developed in part from the CSS-2 (DF-3) land-based ballistic missile, which has a range of 2700 km and which carries a single 1–3-MT warhead (and, in its newer version, 3 MRVs, 50–100 kT each). This missile was first fired by a Xia-class submarine during July 1988. The Chinese designation is Ju Lang 1 (JL-1).

An improved C-SS-NX-4 is currently under development; reportedly this improved version carries a 2-MT warhead.

FRANCE

Submarine-launched ballistic missiles are ejected from their tubes by pressurized air, stowed in bottles (M20), or by gas generators (later weapons).

◆ M20

Dimensions: 1.5 × 10.4 m (5.2 m first stage, 2.6 m second stage) [59 in × 34.1 ft; 17.1 ft, 8.5 ft]

Weight: 21,000 kg [46,300 lb]

Warhead: megaton range (TN-60); later replaced by an improved TN-61

Propulsion: solid-fuel rocket: Type 904 first stage, Rita IIP6 second stage. Burn duration: first stage 50 sec (45,000-kg thrust); second stage 52 sec (32,000-kg thrust). [99,200/70,500-lb thrust]

Range: 3000 km [1900 nm]

M20 was the second-generation French naval ballistic missile, succeeding the original M1 and the longer-range M2. M20 is an M2 with a megaton warhead accompanied by penetration aids (decoys); it is intended specifically to penetrate the missile defense around Moscow. The thermonuclear warhead is hardened against ballistic-missile defenses, presumably such radiation effects as neutrons and EMP. This missile may also be designed to use a steep energy-inefficient trajectory that limits exposure to defensive radars by reducing time spent in their beams.

The M20 missile is cold-launched by compressed air and is aerodynamically unstable. The second stage and the warhead are the same as those of the S3 ground-launched strategic missile. M20 became operational in 1977 (on board the submarine *Indomptable*). Only 1 submarine, *Le Redoutable*, still carries this missile; all of the other submarines have been converted to fire the newer M4.

◆ M4

Dimensions: 1.93 × 11.05 m [76.0 in × 36.2 ft]

Weight: 35,000 kg [77,140 lb]

Warhead: six 150-kT TN-70 (MIRVs)

Propulsion: 2-stage rocket with powered MIRV bus. First stage: Type 401(P10), 71,000-kg thrust; second stage: Type 402(P6), 30,000-kg thrust; third stage: Type 403, 7000-kg thrust. [156,500/66,100/15,400-lb thrust]

Range: 4500 km [2900 nm]

M4 is the MIRV successor to M20. Almost twice as heavy as M20, M4 is designed to fit the launch tubes of existing French strategic submarines. Exploiting French research into small thermonuclear warheads, the French government decided to proceed with M4 in December 1974. Compared to M20, M4 is an all-new missile with new first- (401), second- (402), and third- (403) stage motors. The last powers the warhead-dispensing bus.

The M4 missile is launched by a powder charge; M4 can be fired at greater depths than M20 and can be fired in closer sequence than the earlier weapon. The 6 TN-70 warheads are spread over a 150 × 350-km [97 × 227-nm] area.

M4 was first fired at sea on 10 March 1982 and became operational in 1985 on board the submarine *L'Inflexible*. M4 now arms all earlier strategic submarines except the *Le Redoutable*; conversion of that ship would have required the installation of new (rather than modified) launch tubes.

Delays in M5 development have led to a new program for an interim weapon, M45, which is to enter service in 1994 on board the submarine *Le Triomphant*, the first of a new generation. M45 can carry a TN-71 warhead to a nominal range of 5000 km [3200 nm]; however, an M45 carrying a single warhead reached 6000 km on 4 March 1986. Operational M45s will carry 6 new TN-76 "stealth" warheads, presumably to evade Soviet ballistic-missile defenses.

◆ M5

The M5 missile is under development for projected second-generation strategic submarines (the first missiles will go to sea in the third submarine of the class). Design requirements include a range of 3240 nm and 8–12 TN-75 MIRV warheads; radar signature may be reduced, and penetration aids added, to counter Soviet ballistic-missile defenses. This weapon was initially described as M4C.

◆ ASMP

Dimensions: 0.30 m × 5.38 × 0.96 m over fins [11.8 × 211.8 × 37.8 in]

Weight: 840 kg [1851 lb] **Warhead:** 300-kT

Propulsion: integral rocket-ramjet; maximum speed Mach 3.5

Range: 80+ km at Mach 2, low altitude; 250+ km at Mach 3, high altitude [52 and 162 nm]

A medium-range nuclear standoff missile, ASMP (*Air-Sol Moyenne Portée*) is designed for use against both tactical and

The French submarine-launched ballistic missile M5 emerging from the water. (Armées d'aujourd'hui—SIRPA)

ASMP under the wing of a Super-Étendard. (Aerospatiale)

strategic targets. ASMP is carried by 24 (of a total of 55) Super Étendard carrier attack aircraft as well as by French land-based tactical (Mirage 2000N) and strategic (Mirage IVP) aircraft. In French official parlance the word "tactical" was changed to "prestrategic" before the ASMP went into service, to emphasize French reliance on deterrence through the threat of escalation. In the case of the Super Étendard, ASMP replaces a standard nuclear gravity bomb (the 60-kT AN-52, first deployed in 1977). This program began in March 1978 after a government decision to proceed with an aircraft-carried standoff weapon for attacking hardened targets. ASMP was, therefore, primarily a way of extending the usefulness of the French strategic air arm.

The carrier *Foch* was refitted in 1987–88 to carry ASMP in place of the earlier AN-52 bombs. However, her sister, the *Clemenceau*, is not being refitted because she is to be replaced by the new nuclear carrier *Richelieu* about 1996. It is reported that the French Navy wanted a lower-yield version for antiship attack, but finances precluded development of 2 versions of the basic weapon.

The size of the missile was limited so that it could be carried by a Mirage 2000N. The missile design has some stealth features, including some radar absorbing material. In addition, ASMP is hardened against EMP.

ASMP's aerodynamic design is unusual, having 2 prominent angled air intakes, whose fairings lead back to the after end, but no wings as such. At very high speeds, the intakes and fairings provide sufficient lift, and the only special aerodynamic surfaces are the 4 fins at the tail. The intake fairings carry such auxiliary

equipment as the actuators for the fins. The air intakes are modeled on those of the Concorde airliner.

There are 3 alternative flight modes: high-altitude/terminal dive, low-altitude terrain following, or low-altitude with terminal pop-up for air burst (against naval targets). In the last case, the missile would attack from relatively short range (effective range is limited to about 60 km [39 nm] by the radar horizon of a low-flying attack aircraft). All 3 flight modes include preprogrammed evasive maneuvers.

The engine is probably the most interesting feature of the missile. The initial choice, a solid-fuel rocket, was rejected because it would have been much too heavy, resulting in an unacceptable 3–4-ton missile. Instead, a solid-fuel booster is used to accelerate the missile to Mach 2, at which speed the main ramjet is efficient. The rocket burns out in about 5 sec, and about 1/20 sec later the nozzle is ejected. The burnt-out booster becomes the combustion chamber, a "swirl type" developed since 1972. There can be no conventional flame holder (since all the volume of the chamber is occupied by the solid booster), so the flame is stabilized by the 2 jets of air from the air intakes, forming what amounts to a fluid flameholder. The fuel is conventional kerosene rather than the denser Shellodyne used in U.S. cruise missiles, the former fuel being much better known in France when ASMP was designed. However, a second-generation cruise missile will use denser fuel.

ASMP first flew on 23 June 1983 and was the first European missile to shift automatically from rocket to ramjet mode. The missile became operational on 1 May 1986 on board Mirage IVP bombers of the FAS (*Forces Aériennes Stratégiques*). Total planned production is about 100 weapons.

USSR

Reportedly, Soviet liquid-fueled missiles are floated up from their launch tubes before being ignited at the surface. If that is true, then they cannot be surface launched (they cannot be ignited in their launch tubes). The disadvantage is that they cannot be fired by surfaced submarines in the Arctic. On the other hand, a submarine could escape before her missiles, floating at the surface, ignited, thus not disclosing her position to possible counterattack. The denser solid-fueled rockets (SS-N-17 and -20) are, again reportedly, launched from their tubes by gas generators, as in U.S. service. They are, therefore, suitable for surface firing, e.g., in the Arctic. A DoD painting shows a Delta-IV-class submarine surfaced in the Arctic, firing her SS-N-23 missile. Presumably, then, this class uses a gas generator to eject its weapon.

◆ SS-N-3 Shaddock

See the Strike/Surface Warfare section for the strategic version of this tactical missile.

◆ SS-N-5 Sark (R-21)

With the retirement of the Golf-class submarines, this missile is extinct. See the first edition of this book for details.

◆ SS-N-6 Serb

Dimensions: 72 × 390 in **Weight:** 41,600 lb
Warhead: one 1-MT in Mod 2, two 350-kT RV in Mod 3
Throw weights: 700 kg for Mod 2, 2350 kg for Mod 3
Propulsion: 2-stage liquid rocket
Range: 1300 nm (Mod 1); 1600 nm (Mod 2); 1600 nm (Mod 3)
CEP: 1640 yd

SS-N-6 was the first modern Soviet naval ballistic missile, carried on board Yankee-I-class submarines. It is reported that about 1000 were built. Because range was only 1300 nm at first, submarines carrying Serb had to approach the U.S. coast to fire. That range reflected the secondary role assigned to Soviet naval forces when the weapon was conceived (probably about 1960) and deployed (1968). Official doctrine then was that submarines would remain in reserve while the land-based strategic rocket force engaged targets in North America; the submarines would be used either for terminal bargaining or for a second-phase

SS-N-6 was the first modern Soviet sea-launched ballistic missile, enough smaller than SS-N-4/5 that a useful number (16) could be carried by 1 submarine. This ship, a Yankee-class submarine, was designed to carry SS-N-6. From 1967 until the advent of Typhoon in the 1980s, all Soviet ballistic-missile submarines were direct developments of the Yankee. SS-N-6 could be carried in numbers because it was so much shorter than SS-N-5, which filled not only the depth of the submarine hull but also the height of its sail. SS-N-6 required only a small protrusion above the submarine hull. (U.S. Navy)

attack. The surge requirement explains the Western assumption that the contemporary Victor-class ASW submarine was conceived as a Yankee escort.

In practice, Yankees patrolled off the U.S. coast during the 1970s and 1980s; some analysts assumed that the assigned role of these submarines was to destroy key U.S. command/control facilities at the outbreak of war. The Soviets would certainly not have expected these boats to survive very long after the outbreak of war, in waters dominated by the U.S. Navy. By 1988 the Yankees had been withdrawn to European waters, perhaps to replace the SS-20 land-based missiles scrapped under the new INF treaty. Yankees returned to the U.S. east coast during the summer of 1988, after the treaty had been ratified.

SS-N-6 is liquid-fueled, the fuel being replaced periodically and the missile refurbished. Possibly because of problems with missile fuel, a Yankee-class submarine suffered a missile tube explosion in the Atlantic, ultimately sinking on 6 October 1986 off Bermuda. It is difficult to avoid concluding that these weapons are deteriorating despite maintenance and, therefore, that the force as a whole may be losing its effectiveness.

All operational missiles are SS-N-6 Mod 3, carrying 2 MRVs.

SS-N-6 was reportedly designed by the Chelomei bureau, which was also responsible for some cruise missiles. This missile reportedly shared some characteristics of the earlier land-based SS-11, which Chelomei also designed, and was reportedly developed as part of Khrushchev's 7-year plan (1959–65), the tactical-technical requirement having been drafted in 1958. According to a former Soviet naval officer involved in missile development, the original requirement was for a single-stage underwater-launched missile 180×1000 cm [71×394 in], i.e., 4 m [157 in] shorter than the existing SS-N-4, with a maximum weight of 19 metric tons, a range of 2400 km [1300 nm], and a CEP of 1 km [0.54 nm]; the missile would carry a single 0.7-MT reentry vehicle. The rival Yangel bureau had just completed work on the SS-N-5 (1300-km [700-nm] range) and was concentrating on land-based missiles (SS-9). SS-N-6 was first flight-tested in 1966, and it entered service in 1968. Mod 2 was an interim longer-range version, developed by the Chelomei bureau while work proceeded on SS-N-8; Mod 2 provided 550 km [300 nm] more range, partly by reducing warhead weight (to 650-kT yield).

◆ SS-N-8 Sawfly

Dimensions: 65 × 504 in **Weight:** 30,000 kg [66,000 lb]
Warhead: one 800-kT (Mod 1) or two 500-kT (Mod 2)
Propulsion: liquid-fuel rockets
Range: 4240 nm (Mod 1); 4950 nm (Mod 2)
CEP: 0.84 nm (Mod 2)

SS-N-8 symbolized a shift in Soviet strategic doctrine: the navy achieved parity with the strategic rocket force. Submarines had to be able to fire at any time after the outbreak of war. This missile, therefore, was given sufficient range for it to be fired from its peacetime operating area, i.e., from a sanctuary (basin) area dominated by the Soviet Navy. SS-N-8 incorporated

Delta, carrying the SS-N-8 missile, is essentially a Yankee (SS-N-6) with longer missile tubes. The original Delta, shown here, even retained the lower after end of the missile tube section, and the difference in height is a measure of the difference in missile length. (U.S. Navy)

stellar-inertial guidance, in hopes of achieving useful accuracy even from the bastions. Reportedly, the stellar-inertial system was not always reliable, and initial reports of spectacular accuracy were exaggerated. The maximum range achieved during testing has been 9200 km, which is the longest of any current naval strategic missile.

Sawfly is carried by Delta-I- and -II-class submarines and by the sole Hotel-III, which was 1 of 2 test ships, along with a Golf-III. The Golf-III was discarded in 1987. SS-N-8 entered service in 1973. This missile's design is reportedly based on that of SS-N-6.

◆ SS-N-17 Snipe

Dimensions: 1.7 × 10.6 m [66.9 × 413 in]
Weight: 20,290 kg [44,700 lb]
Warhead: one 800-kT or two 500-kT
Propulsion: solid-fuel rocket **Range:** 2100 nm
CEP: 1400 m [1500 yd]

Snipe was the first Soviet solid-fueled naval ballistic missile, and also the first with a postboost vehicle (i.e., with MIRV potential). It is carried by a single Yankee-II-class submarine, apparently a system test ship. SS-N-17 was first tested in 1975, and it became operational in 1980. Design probably began in 1969. This missile reportedly uses some SS-16/20 technology (the missiles all have similar postboost buses) and itself led to SS-N-20. There was speculation that SS-N-17 was intended as a direct replacement for SS-N-6 (hence its appearance on board a modified Yankee), but that it was not deployed because of its limited range, difficulties with its rocket motor, and SALT I numerical limitations.

◆ SS-N-18 Stingray (RSM 50)

Dimensions: 1.7 × 13.6 m [66.9 × 535 in]
Warhead: three 200-kT MIRV (Mod 1), or one 450-kT (Mod 2), or seven 200-kT MIRV (Mod 3)
Propulsion: liquid-fuel rockets (2 stages)
Range: 3530 nm (Mod 1 or Mod 3) or 4350 nm (Mod 2)
CEP: reported as 875 or 1200 yd

SS-N-18 was the first Soviet naval MIRV missile, using storable liquid propellant as in SS-N-6/8. Like SS-N-8, SS-N-18 has stellar-inertial guidance, reportedly improved by the ability to take multiple star sights. Design work probably began in 1964, with R&D and tests in 1970–75. Mod 1 first flew in 1975 (first flight from a submarine was in November 1978). Mod 2 flew in 1977 and entered service in 1979. Mod 3 first flew in 1981–82. SS-N-18 is carried on board Delta-III-class submarines. When it entered service, it was the largest naval strategic missile in the world.

The height of the missile section of this Delta-III is a measure of the great length of its SS-N-18 missile; the sail proper, at the forward end of the missile section, is the same height as that of a Yankee. (U.S. Navy)

◆ SS-N-20 Sturgeon (RSM 52)

Dimensions: 2.17 × 14.7 m [85.4 × 579 in]
Warhead: six-nine 100-kT MIRV
Propulsion: solid-fuel (3 stages)
Range: 4300 nm **CEP:** 550–650 yd

SS-N-20 is carried by Typhoon-class submarines. It was first tested, unsuccessfully, in January 1980 (1 source gives a 1979 date), but successful tests were reported in 1981, and 4 were launched by a submerged submarine in October 1982. The system was considered operational as of 1983. A single Golf-V submarine in the Black Sea was modified to test SS-N-20. In March 1986, SS-N-20 was the only Soviet SLBM in series production. Design work probably began in 1972; in 1974 Leonid Brezhnev told then-President Ford that unless the United States abandoned its Trident program, Typhoon would go ahead. Reportedly, problems with this weapon delayed the Typhoon program, the submarine being ready well before the missile had become sufficiently reliable.

Although previously credited with 6–9 RVs, SS-N-20 is counted with 10 under the START treaty rules.

This missile reportedly embodies SS-N-17 technology.

A modified version of SS-N-20 (Mod 2) was probably tested in 1988, and a completely new SLBM (presumably to be designated SS-N-26) is reported under development.

◆ SS-N-21

Dimensions: 51 cm × 8.09 m (canister: 65 cm × 8.39 m) (span approx 300 cm) [20.1 × 318.5/25.6 × 330.3 in]
Weight: 1700 kg (2440 kg with canister) [3747/5378 lb]
Propulsion: turbojet with rocket booster **Range:** 1600 nm

SS-N-21 is the Soviet equivalent of the U.S. Tomahawk strategic cruise missile. There are 2 other versions: the land-based SS-C-X-4 and the air-launched AS-15 (KENT). Details were

No photo of SS-N-21 has been released, but in connection with the Intermediate-Range Nuclear Forces Treaty the Soviets did release this photograph of its land-based version, SS-C-4. (Department of Defense)

taken from the Soviet description of SS-C-X-4, released as part of the INF treaty. SS-C-X-4 is carried in a 65-cm canister; it seems likely that the naval version is carried similarly. It follows that the weapon can be fired only from a 65-cm torpedo tube. Reported speed is Mach 0.7. SS-N-21 follows a low-altitude (approx 190–200-m altitude, [600–650 ft] flight path).

Yankee-class submarines are being converted to carry this missile, in a new midships section with horizontal launching tubes. The estimated capacity is 20–40 missiles.

The Soviet designation of the associated land-based weapon (SS-C-4) is RK-55.

◆ SS-N-23 Skiff

Dimensions: 1.8 × 14 m [70.9 × 551 in] **Weight:** 40,000 kg (88,000 lb)
Warhead: 7 MIRV
Propulsion: liquid-fuel rockets (3 stages)
Range: 5000 nm **CEP:** estimated 500 m [550 yd]

SS-N-23 is carried by Delta-IV-class submarines and may later be retrofitted to Delta-IIIs. It is similar in size to SS-N-18 but has greater throw weight and is more accurate. Flight tests began in June 1983, and the missile entered operational service about 1987; it was not yet in series production as late as March 1986. There were apparently early reliability problems.

For treaty purposes, SS-N-23 is now credited with 4 RVs, although as many as 10 have been reported in the past. A modified version of this missile probably completed sea testing in 1988.

◆ SS-N-24

Dimensions: approx 1.25 × 12 m; span 5.9 m [49 × 472 × 232 in]
Propulsion: jet, Mach 3.0 **Range:** 1600 nm

SS-N-24 is a very large, new cruise missile; range estimates are as great as 4000 nm. This missile may correspond to

SS-N-24 cruise missiles being fired by a converted Yankee-class submarine. (Department of Defense)

SS-N-21 as SS-N-8 corresponds to SS-N-6, i.e., SS-N-24 may be a strategic cruise missile that can be fired from within a bastion. The only published sketch suggests that this missile is launched without any canister, spreading its wings after emerging from the water. The only launch platform to date is a modified Yankee-class submarine.

A ground-launched version, SSC-X-5, under development, was canceled because of the INF treaty. Development began before 1983.

UNITED STATES

U.S. naval ballistic missiles are fired using gas generators; the missiles are ignited when they reach the surface. They can, therefore, be fired by a surfaced submarine. However, reportedly, a Trident I (C-4) cannot be surface launched without some risk of damage to the firing submarine.

♦ Polaris (UGM-27C)

Dimensions: 54 in × 387.5 in **Weight:** 35,000 lb

Warhead: six 150-kT (three 200-kT in U.S. version)

Propulsion: solid-fuel rocket (first-stage thrust, 36,000 kg)

Range: 2500 nm

Although no Polaris missiles remain in U.S. service, this weapon equips the 4 British strategic submarines, under the 1962 Nassau Agreement. Britain maintains a facility capable of manufacturing and servicing Polaris missiles, and the weapons are armed with a British multiple warhead, Chevaline. Chevaline was developed as a penetration aid, and it is described as a compromise between the multiple (but cotargeted) warheads of

U.S. Polaris missiles and the fully independently targeted warheads of Poseidons. The 6 warheads are carried on a maneuvering penetration aid carrier (PAC), which incorporates a computer-controlled stable platform; it also carries decoys. Reportedly, the warheads can hit points as much as 40 nm apart.

The original A-3 missile fired 3 warheads, but their distribution could not be adjusted to attack different targets. They were ejected from the missile's second stage by rockets, which also imparted some spin to improve accuracy as they fell. Presumably, the PAC can maneuver to a very limited degree to aim the warheads independently. A full postboost vehicle (PBV) would provide a wider spread, achieved by maneuvering for a longer period or through larger angles. The distinction may be that the PAC can change only the overall pattern of warhead distribution, whereas a PBV can maneuver to drop each warhead separately.

Chevaline was developed from a U.S. penetration aid system, Antelope, which used a modified (Mk 2 Mod 1) guidance system. An Antelope missile could be fired into a special lofted (steeply falling) trajectory, to minimize exposure to a ballistic-missile defense system's radar. The Antelope computer was also specially hardened against EMP pulses from the explosions of defending nuclear missiles. It had special metallic gaskets. In addition, the Mod 1 computer periodically stores its data content in a protected module. It was assumed that the main effect of an EMP pulse would be to corrupt current data; such corruption was detected by a special circuit, the current data discarded, and the stored data returned to main memory. That response still made for some inaccuracy since the stored data were at least 1 computer-storage-cycle old.

Chevaline flight tests from ground pads began in September 1977, and sea trials in November 1980; the last development launches were made in February 1982. A remotoring program was conducted in 1981–86, as the original motors were deteriorating. The A3 missile itself was a radical redesign of the original Polaris single-warhead weapon, maximum range increasing by two-thirds. The secretary of defense approved development in September 1960, the project was funded in October, and the first missile was launched on 26 October 1963.

The first U.S. Polaris submarines carried a Mk 80 fire-control system; the versions controlling the A3 missile were Mod 2 in the original *George Washington* class and Mod 3 in the *Ethan Allan* (SSBN 608) class. Mk 84 was installed in the *Lafayette* class, which were later converted to Poseidon operation. Mk 84 is also the fire-control system of British Polaris submarines. Details below apply to the original U.S. Mk 80 system.

Missile flight parameters were calculated for a specific launch point and for nominal flight conditions. These data were punched into computer cards, together with the proportional or interpolation constants and the coefficients used to correct these values for the actual launch point (as measured by the submarine navigational system) and for the actual flight conditions. The submarine patrol area was divided into launch squares, each small enough that the interpolation constants were accurate enough (20' in latitude × 20' in longitude), and a separate card produced for a launch reference point in each square. Nine launch squares formed a launch complex 1 deg in latitude × 1 deg in longitude. The launch squares were small enough that a launch reference point remained valid for a submarine 5 min into the adjacent square, so a card remained valid for a useful period of time, as the submarine moved through the water.

The cards were punched out on board the submarine but before the sub reached a particular firing area. The specialized dual Polaris Target Card computer system had paper tape input for both program and targets (targets could also be input directly, by typewriter at the computer console). At this stage of computer development, the calculations involved were far too complex to be carried out in real time; the digital-computer element of the system was off-line. This system in turn replaced the earliest technique, which was to punch out the cards ashore, at Dahlgren. Presumably, the increased range of the A3 missile,

Polaris A-3, as currently used by the Royal Navy. (U.S. Navy)

which greatly expanded the possible submarine patrol area, made it less practical to prepunch cards for stowage aboard the submarine.

Mk 84 incorporated a digital computer, but it is not clear whether the computer allowed real-time operation. The next system, Mk 88 (for Poseidon), eliminated this step, using a much faster computer (see the Poseidon entry below).

The effect of the punched-card system shows in the sequence of submarine operational conditions. A submarine in the patrol area could operate in condition 3SQ, i.e., at 2 hrs' notice after targets had been designated. Presumably, 2 hr were required to align the missiles but also (and at least as importantly) to prepare the requisite punched cards. In the next readiness condition, 2SQ, which could be held for 60 days, the submarine was at 15 mins' readiness, with her targets in range and designated, i.e., with punched cards set up. 2SQ was the normal patrol condition. In condition 1SQ, the first missile could be fired at 1 min's notice.

The Mk 80 fire-control system constantly monitored submarine position to ensure that the appropriate card was used. It computed the appropriate bearing, toward which the missile was aimed. This calculation included the effect of the rotation of the earth. It also took into account estimated wind affecting the reentry body near the target, when the body is no longer under positive control. The fire-control system could take into account not only submarine movement but also target displacement from the original position estimate. Thus, the system could, in theory, attack a semimobile target, or a target that had been incorrectly located when the target cards were prepared. Target ballistic wind was periodically received and updated, presumably on the basis of satellite data. Corrections due to submarine roll, pitch, and yaw were also entered into the target data system.

Mk 80 could provide data for 8 targets at a time; typically 2 missiles were assigned to each target. However, each target-data-input unit could provide data to up to 4 missiles, all of which would be aimed at 1 target. The basic system could fire a missile either for a ground burst or for an air burst (at 1 of 3 alternative heights) over the target; the air-burst trajectory was somewhat longer since it had to pass over the target.

The basic missile sensor is the set of gyros and accelerometers on the stable platform in the nose. Before launch, the stable platform is lined up with a vertical axis, a horizontal axis pointing to the target, and a cross-range axis. The gyros measure missile yaw, pitch, and roll relative to the stable platform. There are also 3 accelerometers measuring motion along the 3 axes; the hard-wired digital computer in the missile measures velocity and position from the accelerometers and gyros. The outputs are pitch and yaw steering commands, and velocity yet to be gained before the motor is cut off (the solid-fuel motor cannot be throttled). All of this requires a stable time reference, which is provided by the computer clock (crystal-controlled oscillator).

Alignment is critical to the operation of the system since the missile steers in relation to the aiming axis pointing toward the target.

Missiles are stowed in the tubes with their stable platforms aligned as closely as possible with the axes of the submarine, but there is always a small misalignment, due both to errors in placing the missile in its tube and also to the slight motion of the missile while the submarine moves. Before the missile can be fired, the stable platform must be aligned with the submarine axes so that it can be turned toward the target (target bearing is measured relative to the submarine). The target bearing fed into the missile takes into account the roll and pitch of the submarine, i.e., the difference between its axes and axes set in the earth.

Alignment with the submarine axes is accomplished using optics since light travels in straight lines, and deviation from a path is relatively easy to measure. Each missile has an optical window, and each tube has a corresponding window. The missile also contains a prism on its outer stable platform gimbal, which would point along the ship's axes were it properly

aligned. The gimbal angle is converted into an angle between 2 beams of light, 1 incident on it and 1 reflected from it and then turned through 90 deg (by a prism on a trolley running down the missile bay); the distances are such that even a very small angle produces a noticeable difference between the 2 beams.

The missiles in a Polaris submarine are lined up in 2 rows adjacent to the missile-control center because each missile must be accessible to the optical path from the fire-control system. That arrangement is an important submarine design consideration: the reactor cannot be amidships, as in an attack submarine, but must instead be abaft the missile bay.

Normally, the stable platform is caged (secured). When a missile is prepared for firing, it must be erected, i.e., it must be stabilized with respect to gravity. Once the platform has been aligned with the submarine's axes, the fire-control system can erect it (set the vertical) and aim it (set its horizontal axis in the direction of flight). Erection involves separating out submarine motion components (coarse erection) and separating out the motion of the earth (fine erection); in space, the missile measures its motion with respect to a nonrotating set of coordinates, rather than with respect to the rotating earth.

This stabilization takes time, about 1 min to spin up the gyros, then 1 min for coarse alignment and erection, and about 6½ min for fine erection. During stabilization the optical alignment trolley is used to measure missile misalignment angle, which is an additional input to the alignment angle calculated by the fire-control system.

The Polaris first stage steers by rotating its 4 nozzles to control pitch, yaw, and roll. The second stage steers by injecting liquid freon downstream into the single nozzle. As the freon passes across the line of thrust, it causes an oblique shock wave, which in turn deflects the thrust; the angle of deflection is proportional to the amount of liquid injected. Six openings (connected to 2 ports) are distributed around the nozzle, and they can be used either singly or in combination.

Except for the warhead description, the data are for the U.S. version, Polaris A-3.

◆ Poseidon C-3 (UGM-73A)

Dimensions: 74 × 408 in **Weight:** 65,000 lb

Warhead: up to 14 MIRV to 2500 nm or ten 50-kT RV (Mk 3) to 3200 nm **Propulsion:** 2-stage solid-fuel rocket

Range: 2500 or 3200 nm

Poseidon C-3 (right) compared to Polaris A-3. (Lockheed)

This Lockheed weapon was the second-generation U.S. submarine-launched strategic missile. In 12 *Lafayette*- and *Benjamin Franklin*-class submarines, it was replaced by Trident C-4, which fits the same launch tube. This replacement program was completed in December 1982. Some remaining Poseidons are being "uploaded" with more powerful warheads.

Like Polaris, Poseidon is a 2-stage missile. It ignites 90 ft from the launch tube, before leaving the water; the main stage burns for about 50 sec. Second-stage burn time will vary with targeting, but it is nearly the same as nose-fairing ejection time, which can be set at 22.08 or 33.28 sec.

Unlike Polaris, Poseidon has a powered postboost vehicle (called the equipment platform) carrying its reentry vehicles (RVs) in 1 of 4 alternate configurations. The equipment section maneuvers using a gas generator and 8 two-way thrusters. They can be used either to position the platform between RV firings (to hit several targets in sequence) or to add distance along the line of flight (downrange distance). Four of them provide pitch, yaw, and thrust along the missile's longitudinal axis; the other 4 provide roll control and thrust along the 2 perpendicular axes.

Poseidon uses a Mk 3 guidance system (Mk 2 was Polaris A-3). As in Polaris, Mk 3 continuously calculates the remaining velocity-to-be-gained needed to reach its target, and steering commands are generated to drive that velocity to 0 (i.e., to motor cutoff, which is the only available motor command). The digital Poseidon guidance computer (PGC) has a capacity of 1k 24-bit ROM (wire braid memory) and 1k 96-bit running memory; the long words are used to achieve high precision in arithmetic. Characters are 6 bits in length. Clock rate is 3.9 MHz.

Guidance is more flexible than that of Polaris, allowing for variable loft angles and variable range between 500 and 3500 nm. Unlike Polaris, Poseidon uses thrust vectoring for control in both its first and second stages, in both cases with a single nozzle.

Unlike Mk 80, which uses a hybrid digital-analog computer, Mk 88 is wholly digital, using a general-purpose digital control computer (DCC). One DCC can provide guidance inputs for 16 missiles; each submarine has duplicate systems for reliability. Normally they operate in parallel, each controlling 8 missiles. Each DCC has 16 kwords (24-bit word) of magnetic-core memory, with 4 input and 4 output channels. There are 44 instructions. The 2 DCCs share a 2.25-Mword mass store (magnetic disk pack or file, consisting of 20 recordable surfaces; read rate is 28 kwords/sec), containing all the tactical, test, and maintenance programs and all the target data. Guidance constants for each missile are provided on a punched Mylar tape, compiled before patrol, which can be read into the mass memory. These data might include, for example, the gyro drift rate of the particular missile. The DCC generates launch-bearing, fuze-set, and guidance data; there is no need to define launch squares or to precompute before entering a launch area.

The DCC drives a command-slew subsystem (CSSS), an alignment subsystem (ALNSS), and an erection subsystem (ESS), which control the stable platform in the missile. Command slew is the initial, quick (15-sec), coarse adjustment of the stable platform, signals being sent directly to the gimbal torque motors (bypassing the inertial gyros, which are much slower because they have to measure angles very precisely).

The 2 DCCs are part of the digital geoballistic computer (DGBBC), which also serves the submarine's Mk 113 underwater fire-control system (a new Mod of this system was associated with conversion to Poseidon, i.e., with installation of the computer). The system includes 2 magnetic disk files, which can be manually switched between the 2 DCCs.

As in Polaris, the missiles are aligned optically.

Poseidon grew out of work on an enlarged (74-in- rather than 54-in-diameter), single-target missile, provisionally designated B3, and also out of navy interest in the ongoing air force MIRV program of the time. There was some interest, too, in adopting the air force Mk 12 or Mk 17 reentry vehicle, although ultimately Poseidon used a much smaller Mk 3. C3 was a MIRV version of B3, and it was first announced on 18 January 1965,

President Johnson choosing to use a new missile name despite its strong connection to earlier versions of Polaris. The MIRV development was formally approved on 13 January 1966, and flight testing began in January 1968. The first submarine to deploy with Poseidon was the USS *James Madison*.

Poseidon is credited with 8 times the effectiveness of A3. Reported CEP is 600 yd, although the missile was more commonly regarded as a relatively inaccurate soft-target killer. The hard- vs. soft-target issue became quite heated in the 1970s, when an inability to hit hard targets was equated with arms-control stability (a hard-target killer could be construed as a first-strike weapon since it could disable enemy missiles before launch). By this time the navy was already working on improved accuracy and yield, the CNO first having announced his interest in hard-target-killing capability in October 1962. Initial evaluation of a stellar-inertial guidance system followed early in 1966, and work on a Mk 4 stellar-inertial system began in 1968. Congress later expressly prohibited the navy from deploying either the guidance system or a new high-yield warhead; both decisions were reversed in the development of Trident.

Although 14 RVs can be carried, the usual load is 10. The missiles can be ripple-fired. In a test, the USS *James Madison* took 56.3 sec/missile, a total of about 15 min for all 16.

♦ Trident C-4 (UGM-96A)

Dimensions: 74 × 408 in **Weight:** 70,000 lb

Warhead: eight 100-kT Mk 4 MIRV **Propulsion:** solid-fuel rocket
Range: 4350 nm **CEP:** 1500 ft

Trident I is Poseidon's successor, designed to fit existing tubes and to achieve 4000-nm range without losing the accuracy of the predecessor. Its postboost vehicle (MIRV bus) incorporates a stellar sensor for positional corrections, thus achieving greater accuracy. This missile became operational in 1978.

Compared to Poseidon, Trident I was conceived as a longer-range missile with about the same throw weight. Trident I achieves greater range partly by increasing its effective length, extending an aerospike at launch. The spike is credited with

Trident C-4 (right) compared to Trident D-5 (left). Note the aerospikes. (Lockheed)

Trident C-4 launching, with the aerospike extended. (U.S. Navy)

reducing frontal drag by 50%, i.e., with adding 300 nm to the missile's range. The aerospike also made it possible to use a very blunt nose that could accommodate a third rocket stage together with the warheads. C-4 also benefits from advances in propellant chemistry, making fuller use of its fuel. Instead of blowing open ports (and thus neutralizing thrust) at a precalculated point in second-stage flight, it burns all its fuel and then calculates the appropriate third-stage trajectory. The new high-energy fuel is credited with about 40% of the range improvement, another 35% being credited to the use of improved chamber material (Kevlar), which allows increased propellant loading and higher operating pressures.

C-4 uses the stellar-inertial-update guidance proposed for Poseidon to help overcome the effects of uncertainty in a submarine's position. The missile is credited with a CEP of 500 yd (8 Mk 4 RVs with W76 100-kT warheads), and in 1982 it was stated that improvements in guidance optics could reduce CEP to 250 yd. The Mk 500 Evader MARV, carrying a 100-kT weapon, was developed by Lockheed as an alternative warhead but has not been procured.

The guidance system, Mk 5, can function in all-inertial or stellar-inertial modes. Two proposed versions of C-4 were dropped because D-5 development was accelerated: C-4U, with improved guidance, and Long C-4 TFS (44 ft long, i.e., as long as D-5, with a Terminal Fix System for improved CEP). There was also a proposed "flat deck" version in which the third-stage motor was eliminated in favor of more RVs, reportedly up to 10 Mk 12A.

C-4 development was approved on 14 September 1971.

Lockheed received the C-4 contract in 1974, and the first missile was launched in January 1977. The *Francis Scott Key* was the trials ship, beginning her first Trident patrol in October 1979. The entire 12-ship Poseidon-to-Trident conversion program was completed in March 1982. The C-4 procurement objective was 570; procurement ended in FY84 (72 in FY83, 52 in FY84).

◆ Trident II (D-5)

Dimensions: 83 × 528 in **Weight:** 130,000 lb

Warhead: 8–12 Mk 5 RV (300–475-kT warheads) or fourteen 150-kT MIRV or seven 300-kT MARV; initially D-5 will use the Mk 12A RV of the Minuteman and MX land-based missiles (475-kT)

Propulsion: 3-stage solid-fuel rocket; burn time about 65 sec for each of 2 lower stages, and 40 sec for the third stage
Range: 6000 nm **CEP:** 400 ft

The fire-control system on the submarine matches that of Trident I but adds a gravity sensor and a new navigation sonar. The missile itself uses a new epoxy case for all 3 stages and a new high-energy propellant similar to that of the land-based MX. As of early 1988, the first full system tests (submarine launches) were scheduled for March 1989.

Production of the first 21 missiles was authorized under the FY87 program (66 under each of FY88/89); the total objective (1988) is 845 missiles (for 19 SSBNs, with 30 missiles for testing). Alternative loads: 10–15 MIRV, or 11–13 Mk 4 RVs, or 6–9 Mk 5 RVs. Guidance is stellar-inertial, for a reported CEP of 400 ft (1500 ft for Trident I). The Mk 5 vehicle/W87 combination was selected in October 1982. All missile tests up to September 1987 used 8 warheads; in September 1987 a D-5 was tested with 10 smaller warheads. However, in December 1987 President Reagan and the Soviet General Secretary Mikhail Gorbachev agreed that, for arms-control purposes, the missile would be credited with no more than 8 warheads.

The first sea test (21 March 1989, from the USS *Tennessee*) was a failure; the missile pinwheeled. D-5 flew successfully on 2 August 1989, but it failed again on 15 August. The missile then flew successfully in December 1989. The effect of the failures was to push initial deployment back from late 1989 to March 1990. The failures were apparently caused by damage to rocket nozzles by the column of water that rises with the missile. This water surge is much larger than in earlier Trident, Poseidon, and Polaris missiles and was not allowed for in the D-5 tail design. The solution was reportedly a mesh cover for the rocket nozzle that keeps water out while the missile is rising; the cover is blown out by missile ignition.

This program was accelerated in 1982 by Secretary of the Navy John Lehman, the object being to introduce the missile as early as possible so as to avoid the cost of refitting submarines completed to carry the earlier C-4. The planned introduction date of 1989 (on board the *Tennessee*) was 3 yr earlier than originally projected. At the same time, the planned number of D-5 submarines was increased to about 20. Full-scale engineering development of the D-5 (UGM-133A) missile began in October 1983, in parallel with its new W87 warhead (300–475-kT yield), the latter to deal with superhardened silos and similar targets, invulnerable to existing warheads.

The FY90 program includes 63 missiles, with 52 in FY91; unit cost is \$28.4M in FY90.

Britain has chosen Trident D-5 for the next-generation *Vanguard*-class strategic submarines. They will carry British warheads; but the missile bodies will be maintained by a U.S. facility, the Royal Navy turning missiles in for maintenance and drawing refurbished ones (which the British will then arm with their own warheads). Critics of the British Trident program have derided this practice as "rent a missile." The Anglo-American agreement was signed on 14–15 July 1980; 80 missiles will be acquired (16 per submarine plus enough spares to fill another submarine).

◆ Tomahawk (including nonnuclear versions)

Dimensions: 20.9 × 252 in **Weight:** 3181 lb

Warhead: 200-kT (W80 warhead)

Propulsion: F-107 turbojet sustainer

Range: 1350 nm (250 nm for TASM, 675 nm for the conventional land-attack weapon, and 472 nm for the land-attack submunition weapon)

Tomahawk was conceived as a weapon not covered by existing arms-control treaties and, therefore, as an initiative the United States could take to counter growing Soviet strategic forces. The initial DoD cruise-missile studies were ordered in 1973, and it is reported that then-Secretary of State Henry Kissinger favored the weapon as a bargaining chip in SALT II negotiations. Tomahawk then acquired a life of its own, and critics of arms procurement have cited cruise missiles as examples of

Tomahawk programmed conventional air burst over a revetted bomber, demonstrating the ability to attack large aircraft. (General Dynamics)

how a bargaining chip can become a permanent fixture of military forces. The Carter Administration resisted deploying this strategic cruise missile for fear that it would breach the observability requirement built into the SALT II treaty. Late in 1980, however, the decision to deploy the tactical version of Tomahawk opened the way to deployment of the strategic version.

The navy had been very interested in a small and easily deployed strategic weapon before 1973 as a way of spreading U.S. strategic firepower over a much larger number of platforms. One advantage of such dispersal for the U.S. is that the Soviets, preoccupied with nuclear weapons, must dissipate their own efforts by targeting (hence tracking) a much larger number of U.S. ships and submarines. This U.S. strategy is a form of jujitsu: if the war is unlikely to turn nuclear, it is a way of using the existence of nuclear weapons to gain decidedly nonnuclear ends (greater survivability of individual valuable ships, such as aircraft carriers). The idea of reversing the significance of nuclear forces can also be seen in more recent maritime strategic approaches to Soviet bastions: threatening Soviet nuclear forces there will, it is hoped, concentrate Soviet naval attention away from the sea lines of communication, at least early in a war.

Tomahawk can be dated to a 1971 internal navy study of basing options for a future U.S. sea-based cruise missile. The 2 alternatives studied at the time were a 2000-nm weapon, 6 of which could fit a standard Poseidon tube (and which could be ejected together), and a 1500-nm torpedo tube-launched weapon. The latter was adopted, and the SLCM program was formally approved on 2 June 1972. On 6 November the SLCM

project was merged with a program for a 300-nm submarine-launched tactical (antiship) missile, STAM, which had originally been conceived as an extended-range Harpoon.

General Dynamics won a fly-off against LTV's ZBGM-110; more recently, McDonnell Douglas has been selected as a second source, for competitive annual bidding. The first guided Tomahawk flight was in December 1976.

Missile diameter is slightly less than the 21 in usually quoted: the missile in its canister fits the standard 21-in torpedo tube. The data above, except for range, are for the strategic version. Quoted ranges differ widely, figures as great as 2000 nm being claimed for the strategic missile and 400 nm for the tactical version armed with a Bullpup warhead.

Both strategic and tactical versions are in service. Under the INF treaty, land-based Tomahawks in Europe (operated by the U.S. Air Force) are being destroyed. This does not affect the naval versions. Air-launched versions, both long- and medium-range, have been proposed, but they have not entered service. Soon, then, Tomahawk will exist only in surface-ship and submarine versions. The planned total naval procurement is 3994. Surface ships carry Tomahawk in 4-missile armored box launchers and in the Mk 41 vertical launcher. Submarines carry Tomahawk either in torpedo tubes or in special vertical tubes.

The effective range of the antiship version is limited by the need to search for the target at the end of what may be a lengthy flight. Land-attack range is limited by the weight of the warhead. Guidance is by terrain-matching (TERCOM) and inertial navigation, a system designated TAINS (TERCOM-Aided Inertial Navigation System). Unlike a ballistic missile, a TERCOM-guided cruise missile can attack only over suitable (and suitably mapped) territory, and that requirement in turn may somewhat limit Tomahawk operations. Tactical versions use DSMAC (Digital Scene-Matching Correlation), in which the scene viewed optically is compared to an on-board digital map. In a 24 April 1988 night test, the optical viewer was assisted by a strobe light. The antiship version of Tomahawk incorporates Passive Identification/Passive Direction Finding (PI/DF) equipment intended to enable the missile to discriminate among potential targets, presumably on the basis of their characteristic emissions. The 4 antennas are flush-mounted on the missile skin, feeding a microwave receiver.

Versions (navy procurement goal in parentheses): BGM-109A, nuclear land attack (758); BGM-109B, antiship (593); BGM-109C, conventional land attack (2643, of which 1486 are Block IIA with Bullpup unitary warheads and 1157 are Block IIB with bomblet warheads); BGM-109D, land attack with bomblets (0); BGM-109E, antiship (0); BGM-109F, land attack, antiairfield (560); BGM-109G, ground-to-ground nuclear, with variable yield (0). AGM-109C was the abortive medium-range air-to-surface (MRASM) terrain-following missile; AGM-109I was a proposed MRASM with an infrared seeker, and AGM-109J was a proposed MRASM carrying bomblets. The Tomahawk land-attack missile with a nuclear warhead is sometimes denoted TLAM-N; the Tomahawk antiship missile is TASM; and the Tomahawk conventional land-attack missiles are often denoted TLAM-C (unitary conventional warhead) and TLAM-D (bomblet dispenser).

TLAM-C Block IIA, which carries out an optional terminal maneuver (pop-up and dive), was approved for production during FY86. The terminal maneuver is selectable before flight. Other improvements are provisions for a mobile launch point and for alternative selection of over-water waypoints. A programmable warhead detonation (PWD) for this version has been tested.

TLAM-C Block IIB is the bomblet version, tested in FY86. It carries 166 Aerojet Ordnance BLU-97/B combined-effect bomblets in 24 packages, 22 of them holding 7 bomblets each (6 each in the other 2). Each bomblet (2.5 × 6.6 in, 3.4 lb) carries an incendiary fuze, a fragmenting case, and a shaped charge. The missile can eject bomblets to hit several targets per pass; in a November 1987 test, a submarine-launched Tomahawk dropped bomblets on 3 targets and dove on the fourth. The bomblet version became operational in FY88.

Tomahawk attacking multiple targets using submunitions. (General Dynamics)

An Improved Sea-Skimming Variant (ISSV) was operationally tested in December 1985 through May 1986.

A Block 3 Improvement Program, now in development, will enter production in FY91. Changes include an improved turbofan engine (19% more thrust, 3% less fuel consumption), GPS, an improved form of DSMAC, and improvements for better coordination with tactical air strikes.

The supporting weapons system is Mk 36/37 (submarine/surface-ship vertical launcher). It is being modified (Block II) to accept data from fleet intelligence sources and sensors, presumably as an outgrowth of Outlaw Shark (see OSIS and TFCC under Surveillance and Control).

Late in April 1988 the navy briefed contractors on requirements for a stealthier next-generation SLCM, with better accuracy and greater range.

Late in 1988 the U.S. Navy awarded a contract to McDonnell Douglas Astronautics for an extended-range Tomahawk, for completion in 1992. The contract includes the use of the GPS satellites, time-of-arrival software (so that different missiles can make a near-simultaneous attack, to saturate terminal defenses), an improved version of DIGISMAL, and an insensitive-munitions/extended-range payload section. The changes are to be such that older missiles can be modified to the new standard when they arrive for maintenance every 3 or 4 yr; no additional missile purchase is involved.

Early in 1990, when the cancellation of the Sea Lance ASW missile was announced, some funds were transferred from that weapon to Tomahawk. There was an official suggestion that Sea Lance might be replaced by a Tomahawk variant carrying a Mk 50 torpedo. It is not clear just how serious these suggestions were; Tomahawk is much slower than Sea Lance. It could, however, be a credible replacement for the *surface-launched*

version, provided that the missile's target could be updated after launch by a data link either from the launching ship or from a helicopter prosecuting the contact. A Tomahawk variant, equipped with sonobuoys, was an unsuccessful contender for the original Sea Lance contract in 1980.

◆ Excalibur (LRCSW)

Excalibur is a navy project for a long-range highly accurate cruise missile, a Tomahawk successor, which might be used to deliver nonnuclear warheads. The missile will presumably exploit new high-accuracy technology that was first publicly described in the summer of 1987 and that may use lasers for very accurate map-reading. Some have suggested that long-range

General Dynamics's version of LRCSW. (General Dynamics)

McDonnell Douglas's version of LRCSW. (McDonnell Douglas)

conventional cruise missiles can take over some roles currently reserved for strategic nuclear weapons and that, therefore, such missiles may have a revolutionary impact on future warfare. In particular, in 1987 both the Blue Ribbon panel on a new U.S. national strategy (which conceived the concept of "discriminant deterrence") and a Defense Science Board study of Strategic Nonnuclear Capabilities (SNNC) pushed for the development of what they called Long-Range Conventional Cruise Missiles (LRCCM). The air force requested \$50 million to begin development in FY89. Ultimately the program was moved into the Joint (i.e., air force and navy) Stand-Off Weapons program, which also includes the AIWS and MSOW described in the Strike/Surface Warfare section.

Excalibur is a navy LRCCM program proposed as an alternative to the JSOW weapon; the navy proposal for development during FY90-94 reportedly includes ship-, submarine-, and air-launched versions. The key difference between a navy-developed LRCCM and an air force-oriented weapon would almost certainly be the navy requirement that the weapon fit a standard submarine torpedo tube, whereas the dimensions of the air force weapon would probably be limited by those of the standard bomber rotary launcher. Because of just these requirements, Tomahawk is so different from the contemporary air force ALCM.

The U.S. Navy established a Tentative Operational Requirement (TOR) for an advanced sea-launched cruise missile (ASLCM) on 9 March 1988; the U.S. Air Force established a Statement of Need (SON) for a conventional cruise missile (CCM) on 28 February 1989. The Joint Chiefs of Staff had already issued a Joint Mission Needs Statement in November 1988, and concept development formally began on 22 September 1989. In December 1988 the navy was made the lead service in a joint navy/air force program, the navy term being LRCSW and the air force term LRCCM. The air force is responsible for propulsion, in a program located at Wright-Patterson Air Force Base.

As of early 1990, there are to be 2 versions, for long and short (one-quarter of long) ranges, both carrying 1000-lb warheads. Unit cost limits are, respectively, \$1.5 million and \$900,000 (goals are \$750,000 and \$500,000). Maximum weights are, respectively, 3600 and 2250 lb.

In November 1988 the Naval Air Systems Command awarded Lockheed Missiles and Space Company a contract to study guidance, mission planning, and survivability for an Advanced Sea-Launched Cruise Missile (ASLCM) to replace Tomahawk. The ASLCM is to have a greater range. The Lockheed study will concentrate on the surface-launched version. Lockheed suggested that the contract might lead to hardware design and construction and then to demonstration validation flights.

Three companies exhibited alternative long-range conventional cruise missiles at the U.S. Navy League show in March 1989: Boeing, General Dynamics, and McDonnell Douglas. Each missile was powered by an unducted-fan (propfan) jet at its tail, driving contra-rotating propellers of the type also proposed for full-scale aircraft. The program is entering the concept-definition stage, and the navy is expected to request bids during FY90. At this writing the final designation of the program is uncertain. Excalibur is a name used within the navy. The original ASLCM designation was succeeded by LRCCM, then by LRCSOW (long-range conventional standoff weapon), and then by LRCSW (long-range conventional standoff weapon).

The versions shown at the U.S. Navy League show in April 1990 all had sharp noses and chined (faceted) bodies, to reduce radar cross section by reflecting radar signals away from the transmitter.

At least 3 alternative guidance techniques are being investigated: laser radar scene-matching (CMAG, cruise missile advanced guidance, developed as an air force program since about 1983), imaging infrared, and a synthetic-aperture radar (SAR). Loral exhibited its own SAR at the 1989 show. Besides the terrain comparison navigation used by the current Tomahawk, a very precise future cruise missile might employ feature navigation

The Boeing version of LRCSW, in its folded and unfolded configurations. The wing is oblique. (Boeing)

gation (i.e., comparison with the relative positions of features on the surface, such as crossroads, rather than with the absolute height of terrain). In theory, feature-navigation data might be derived from conventional maps and so might permit the use of long-range missiles against targets for which special terrain-contour maps had not been prepared.

Loral displayed its autonomous SAR seeker at the Navy League show; this device is probably typical of those being considered for LRCSW guidance. It is 15 in in diameter and 23 in long, weighs 74 lb, and requires 392 W of power. This seeker employs a conventional-looking flat plate array antenna, which can swivel to the side (for SAR) or can look straight ahead. The seeker can, therefore, be used for conventional terrain avoidance and even terrain height matching as well as for scene matching by imaging. Typically the radar would be used for at least 1 mid-course match with some prominent terrain feature and then would produce a series of target images of successively finer resolution as the missile approached. Compared to the current height-matching system, a SAR is much easier to program since it needs only a series of images of terrain. Loral claims that missions can be planned (i.e., weapons programmed) in minutes rather than hours at the squadron level.

The General Dynamics version of LRCSW. It has an unducted-fan engine, which is not visible here. The wings and tail are swept forward at a small angle, and the vertical fin extends below the missile. (General Dynamics)

The McDonnell Douglas version of LRCWS, showing the shape of its nose and body. Note the small flip-out fins forward of the unducted fan. (McDonnell Douglas)

The 3 proposed weapons differ in configuration. Boeing showed a missile with a single wing pivoted along its upper surface; after firing, the wing would turn into an oblique position. General Dynamics showed 2 forward-swept wings, carried internally, that would pop out after firing; its missile also showed small canard foresurfaces. McDonnell Douglas showed 2 pivoting wings (carried 1 over the other) below the upper surface of the missile; these wings would also pop out after firing. McDonnell Douglas's and Boeing's configurations leave considerable space under the wing for a submunition-dispensing warhead (although McDonnell Douglas's sketch showed a 1000-lb unitary reactive case warhead, 17.3 in in diameter and 46 in long). Boeing emphasized commonality between different LRCWS versions, for vertical launch, torpedo-tube launch, and air launch; Boeing had already conducted a study of a propfan derivative of its air force air-launched strategic cruise missile (AGM-86B).

A possible Excalibur power plant is this new propfan engine by Teledyne-CAE. Total length is 35.53 in, and diameter, with the blades folded, is only 16 in. The entire engine weighs 150 lbs. In comparison, the Harpoon missile's J402-CA-400 sustainer, which was the first to be designed for "wooden round" use, weighs 101.5 lbs and is 29.2 in long, with a maximum diameter of 12.5 in. Teledyne also offers a bypass turbojet for next-generation cruise missiles, presumably a rival to the propjet. This turbojet would weigh 135 lbs, with a diameter of 13.2 in, and would produce a thrust of 1100 lbs (compared to 660 for the Harpoon engine), with a specific fuel consumption of 0.9 lbs/hr/lb-thrust (compared to 1.2 for the Harpoon engine). (Teledyne-CAE)

Since a major LRCWS application is submarine launch, the missile is probably limited by the torpedo tube's dimensions, which include a 21-in maximum diameter. McDonnell Douglas showed a length of 235 in, which is presumably the maximum allowable.

LORAL
Defense Systems - Arizona

LORAL SAR SEEKER

A synthetic-aperture seeker for advanced cruise missiles. (Loral)

LRCSW will almost certainly be propelled by an unducted fan; the blades must fold (for tube stowage), and they must also be stealthy. On the other hand, the missile is launched at nearly Mach 0.75, the speed at which it flies to its target, so there is no need for variable pitch. A half-scale engine is to be tested late in 1990. The current competitors are: Teledyne/GE, Allison/Hamilton Standard, Garrett (folding propfan blade technology), Williams International (improved version of current F107). The first 2 are concentrating on complete engines. Allison plans a development version of its Model 250-C30 as the core of a future engine. Teledyne is looking at an engine derived from the GE 36 engine demonstrated on a 727 airliner. The company is also working on a private-venture 700-1000-lb core engine specifically designed for propfans.

Several of these companies displayed prospective LRCSW engines at the 1989 Navy League show. All should be more economical than current turbofan cruise-missile engines, providing either more range with current warheads or larger warheads. The existing Tomahawk makes its long range only in its nuclear version, and in that case the warhead weighs less than 300 lb. Tomahawks carrying substantial nonnuclear warheads cannot carry enough fuel to go nearly as far, yet the hope of the LRCSW is that it can reach full Tomahawk ranges and still carry large conventional warheads (and achieve virtually zero CEP).

The LRCSW engine is conceived as a possible modular-engine replacement for the Tomahawk turbofan.

STRIKE/ SURFACE WARFARE

This section includes all weapons and fire-control systems intended primarily for antiship or ground attack. The 2 applications are often extremely difficult to distinguish, as many weapons, such as cluster bombs, intended primarily for use against land targets have important antiship applications. For example, during the fighting in the Persian Gulf in 1988, U.S. A-6 Intruders used Paveway laser-guided bombs to attack Iranian ships, while cluster bombs were used during attacks on Libyan ships in March 1986. The Maverick ground-attack missile has reportedly been used by Iran to attack tankers, and indeed the U.S. Navy uses a special antiship version of Maverick.

From a missile's point of view, ships and land targets all move relatively slowly; therefore, they impose very similar loads on propulsion and aerodynamics: hence, the dual-purpose weapons. However, a ship almost always presents great contrast to its surroundings and, therefore, is a relatively easy target for a fire-and-forget weapon. Most land targets show much less contrast with their surroundings and, therefore, must be identified by eye, at least at present. In some cases, there is sufficient contrast for an autonomous seeker, but in most an artificial signature must be imposed. Hence, the widespread current use of laser designators and the considerable interest in imaging infrared seekers (which allow an operator to designate a target for a missile or guided bomb). The great drawback of the laser is that its designation platform must remain in position while the weapon is in flight. Even in the case of ships, the situation may not be very simple. The target ship may well be part of a formation, and other, lower-value parts of the formation may be larger radar targets.

Weapons' characteristics largely shape attack tactics. The issue for the designer is how best to penetrate terminal defenses. The techniques, very broadly, are speed, saturation, and stealth. Very high speed penetrates by limiting the number of shots a defense can fire while the attacker passes through that defense's effective-range band. Examples include most recent Soviet antiship missiles, which fly at about Mach 2.0. Alternatively, an attacker may fire numerous weapons at the target, preferably from many different directions. Several recent antiship missiles, such as current versions of Harpoon, incorporate programming for way points. The missile is fired along a course away from the target and then turns sharply into the target. This maneuvering has 2 effects. First, it limits the value of early-warning since the missile does not remain on its initial course long enough to be engaged. Second, the maneuver enables a single attacker to execute a coordinated multidirectional strike, with missiles appearing on target from several angles at once. Waypointing may allow an attacker to overwhelm the limited number of defensive channels that most ships have. Finally, there is stealth, the best-known example of which is the use of sea-skimming trajectories that limit detection time (as long as the defender has no airborne radar). The desire for stealth affects the choice of missile seeker (e.g., IR rather than radar, or 1 type of radar rather than another) and of targeting device (the presence of a radar platform may warn a target that it is about to be attacked, even when the attack itself is stealthy). Generally, stealth limits the defense's reaction time.

These techniques work not only for attacks on shipping but also for other forms of strike warfare. For example, a pilot attacking a concentration of vehicles on land can probably make a single successful pass if the approach is at very low altitude because there would be the advantage of surprise—in effect, the benefit of stealth. However, if that pass is used merely to decide which vehicle to hit, the pilot may well die on the second pass, when the defense is alerted: hence, the advantages claimed for current single-pass/multiple-shot systems (e.g., for Maverick). Similarly, modern attack tactics often envisage several aircraft suddenly appearing on radically different bearings, a single formation having split up beyond the target's radar horizon. That is saturation. As a target's defensive capacity increases (in terms of the number of defensive channels), the attacker is forced to allocate more weapons per attack, in turn reducing the lethality of those weapons that do penetrate. Similarly, an attacker forced

to use faster weapons may not be able to fly those weapons at very low altitude, and the weapons themselves may emit so much infrared radiation that the target enjoys earlier warning.

This section includes airborne surface-search radars, although some of them are intended primarily to detect submarines. This section does not include standard shipboard surface-search and navigational radars. They are described in the Antiaircraft Warfare section. Some of the radars listed are intended primarily to help enforce EEZ, particularly in the Third World. Such radars, because they can detect and locate small surface craft (such as those used by smugglers), have an important potential either for direct targeting or for directing other missile-bearing aircraft. In the Falklands War, for example, an Argentine Neptune with a long-range APS-20 radar reportedly directed Exocet-carrying Super Étendard fighters, which had only to pop up briefly to fire and could thus avoid extended exposure to British detection. The standard U.S. AEW radar (APS-120 series) has the same capability but is listed in this book under AAW because air-to-air detection is that radar's primary role.

Probably the most important current antiship-sensor development is inverse synthetic aperture radar (ISAR). An airborne synthetic aperture radar (SAR) achieves its very high resolution (sufficient for imaging) from the motion of the airplane along a straight and level course. High resolution would normally require a very large antenna. A conventional radar scans as it moves, so that by the time it has moved a significant distance, the radar is no longer looking at the same scene. In contrast, a SAR does not scan. Since it is constantly staring in the same direction, pulses emitted at any point along the SAR's path and received later on contribute to the overall radar picture. A SAR's effective aperture (antenna size) is the distance the radar travels while those pulses build up, the product of the aircraft's speed (along the straight flight path) and the period of time during which pulses build up in a coherent way (the integration time). The latter depends in part on the amount of memory built into the SAR system, since the radar has to remember earlier echoes to compare them with later ones, taken further along the flight path. A SAR can achieve very impressive resolution but can look only to the side. Targets are more often straight ahead.

ISAR solves this problem by using the motion of the target (roll, yaw, or pitch) rather than that of the airplane. The resulting image generally lacks the quality associated with SAR but may suffice for crude ship recognition and for attack assessment (comparison of before and after images). The radar may be able to measure target course relative to the radar, reassembling what amounts to a target silhouette; and crude recognition may be automated. In this form ISAR may be applicable to future antiship missiles.

The key is that the angular velocity of the target as a whole equates to different linear velocities (e.g., in ft/sec) at different distances from the distant radar. Each such linear velocity (in the direction of the radar) causes a doppler shift in reflected radar echoes. Thus different doppler shifts are associated with different distances from the line about which the target is moving (for example, its centerline in the case of rolling motion). The line about which the target moves becomes a reference line, and an image of distances can be built up. In the case of roll, with the radar abeam, a plan image of a ship results. Similarly, the doppler frequencies associated with the pitching of a ship give the heights of points along its length, so that a series of measurements by a radar pointing bow to stern gives a target silhouette. Since the target is unlikely to be either directly in line with the radar or directly abeam of it, the ISAR should be able to produce a nearly 3D image.

This section also includes infrared detectors. They fly on board all ASW aircraft and on board many attack aircraft; some are intended primarily to detect hot snorkel exhausts, and others are primarily for land attack. All have some capability to detect and image (and hence to help classify) surface targets; therefore, they are included here.

The central distinction in classifying weapons, whether they are attacking fixed or moving targets, is between point-attack

and area-attack weapons. Improved technology makes it possible for weapons to be delivered with extremely small errors (CEPs, or circular errors probable, of 10 ft or less are now quite common). Some analysts have, therefore, suggested that the future of munitions lies with relatively small numbers of essentially zero-CEP devices, some of them perhaps deliverable from extreme distances. However, the efficacy of such weapons depends in turn upon how well the targets can be located. Therefore, this section also includes some tactical reconnaissance systems. The ones listed should be taken as typical rather than comprehensive; but the reader should be aware that, no matter how precise the weapon, it cannot reach a valuable target unless that target can be located in the first place. That makes it difficult, for example, to attack individuals who may not be home when the missiles arrive to greet them.

The alternative is to cover a suspected target area with large numbers of relatively imprecise weapons. Area-attack has certainly been the approach in the past, and at present this approach is represented by bomblet-dispensing munitions such as the U.S. Rockeye and, presumably, also by fuel-air explosives. Area-attack is useful not only because targets may not be precisely located but also because the targets themselves may be spread out over a considerable area. For example, it may be impossible to fire a separate long-range weapon at each of numerous troops dug-in around a target area; however, area-attacks on the troops may kill many of them and may so demoralize the rest as to make them ineffective.

It is common, then, to distinguish between "dumb," "smart," and "brilliant" weapons. A "dumb" weapon is entirely unguided after release; all the intelligence in the system is concentrated in the launch vehicle, be that an airplane or a ship. A "smart" bomb attacks a target designated by the launcher, homing on some element of the target's signature picked out in advance or on a signature, such as a laser spot, imposed by the launch vehicle or by some cooperating platform. Finally, a "brilliant" weapon will choose its own target. No "brilliant" weapons are currently in service, but many analysts have suggested that these weapons are the future of guided munitions.

There are several major ground-target categories. In amphibious operations, it is essential to neutralize troops and coast-defense weapons (such as truck-borne antiship missiles) dug-in at the objective area. There is some hope that modern high-mobility amphibious forces can evade such fixed defenses altogether, although evasion may not be possible when geography clearly dictates the choice of landing zone. Generally, it will be important to disable opposing enemy air forces and air defenses. Once amphibious forces have landed, an enemy will try to counter them with mechanized troops, tanks, and perhaps attack helicopters. Thus, antiarmor/antivehicle weapons are extremely important. Naval forces may also be called upon to execute classical, deep air strikes, e.g., at enemy industrial targets, air bases, roads, highways, and bridges, as in Vietnam. Given sufficient lifting capacity, the naval air-to-ground arsenal is not so different from that available to the land-based tactical air force, and many of the weapons listed here are air force types.

The major problem in ground attack is that the targets (which may be both small and camouflaged) must be distinguished from considerable ground clutter and then must be designated to a bomb or other munition. The pilot's eye is likely to be more effective than any automated system, but the pilot may be subject to antiaircraft fire as the targets are chosen. The longer the pilot takes to decide, the more vulnerable the pilot is. In theory, a pilot can designate a target to a purely ballistic system. However, a bomb, rocket, or cannon shell that is unguided after launch will probably miss because of such random factors as windage between release and impact. The closer the pilot is to the ground at the time of release, the more accurate the delivery, but also the greater the danger to the airplane.

The next step, then, is to provide some sort of post-release guidance. A bomb can be made to home on a laser spot on the designated target, and the laser can be manipulated either by the pilot or by someone on the ground. An alternative is to

direct the bomb to home on some feature of the target as it is seen from the airplane, using either optical or infrared wavelengths, so that the pilot need not wait for the bomb to hit; but the target may have insufficient contrast for homing. In both cases, homing must be continuous after the bomb begins to approach its target, and experience shows that homing may be thrown off completely by the dust and debris thrown up by an earlier bomb, by clouds, or by smoke. If laser homing is used, an enemy who is aware of which laser wavelengths are in use may be able to provide alternative targets.

Moreover, the attacking pilot has to keep a laser on the target during the missile's flight, so must remain within the target area, and that is quite dangerous. However, few ground targets show sufficient contrast for autonomous television (electro-optical) homing.

A variation on these themes is to provide the missile with an optical or infrared seeker and a data link to the launch airplane. The missile can then be fired at a target that the pilot cannot see but that can be designated via the data link once the missile spots the target. The U.S. Navy developed just such a weapon, Condor (AGM-53); but the jam-resistant data link proved extremely expensive, and the project had to be abandoned. More recent (and less ambitious) data-link projects have, however, survived, as in the case of Walleye. As with laser designation, the data-linker must remain in a restricted air space and, thus, may itself be vulnerable to enemy attack. On the other hand, it is further from the enemy than it would have been had it fired a lock-on-before-launch missile. This situation is not very different from that of a Soviet submarine or surface ship firing an SS-N-3 or SS-N-12 antiship missile. Indeed, it is sometimes suggested that the latest Soviet air-launched antiship missiles incorporate data links that permit them to lock the missiles on after, rather than before, they are launched.

One other possibility that has recently arisen is inertial guidance: the pilot designates the target as a point in space, and the bomb or missile flies itself into that point, without reference to the ground. In principle, this is precisely what a long-range ballistic missile (which is, after all, a ground-attack weapon) does, but in this case over a much shorter distance and a much shorter time.

Another important near-term improvement is millimeter-wave (MMW) homing. Millimeter-length radiation is at the long-wave end of the infrared spectrum, short enough to provide some imaging, but long enough to cut through such natural obstacles as smoke. Millimeter-length radiation can also be generated by extremely high frequency radar techniques. There is some hope that MMW will make direct (fire-and-forget) homing on tanks and other vehicles possible. At present there is no really effective means of homing on such objects, unless they are generating considerable heat against a cool background. Most "brilliant" antiarmor submunitions (weapons intended to be carried within larger warheads) now under development in the United States seem to use some type of millimeter-wave homing. In the absence of such techniques, antiarmor munitions depend either on continuous guidance by the operator (e.g., wire guidance, as in the TOW missile) or on a percentage chance of hitting (as in bomblets).

Somewhat further in the future are imaging techniques using artificial intelligence (AI) to enable an incoming weapon to decide for itself which target to hit. These techniques are unlikely to end the story because, just like a human eye, a mechanical sensor can be misled by clever forms of camouflage and decoying. It is not at all clear, either, whether future "smart" or "brilliant" antiarmor weapons will be cheap enough to apply on a large scale.

All of these techniques are applicable to shells, and laser-guided artillery shells now exist.

For simplicity of reference, torpedoes are all included under ASW weapons, although in many cases torpedoes are intended for use against only surface targets. Similarly, antiship mines are listed separately in the Mine Warfare section. Guns are all

listed in the AAW section; in some cases their antiaircraft capability may be marginal.

RECONNAISSANCE SYSTEMS

Aircraft-Carried Sensors

UNITED STATES

◆ ATARS

The joint-service Advanced Tactical Air Reconnaissance System will be the first airborne reconnaissance system to replace film with electronic data storage (as currently used in satellites) so that information can be data-linked back to base while the ATARS platform is still airborne. Because there is no need to store large quantities of film, the system can fit in an RPV. Reportedly, the greatest technical challenge in the project is the very-high-data-rate digital recorder required.

The sensors will all, therefore, be electro-optical: as in TARPS (see below), 2 visual for daylight (low-altitude/wide field of view and medium altitude/stand-off) and 1 IR (night).

This program is air force led, and the first application will be to existing RF-4Cs. The initial navy application will be to the mid-range RPV (MR-RPV), and the marines will use ATARS on board F/A-18Ds. ATARS will also replace TARPS pods on board F-14Ds.

Bids were submitted in July 1987, and Control Data Corporation was chosen as manufacturer in May 1988. Initial flight tests, on an air force RF-4C, are scheduled for the fall of 1990. ATARS-equipped RPVs will also be used.

◆ TARPS

Tactical Air Reconnaissance Pods can be carried by F-14 and F/A-18 fighters. Currently, 2 F-14As in each carrier air wing are fitted to accept these pods, and 3 aircrew are trained to use TARPS. All new F-14Ds will be wired to accept TARPS.

TARPS replaces the specialized equipment built into such aircraft as the RF-8 and RA-5C and was bought as an alternative to a new specialized reconnaissance airplane, which would have been a modified F-4 Phantom (the marines did buy a specialized RF-4B). The pod is conceived primarily as a strike-planning and battle-damage-assessment system, and TARPS was widely used during the operations off Lebanon in 1983-84.

The pod carries 2 cameras (Fairchild KA-99 low-altitude panoramic, with 9-in focal length; and CAI KS-87B frame camera, with 12-in focal length) and an infrared line scanner (Honeywell AAD-5A, with both wide and narrow fields of view). Total weight is 1700 lb.

TARPS was developed by the Naval Air Development Center and is produced by the Naval Avionics Center. The system is to be replaced by the new ATARS.

The marines have not followed the same development path. Instead, they are developing an internal reconnaissance pallet for 2-seat F/A-18D fighters, about one-third of which will be wired to accept the pallet. Installation of the pallet requires removal of the internal 20-mm cannon of the F/A-18, and the pallet can accept any 2 of the 3 TARPS cameras.

◆ UPD-4/9

UPD-4 is a Goodyear SAR, used on Marine Corps RF-4Bs. When these aircraft retire, their F/A-18 successors will carry a podded UPD-9, similar to the air force UPD-8. UPD-9 adds a data link so that the radar image can be received on the ground before the airplane returns. Data-link range is about 200-250 nm; radar range is about 50 nm. The pod, which can be carried by the F/A-18D, weighs less than 1500 lb and is cooled by ram air. At least some of the new marine pods are repackaged UPD-4s. The pods are about the same size as the standard 330-gallon center-line fuel tank and weigh about 1500 lb each.

Production development of the pod began in July 1987; by that time the prototype had already flown on board an RF-4.

UAVs

This section has been renamed UAVs (unmanned air vehicles) instead of RPVs (remotely piloted vehicles) because many UAVs operate autonomously. The earlier designation is still widely used, even for autonomous craft.

CANADA

◆ CL-227 Sentinel

Engineering development of this small helicopter RPV began in 1977, with the first systems-test vehicle flying in 1980. In 1985 the Canadian government agreed to support the final development phase, so that fully militarized aircraft were available from late 1987 onward. CL-227 consists of a pair of turbine-driven contraprops with bodies above and below; guidance is based on a strapdown inertial sensor. Sentinel can fly at the end of a 200-m [655-ft] tether; powered by a Wankel engine, the prototype made its first flight on a tether on 25 August 1978. Most of the flight experience has been gathered with a slightly enlarged Phase 2 RPV powered by a 32-HP Williams International WR34-15-2 engine, which first flew untethered on 14 December 1981. The current Phase 3 version is slightly larger yet (details below).

The Sparton dwarf buoys (described in the ASW section) and their related seeder magazine were intended specifically for the Sentinel RPV. The magazine, 50 × 36 cm [30 kg], carries 20 miniature LOFAR omnidirectional buoys, or 4 DIFARs, or 4 SSQ-529 DICANCASS buoys. The DICANCASS transducer would be lowered into the water while the RPV hovered, functioning as a miniature dipping sonar.

Dimensions: rotor diameter 2.80 m [9 ft 2.25 in]; height, including landing gear 1.64 m [5 ft 4.5 in]; maximum take-off weight 190 kg [419 lb], including 88 kg [194 lb] payload (up to 54 kg [119 lb] fuel and up to 45 kg [99 lb] disposable payload).

Performance: maximum air speed 130 km/hr [84 kt], ceiling 3000 m [9840 ft], climb rate 3 m/sec at 1500 m [9.8 ft/sec at 4920 ft], endurance 4 hr at 1000 m [3280 ft].

The CL-227 program began in 1964 and was substantially reoriented in 1968. Customer flight trials began in 1980. The current \$60-million program, including production of 10 vehicles, is supported in part by the Canadian government (agreement announced 7 May 1985) and began in 1986. The first full production prototype flew on 20 November 1987.

The Canadair CL-227 Sentinel RPV. (Texas Instruments)

The NATO Group 11 demonstration planned for the summer of 1988 was canceled, but in August and September 1989 a CL-227 successfully flew 9 missions from the U.S. Army vessel *Jan Tide* off Point Mugu. The UAV used a real-time data link to direct it to find and intercept a target ship, and it used its own sensors to provide visual identification and target classification. At this time CL-227 was a candidate for the U.S. close-range RPV requirement.

◆ CL-289 (AN/USD-502)

A surveillance RPV designed initially for land use but proposed for the U.S. MR-RPV (see below), CL-289 was derived from CL-89, a joint Canadian-German project begun in 1961 and first flown in 1964. Production of CL-89 began in 1967, and as of 1987 more than 500 had been delivered to the British, German, French, and Italian armies. CL-289 was conceived as a corps-commander support-device, i.e., for area surveillance over ranges greater than those achieved by CL-89. CL-289 is a joint Canadian-German project; work began in July 1976, and France joined the program in March 1977. CL-289 first flew on 3 March 1980, and full-scale production began in 1987, initially for the French and German armies. The RPV is powered by a KHD T117 (240-lb thrust) turbojet. Speed is described as considerably more than that of CL-89, which achieves 400 kt. Dimensions: 1 ft 3 in × 11 ft 6.5 in (plus 3 ft 9.5 in booster); span is 4 ft 4 in.

GERMANY

◆ Geamos/Seamos

This Dornier private-venture helicopter UAV was announced early in 1989; the names indicate the mission (ground or maritime reconnaissance). It has an 80-km [44-nm] radius of action and can operate either autonomously or under remote control. It uses U.S. DASH (QH-50D) rotors and dynamic controls, with Dornier avionics, electronics, and system integration. The power plant is a 330-SHP Boeing T50-BO-12 turboshaft. The payload is supplied by LCTAR (Thomson-CSF). The GEAMOS UAV was successfully tested in August 1989. Dornier hopes to demonstrate the SEAMOS shipboard version in 1991.

◆ Submarine-Launched RPV

As of 1989, the German Navy is considering a submarine-launched RPV. Working with fast attack craft, it would provide both OTH target acquisition and target data relay. As of 1989, the tactical concept was being developed by the NATO Naval Armament Group. The planned technical demonstration had to be postponed by 2 years. CL-289 is the most likely candidate, but the group is also considering 2 U.S. models and the Dornier SEAMOS.

INTERNATIONAL

A NATO study group on RPVs for small ships was formed in December 1986 to establish a 2-year program to develop requirements because an earlier study (1985) had shown that there were no funded national programs for maritime-suitable RPVs. The U.S. Navy is chairing the group, which includes representatives of Canada, France, Italy, Spain, West Germany, and the United Kingdom. Four ship categories are involved: 500-ton fast patrol boats (as in the German Navy); corvettes; frigates; and 5000–8000-ton surface warships. RPVs had to be operable in 85% of weather conditions, which meant launch/recovery at: (figures for frigates, with FPBs in parentheses) pitch 4 (5) deg, roll 10 (15) deg, acceleration at the bow 9 (5) m/sec. The required radius of action was 35 nm for a fast patrol boat and 75 nm (100 nm desired) for a larger ship. Fuel had to be compatible with the host ship (JP-5 preferred), and the controlling data link had to be difficult to jam and to intercept.

Typical missions included

Early detection of an air threat along a known axis, using

ESM, focal planar array, IR search-and-track: endurance 1 hr, radius 40–60 nm.

OTH area reconnaissance/missile damage assessment, day/night imaging system: endurance 1 hr, radius 75–100 nm.

Gunfire-support targeting, day/night imaging plus laser range-finder/designator: endurance 3 hr, radius 30 nm.

EW, ESM, active/passive ECM, decoys: endurance 2 hr, radius 75–90 nm.

Communications Relay, 2 VHF/UHF radios back to back: endurance 3 hr, radius 80 nm.

ASW, sonobuoys and/or dipping sonar: endurance 3 hr, radius 60 nm.

Initially, the greatest interest was shown in vertical take-off RPVs such as the Canadair CL-227 Sentinel, the British Sprite, and the U.S. Pointer (now named Tracer). There was also a Dornier design study, SEAMOS.

As of mid-1988, Canadair was scheduled to demonstrate its CL-227 on board a frigate in September 1988. M. L. Aviation (Great Britain) was scheduled to demonstrate its Sprite RPV helicopter from a "Castle"-class OPV in November 1988, and there were tentative plans for a demonstration on board a German fast patrol boat. The Bell-Boeing Tracer tilt-rotor RPV was scheduled for demonstration on board a U.S. ship by the NATO group's December 1988 deadline.

ISRAEL

◆ Helstar

This helicopter UAV, using the rotors and transmission of the old U.S. Navy DASH (QH-50), was announced in the fall of 1989. In Israeli Navy service it will be carried by *Reshef*- and *Aliyah*-class fast attack boats. The latter already carry Kiowa and Dauphin helicopters. The only photograph thus far released shows Helstar with a FLIR ball and a belly radome, for 360-deg scan. IAI hopes to achieve a radar range of 40+ nm from Helstar. The power plant is a 420-SHP Allison 250C-20B. The rotor's

diameter is 20 ft, and height is 10 ft. Maximum take-off weight is 2450 lb (payload 450 lb, plus 900 lb of fuel, for 6-hr endurance). The unit cost is about \$4 million. Helstar first flew on 18 July 1990.

◆ Pioneer

The U.S. Navy bought this Israeli RPV to satisfy a requirement, stated in mid-1984, for a mini-RPV, for both the marines and for naval gunfire support (spotting). The RPV was probably based in part on experience with an Israeli RPV, Mastiff (a design predecessor of Pioneer), which was bought by the United States in January 1984 to support the marines in Lebanon. Mastiff was flown on board the helicopter carrier *Guam* on 26 March 1984. In July 1984 Secretary of the Navy John Lehman directed the Naval Air Systems Command to achieve a minimum operational capability as soon as possible, i.e., to buy an existing RPV. He was later credited with having accelerated the program by at least 2–3 years. The navy, therefore, opened the competition to any manufacturer that could participate in a fly-off by the spring of 1986, the winner to provide 3 years of technical-support services. Only Lockheed and Mazlat could be ready in time, and in 1985 Lockheed withdrew from the competition, leaving only the Mazlat Pioneer. Canadair, which demonstrated its CL-227 to the U.S. Navy in 1984, could not be ready in time. The navy bought 3 Pioneer systems in 1986 (2 shipboard and 1 Marine Corps, ordered 7 January 1986, with options for 2 more, exercised in February 1987), and 4 more in FY88. Successful tests during 1987 led to a decision to seek full-scale production under the FY89 program. In June 1988 the U.S. Navy ordered 4 more Pioneer systems, each including several RPVs. The ultimate navy requirement is 43 RPV systems, each consisting of 8 aircraft and a control unit.

The manufacturer, Mazlat, is a subsidiary of Tadiran/IAI, and the U.S. agent for Pioneer is AAI.

Pioneer was tested on board an LHA in June 1986 and became operational on board the battleship *Iowa* in December 1986 (installed June–December), carrying out reconnaissance over Central America. Pioneer was rocket-launched by the battleship and recovered in a net; the guidance transmitter was in a radome on the second funnel of the ship. Teething troubles caused the loss of 4 of the first 5, 3 to crashes on the ship and 1 to engine failure. The 2 major problems in the RPV itself were insufficient data-link range and an unreliable engine. The required 100-nm range could not be met, but range did increase from 50–67 km [32–43 nm] during tests. A ground-based version could be controlled at 165 km [107 nm], presumably by using a taller antenna.

Pioneer. (AAI)

Pioneer control antenna (at the forward end of the funnel, in the radome), USS *Iowa*, 1988. (A. Raven)

Pioneer is powered by a 26-HP Sachs gasoline engine, and the U.S. Navy wants to replace this engine with one running on JP-5, the standard (and considerably safer) navy-wide gas-turbine fuel. The sensor is a television camera.

In April 1988 it was reported that Pioneers had flown without mishap for 207 hr (70 sorties) from the battleship *Iowa*, during a Mediterranean and Gulf of Oman deployment.

Dimensions: span 5.15 m $\times$ 4.26 m length overall $\times$ 1 m height [16 ft 10.75 in $\times$ 13 ft 11.75 in $\times$ 3 ft 3.25 in]; maximum payload 45 kg [99 lb]; maximum take-off weight 195 kg [430 lb]. Maximum level speed is 48–70 kt; ceiling is 4575 m [15,000 ft], radius 100 nm, and endurance 6–9 hr. Fuel capacity is 11.1 U.S. gallons.

In June 1988 Mazlat announced that it was designing a VTOL RPV for small ships but would not undertake full-scale development until finding either a foreign partner or a launch customer.

In mid-1989 Mazlat was reportedly working on an improved Pioneer, called Searcher, which would be closer to the U.S. SR-UAV requirement. Maximum take-off weight is 700 lb, and endurance is 10½ hr. Searcher is to carry a day/night television sensor and a laser designator; the avionics used in it are compatible with those of the 430-lb Pioneer and the 1000-lb Impact.

◆ Impact

IAI's Impact is a competitor for the U.S. SR-UAV program. It has twin propellers (push-pull configuration) and an underbody sensor. This vehicle is powered by 2 TCM Thrust 45-HP engines and cruises at 60 kt; maximum speed is 110 kt. Rate of climb is 1000 ft/min, and service ceiling is 18,000 ft. Endurance is up to 12 hr. Gross weight is 1250 lb, including 150 lb of useful load and 200 lb of fuel. Wing span is 26 ft, length is 20 ft, and height is 6 ft. Impact has been under operational evaluation since 1988. It is a proposed competitor for the U.S. UAV-SR requirement, offered by a consortium of IAI and TRW Defense Systems Group. As part of this package, IAI is offering a stabilized modular optronics platform, MOSP (multimission optronics stabilized payload). An improved miniaturized version, IMOSP, is being developed for the U.S. Navy under the Nunn program.

The SR-UAV version, offered jointly with TRW, is JIMPACS (Joint Improved Multimission Payload Aerial Surveillance Combat Survivable System). The system as a whole includes 10 aircraft. Span in this version is 26.2–29.2 ft, maximum take-off weight is 1250 lb, payload is up to 250 lb, maximum speed is 120 kt, and endurance (with a 200-lb load) is 12 hr. JIMPACS will be launched from a runway or a zero-length launcher (using a rocket booster); recovery is via an arrested landing, with a parachute for emergency recovery.

IAI's Impact, a competitor for the U.S. SR-UAV program, is shown on display at the Paris Air Show, 1989. (Author)

ITALY

◆ Mirach

Mirach is a family of RPVs manufactured by the Meteor company. The propeller-driven Mirach 20 (carrying either an IR sensor, with a range of 32 km, or a radar) was proposed for the U.S. Navy's short-range RPV (Pioneer was chosen). Mirach 20 was displayed at the Italian naval exhibition, *Mostra Navale*, in 1986. Mirach 20 is powered by a 26-HP Herbrandson Dyad 2-stroke flat-twin engine, and the airframe is built mainly of Kevlar. Dimensions: span 3.83 m, length 3.62 m [12.5 $\times$ 11.9 ft]; weight 95 kg empty, 197 kg max at launch [210/434 lb]; maximum internal combat load 20 kg [44 lb]. Maximum level speed is 108 kt, and maximum endurance is 3 hr. Maximum rate of climb at 1000 m is 240 m/sec [3280 ft: 787 ft/sec].

There is also a larger Mirach 100, proposed for the MR-RPV, powered by a 400-lb-thrust NPT 401 turbojet. Mirach 100 is currently in production, over 150 having been built by early 1987. Users include Libya and Iraq, so that Mirach may well have seen combat service. Mirach is built under license in Argentina as MQ-2 (Bigua). In the U.S. MR-RPV contest, Mirach was offered with a Pacific Aerosystems Mizar data link. Dimensions: 1.8 m span $\times$ 3.94 m [71 $\times$ 155 in]; weight 210 kg empty, 310 kg loaded, internal combat load 70 kg [463/683/154 lb]; maximum level speed 458 kt (Mach 0.92); maximum endurance 1 hr. The normal 1-way penetration range is 485 nm. Mirach can be preprogrammed, e.g., to loiter over a battle area.

UNITED KINGDOM

◆ Raven 200

Flight Refueling, Ltd.'s ultra-light UAV, offered for U.S. evaluation, was derived from the earlier Raven 1. It is 33% larger (60 kg [132 lb] rather than 15 kg [33 lb] weight). Endurance is 4 hr, and radius is 40 km [22 nm]. Raven is essentially a sophisticated model airplane, launched from a rubber-band (bungee) catapult. Span is 3.6 m [142 in], and length is 2.6 m [102 in]; a 12-HP 2-stroke engine drives it at 35–90 kt, with a ceiling of 10,000 ft. Raven either is flown by a remote pilot (who orders heading and altitude) or can be programmed to fly over an area of interest. It can carry day or night sensors, transmitting their imagery back to a ground station. All of the ground equipment can be carried by a single Land Rover.

◆ Sprite

M.L. Aviation demonstrated this helicopter RPV to the U.S. DoD in May 1985. In British tests, Sprite has successfully landed on a rolling platform in gusty winds of up to 20 kt. Overall weight is 88 lb [40 kg], and endurance (depending on payload) is over 2 hr. Rotor diameter 1.6 m, body diameter 0.65 m [5 ft 3 in/2 ft 1.5 in]. Payload is 12 kg, typically 6 kg of fuel and 6 kg of sensors [26/13/13 lb]. The power plant is two 6-BHP Kolbo D238 2-cycle gasoline engines, or two 7-BHP Piper 2/80 2-cycle gasoline engines. Cruise speed is 60 kt, and climb rate (at 45 kt) is 1200 ft/min. Normal operating altitude is 250–500 m, ceiling 3000 m [820–1640, 9800 ft].

The typical payload consists of a thermal imager, a CCD color television camera, or a monochrome LLLTV. These sensors can be steered through 110 deg in elevation, and they can be scanned in bearing by spinning the vehicle on its axis (a capability that is not affected by flight direction). The manufacturer hopes that a future version will be programmable for sector scanning.

Sprite's radar cross section, currently about 0.5 m², is to be reduced to 0.3 in a proposed production version (a cowling will smooth its shape). The manufacturer claims that this vehicle cannot be seen beyond 800 m. The acoustic signature is reduced by venting exhaust gases from the top of the vehicle, to be mixed with cold air in the rotor down wash.

Sprite was developed as a private venture and first flew in January 1983. As of 1989, Sprite was 1 of 2 remotely piloted helicopters (RPH) scheduled for evaluation by the U.S. military,

the other being the Canadian CL-227. The U.S. Navy is considering Sprite for small-ship use, 1 role being communications relay (the "poor man's satellite"). The present variant is an advanced prototype rather than a production version.

UNITED STATES

◆ RPV Master Plan

U.S. UAV development is now being conducted by a JPO (Joint Project Office) established in mid-1988. Congress demanded that the different services' UAV programs be merged after the army's Aquila (MQM-105) program was abandoned in 1987, after 14 yr (and \$1 billion). Congress, therefore, froze FY88 money for nonlethal UAVs pending establishment of a joint program. A JPO was established within NAVAIR, attached to the joint cruise missile office. The JPO produced 2 class requirements: short range (200 km beyond the forward line of own troops [FLOT] and mid-range (JSCAMPS): SR-UAV and MR-UAV. Two more were later established: close-range (over the hill) and long endurance.

A UAV Master Plan submitted to Congress in June 1988 called for 3 categories: short range, medium range, and long endurance. RFPs for the baseline family of RPVs are due in 1990, with evaluation and testing to begin in FY92. There was some fear of duplication of effort between the UAVs and standoff (but loiter) munitions; Tacit Rainbow falls into the gray area between a classical UAV and a standoff missile.

There has been some concern, both in Congress and in DoD, that the delay involved in restarting the program after FY88-89 funds were frozen (in August 1988) would be excessive. This freeze was not the first restructuring of the program. Secretary of the Navy John Lehman significantly accelerated the navy program late in FY85, and in FY87 Congress demanded increased use of RPVs, probably as a reaction to the loss of an airplane and its crew during the Libyan raid. Secretary Lehman's directive was to use, wherever possible, existing equipment. The navy requirement was broken down into short range (Pioneer), medium range (MR-RPV), and long range (high altitude, in combination with the army and DARPA). A reconnaissance version of the existing BQM-74C Chukar target drone was tested during FY86.

The U.S. medium-range UAV is to be designated BQM-129. It is now known as JSCAMPS (Joint Service Common Airframe Multiple Purpose System). As of about March 1989, projected procurement (during FY89-94) was 775, including 230 (150 air force and 80 navy) reconnaissance aircraft equipped with ATARS, 120 non-ATARS reconnaissance aircraft, and 425 targets. Teledyne won the medium-range competition with its Model 350, defeating Northrop and Martin Marietta/Beech.

The version of ATARS to be carried by JSCAMPS will be more compact than that planned for tactical aircraft. The latter carry both electro-optical cameras and an infrared line scanner; the RPV will be designed to carry one or the other.

Early in 1989 the JPO split the short-range requirement in 2, creating a new close-range (CR-UAV) requirement. The SR-UAV is to operate 150 km beyond the FLOT, with 300 km desired. Minimum payload volume is 500 in³, the vehicle to execute 2 separate missions simultaneously (choosing among EW, ELINT, SIGINT, other forms of intelligence collection, and communications relay).

The SR-UAV RFP was issued in March 1989 after industry had objected to an earlier draft. Planned procurement (FY89-94) is 4 prototypes plus 38 systems, each including 8 air vehicles, with a mixture of payloads. Estimated unit cost of a system is \$500-600M. Most are to be bought during FY93-94.

Five offers were submitted by May 1989: GEC with Phoenix; IBM with Heron UAV and MIZAR avionics; IAI/TRW with the Impact vehicle and JIMPACS (Joint Improved Multimission Payload Aerial Surveillance Combat Survivable System); the McDonnell Douglas/DSC Skyeye R4E-50; and the Leading Sys-

tems Amber 450B. In mid-September Phase I contracts were awarded to McDonnell Douglas/DSC and IAI/TRW for, respectively, \$43.1 and \$18.5 million. Evaluation of the 2 alternatives should be conducted between March and October 1991, with a prime contract award early in 1992.

Of the UAVs listed, only Skyeye is currently operational, having entered service with Egypt at the end of 1988. It has also been bought by several other countries. It is also the only U.S.-designed short-range UAV currently under active development. R4E-50 is larger than earlier versions and can carry a combined SIGINT/imaging payload. It is powered by a Teledyne Continental rotary engine and uses a parafoil recovery system (25 kt controlled approach, with a soft landing; it can make a second approach if the first must be aborted).

Current plans call for 3 versions of SR-UAV: Blocks 0, 1, and 2. Block 0 is a baseline system for the army and marines, with a day/night imaging payload. Block 1 is adapted for naval use. Block 2 is to be an improved version, with automatic track/search features, greater survivability, and an engine burning a heavy fuel such as JP-5. Reportedly, the main issue in Block 1 is shipboard handling (which proved difficult with Pioneer); it is estimated that the vehicle itself will account for only 10-15% of the overall system cost. That makes a VTOL such as the Bell Pointer attractive for Block 1. However, to choose such a vehicle would be to reject the congressional desire for a high degree of commonality among all versions of the RPV.

As of early 1989, 36 Pioneers were on hand, with 28 more scheduled for delivery during 1989. Pioneer, originally a navy system, is to replace the army's more expensive Aquila. As of early 1989, 8 Aquilas were on hand, with 8 more scheduled for delivery during the year.

The close-range UAV is defined by a range of 30 km [16.4 nm], an endurance of 1-6 hr, and a speed of 100 kt; it is to be particularly simple to operate. The different services have very different roles in mind. The navy seeks a "flying crow's nest" for small warships; the army and marines want a "view over the next hill"; the air force wants base security and the ability to assess postattack damage to its own airfields. The JPO is conducting 3 Foreign Weapons Evaluations (FWEs) in this category: the CL-227, Sprite, and the Raven 200. It is also considering the Sandia Labs AROD (Airborne Remote Observation Device), which is being evaluated by the marines, and infantry-portable UAVs. As of early 1989, the marines had tested one low-cost device, the Aero-Vironment Pointer. The marines and the army have bought a longer-range very low cost vehicle, the Brandebury Exdrone (Expendable Drone), which has a range of 565 miles and a 7-hr endurance.

A Mission Need Statement (MNS) for the CR-UAV was scheduled for completion early in 1990, with contract award scheduled for FY92, and production and testing for FY94.

Both the SR-UAV and the CR-UAV may carry the Israeli-developed IMOSP (Improved Multi-Optronic Stabilized Platform); it integrates a laser designator with either a FLIR or an electro-optical sensor.

At the other end of the scale, an RFP for a long-endurance vehicle is expected during FY91. The only long-endurance RPV in current U.S. service is the Leading Systems Amber, 6 of which were on hand early in 1989. Four more were delivered during 1989. This figure covers all the services, whose requirements for (and definitions of) high endurance vary. For example, the army's concept of a long-endurance RPV or UAV calls for an endurance of about 36 hr and for operation out to about 300-km range. On 7-8 June 1988 an Amber set what its manufacturer called a world record for UAV endurance by remaining in the air for 38 hr and 27 min. This is still far short of the several days' endurance that a useful long-loiter naval UAV would require. The Amber payload is code-named Skydancer.

As of 1989, full-scale development of the E-UAV was expected in FY93. Competitors probably included an unmanned version of the E-Systems/Garret/Grob Egrett, now being developed for the West German government.

◆ AAV

Martin Marietta's Autonomous Air Vehicle (AAV) was developed for DARPA. AAV is primarily an experiment to see whether enough intelligence could be built into an unmanned vehicle for it to find hidden targets (using a FLIR and a millimeter-wave radar), attack them with smart submunitions, evaluate damage, and reattack if necessary. The end product was a captive flight in October 1989, after a 4-month program.

AAV was, then, primarily an exercise in image processing. Martin Marietta hoped that the vehicle's image of an area could be scanned automatically to show the places most likely to contain targets, e.g., trees in which tanks may take cover. The AAV would loiter near such areas, waiting until targets appeared; it could also seek out soft secondary targets such as aircraft on airfields. The loiter capability would tend to deter an enemy from unmasking its force, i.e., from moving, just as Tacit Rainbow is intended to deter an enemy from turning on its radar. Even if it did not attack directly, the loitering smart AAV could provide such a deterrent when operating in a reconnaissance mode since its information could cue attacks. The original impetus was the need to attack strategic relocatable targets, such as mobile ballistic missiles, but AAV has a major tactical value.

For Martin Marietta, the key to AAV is the company's Geometric Arithmetic Parallel Processor (GAPP), which can analyze thousands of pixels simultaneously. On a terrain board it was able to recognize targets in less than 0.2 sec, compared to several minutes for a conventional serial computer working pixel by pixel. GAPP was developed originally for night-vision systems.

Texas Instruments has a competing development-and-demonstration contract.

◆ Amber

This long-endurance reconnaissance RPV was developed as a classified program by DARPA. Amber is propeller-driven (pusher engine), and the fuselage's length can range from 13 to nearly 20 ft (payload volume 5–15 ft³, capacity 150–300 lb). It was announced in May 1988 that the U.S. Navy planned to buy 96 Ambers, which are suited to ship or ground launch, for radio relay, surveillance, and signals intelligence. At that time 10 had been turned over to the navy. Operational trials were scheduled for late 1989, and the system could become operational in 1990.

As of early 1988, Amber had flown continuously for 31 hr, at altitudes of up to 23,000 ft. In the basic high-altitude Amber 1 configuration (450A45), the power plant is a 65-HP pusher (KH-800) engine, length is 14.3 ft, wing span is 28.4 ft, and gross take-off weight is 750 lb (empty weight 280 lb). Speed is 250–300 kt. Two alternative payloads are being developed: one for radio relay, the other with an electro-optical sensor (as in Pioneer) and a signals intelligence package.

The manufacturer, Leading Systems, was formed in 1983 specifically to develop a high-tech, high-performance UAV. The company is currently producing 10 "maturation" Ambers to test payloads and operational concepts. Leading Systems is currently working on an Amber IV, with a 19-m (62.3-ft) span and a 65-HP KH-800T liquid-cooled 4-cylinder engine. The company is developing a KH-1200TD 3-cylinder 2-stroke diesel, with opposed pistons to reduce vibration, as its next-generation power plant.

As of 1990, 1 Amber system (6 UAVs) had been delivered, but the vehicles were all in storage.

Amber was conceived as a successor to the air force's manned TR-1 and is separate from the HALE program of the Naval Air Development Center.

◆ Condor

Boeing Advanced Systems built this very long endurance UAV for DARPA. Condor was rolled out late in March 1986 but did not fly until October 1988. Delays were caused by difficulties with propulsion, as well as a ground-handling accident, which

The Condor high-altitude long-endurance UAV. (Boeing)

presumably resulted from the light weight (hence flimsiness) of the very long span vehicle. Condor is the air element of the DARPA Fennel program, reportedly designed to carry a large-aperture active-array radar, in support of air defense against cruise missiles. Boeing is seeking support for other missions such as ESM and drug interdiction. To achieve extremely long endurance, Condor uses a very light all-composite structure (its wing weighs only 2 lb/ft²), a sailplanelike very high aspect ratio wing (200-ft span, aspect ratio 36.7:1), and low-powered engines (two 170-HP liquid-cooled turbo-supercharged Teledyne Continental engines, driving 16-ft propellers). It takes off from a dolly and underwing outriggers and lands on a centerline skid. Control is fly-by-wire, presumably to reduce flight loads on the lightweight structure.

Condor has demonstrated an endurance of 60 hr and has reached 67,028 ft.

Early in 1990 DARPA announced an experiment, planned for 1991, to demonstrate the use of a long-endurance UAV, such as Condor, to support submarine AAW. The UAV would act as the system radar platform, and it would communicate with the submarine by means of a 2-way blue-green laser. In theory, this sort of system would permit a submarine, submerged in the Norwegian Sea, to ambush Soviet bombers flying south to attack a carrier battle group. (In practice the bombers might well fly elsewhere, and the blue-green laser uplink might be less than fully covert.)

◆ HALE Projects

HALE is an acronym for High Altitude Long Endurance, and there are persistent reports of U.S. Navy interest in such devices, Amber (above) being a case in point. HALE reconnaissance vehicles were successfully used in Vietnam, and the new technologies of very lightweight aircraft construction and also of lightweight sensors make HALE vehicles quite attractive. The current definition of long endurance seems to be about a week, so that a few HALE could support a deployed surface action group without requiring integrated launch-and-recovery facilities. The current HALE program is described as an investigation of a large unmanned aircraft of extremely long endurance.

In December 1986 the Naval Air Development Center issued an RFP for a HALE for wide-area surveillance and OTH-T; responses were due by 6 February 1987. Requirements included an endurance of 120 hr at a cruising speed of 116–161 kt, and a service ceiling of 65,000–90,000 ft. The required payload was 7500 lb, and wingspan could exceed 61 ft. The RPVs described here are generic HALEs and were not specific responses to this

RFP. They indicate the sort of capabilities that are now available.

In 1983 Lockheed-California announced a twin-engine HALE powered by 2 turbofan/turboshaft engines (driving 14.3-m-diameter propellers, which would be locked for take-off), with a wingspan of 84.1 m. Endurance was 24 hr at 27,400 m.

About 1985 Teledyne Ryan announced Spirit, with an endurance of 80 hr at an altitude of 15,850 m to 160 hr at an altitude of 6100 m. Span was 85 ft and overall length about 40 ft (depending on payload); height at the tail was 14 ft (propeller diameter 20 ft). Weight was 4500 lb, and payload 300–1200 lb (depending in part on fuel load, which could be as much as about 900 lb). Cruising speed was 130 kt, and operating altitude 52,000 ft (absolute ceiling 75,000 ft). The power plant was a single flat-6 pusher engine. Spirit probably flew in 1986.

At about this time, too, E-Systems tested L450F, based on a Schweitzer sailplane and powered by a Pratt & Whitney PT6A engine.

The first high-endurance UAV was apparently the Teledyne-Ryan Compass Arrow (AQM-91A), used for reconnaissance during Vietnam (and capable of 24-hr endurance at 50,000 ft). Surviving examples were placed in storage in 1973. NSA and the Air Force began Compass Cope, effectively an unmanned U-2, in 1972 (55,000 ft, 30 hr); Boeing won the competition, but the program ended in July 1977. At about this time the Naval Air Development Center began its own HALE program, HISPOT (high surveillance platform for OTH targeting); contracts went to Teledyne-Ryan and, in 1987, to Boeing and Northrop (reportedly for a stealthy flying wing). DARPA began its own UAV program, Teal Rain, in the early 1980s, with contracts to Leading Systems (Amber) and to Boeing (Condor).

◆ MR-RPV (JSCAMPS)

The RFP for a medium-range RPV with a target variant was issued in August 1986, and 1 of 2 finalists was to be chosen late in 1988, with production to begin in 1989. The program was restructured as a navy–air force program in 1988, new RFPs being scheduled for April of that year. At that time the navy planned to buy 31 mid-range systems, each including 5–8 RPVs. Funds were frozen in March 1988, pending creation of a joint-service RPV office, to comply with a congressional directive. Industry meetings were held in August 1988 to discuss the restructured program, and at that time it was not clear just when money would be available or just how well the program would be supported; reportedly, there was some official skepticism about the value of such long-range RPVs. The program was renamed JSCAMPS (Joint-Service Common-Airframe Multiple-Purpose System). The new multiple-purpose designator covers alternative use as a target drone. The new request for proposals was issued by the Naval Air Systems Command on 28 June 1988; proposals were due 60 days later.

As of 1986, the specified operating radius of the MR-RPV was 350 nm. Other reported requirements were 2-hr endurance with a 250-lb payload, a speed of at least Mach 0.90, ceiling of at least 40,000 ft, and maximum weight of 2000 lb. The baseline missions were:

- Air launch from an A-6E/G, to fly over an airfield 350 nm away, determining the type, number, and location of aircraft there. The notional field is assumed to be defended by ZSU-23 cannon, with SA-6 and SA-9 missiles nearby. Image data must be available to the battle-group commander within 2 hr. The RPV data link might be jammed in the target area. The RPV would be recovered from the water by helicopters, or directly by a destroyer with a landing device.
- Deck launch by a destroyer, to locate a 3-ship surface action group about 175 nm (accuracy of location assumed to be 15 nm) away, finding type, course, and speed of each enemy ship. Target data would be transmitted to friendly forces, and the RPV would remain in the target area to conduct damage assessment. The RPV would be recovered from the water.

An artist's concept of an F/A-18 fighter carrying 2 BQM-145A (Ryan Model 350) medium-range UAVs. (Teledyne Ryan)

- Ground launch by a marine field unit, to provide images for strike planning against 3 widely separated, defended targets (e.g., bridges, fuel-storage areas, truck/tank parks), 150 nm from the launcher; total flight would be 450 nm. A similar air force mission would involve a target 350 nm away, data to be transmitted in real-time by data link (see ATARS above).

- Air launch by an RF-4C or F-16, for the 350-nm mission.

The MR-RPV ground station must be compatible with that used by the shorter-range Pioneer, which the new RPV will complement.

The original competitors included the Canadair CL-289, the Meteor Mirach (see above), a Martin Marietta/Beechcraft RPV based on the BQM-126, the Northrop NV-144, and the Teledyne-Ryan Model 324 Scarab.

In August 1988 Ryan displayed Model 350, a candidate for the reopened MR-RPV competition, based on Model 324. It is 44 in shorter than Scarab, with an overall length of 16.3 ft and an 11-ft wingspan, and with a weight of 1400–1800 lb. The proof-of-concept prototype is powered by a Teledyne CAE 373-8C (970-lb thrust) engine, and the airframe is built entirely of fiberglass-epoxy composites. Estimated cruising radius is 450 nm. Maximum speed is Mach 0.91, and ceiling is 45,000 ft. Carrying a 307-lb payload, Model 350 weighs 1825 lb and has a cruising endurance of 2.5 hr and a range of 1000 miles. The Model 350 prototype flew for the first time on 22 October 1988, being launched by an F-4C at 15,000 ft. The flight lasted half an hour, the RPV reaching 27,500 ft and Mach 0.75. It was recovered by parachute.

Prototype contracts were awarded to Martin Marietta and Northrop in September 1987 for a 14-month prototype construction phase. In 1989 Teledyne-Ryan won the competition for the restructured program with its Model 350, now designated BQM-145A.

Current (1990) characteristics: span 126 in, length 216 in, maximum weight 1910 lb, cruising range 700 nm.

◆ Cypher

This Sikorsky UAV was announced in June 1990; a smaller proof-of-concept vehicle flew in July 1988. Cypher employs a ducted coaxial (advancing blade) rotor; the duct adds lift to that generated directly by the blades. A version currently under development will have a 130-lb payload (total weight 325 lb), a 65-HP engine, a cruising speed of 80 kt, an endurance of 3–4 hr, and a ceiling of 8000 ft. Dimensions: diameter 5.75 ft, height 1.80 ft. The proof-of-concept vehicle weighed 43 lb and had a 4-HP motor; it was 5 ft in diameter.

Cypher is being developed as a potential SR-UAV, and a version is being built to meet a current U.S. Army Laboratory Command requirement for a target-acquisition system, to view targets up to 20 km [22,000 yd] from a battalion-level command post. The company hopes to sell a naval version, arguing that its small footprint and vertical takeoff and landing peculiarly suit it for naval operations. Sikorsky also argues that the shroud

Sikorsky's proof-of-concept ducted-fan vehicle. (Sikorsky Aircraft)

An artist's concept of a naval version of the Sikorsky Cypher UAV. (Sikorsky Aircraft)

surrounding the propeller should make Cypher safer than a conventional UAV helicopter.

◆ Tracer (formerly Pointer)

Bell-Boeing's tilt-rotor RPV is essentially a miniature V-22 Osprey. Pointer flew for the first time in 1988. The short-range version has a maximum speed of 160 kt and can loiter at 70 kt; ceiling is 25,000 ft and range is 220 nm (endurance 5 hr). Dimensions: 13 ft 5 in length, rotor diameter 7 ft 9 in; empty weight 395 lb (655 lb loaded, including 160 lb of fuel and 100 lb of sensors). The power plant is a 95-SHP Williams International turboshaft.

◆ Skyeye

Skyeye is 1 of the 2 alternatives for the U.S. SR-UAV requirement. It is based on, but not identical to, the existing R4E-50: span has been increased from 20–24 ft, maximum launch weight from 730 to at least 1000 lb, and propeller diameter from 0.99 to 1.22 m. There will also be a new engine more powerful than the original 46-HP Teledyne Continental GR-18. The configuration is twin booms, a fuselage pod, and a pusher propeller. Cruise speed is 100+ mph, and endurance is 8+ hr. Skyeye is catapult-launched and parafoil-recovered (descent speed is 25 kt).

Skyeye lost to IAI in a 1985 U.S. Navy competition because a test model was not available in time for a China Lake flyoff.

AIRBORNE SENSORS

CANADA

◆ APS-503

Band: X (9.2–9.4 GHz) **Beam:** 4×5 deg

Peak Power: 50 kW **Gain:** 30 dB

Pulse Width: 0.5 microsec **PRF:** 400

Scan Rate: 30 rpm **Antenna Dimensions:** 24×18 in

Antenna Weight: total weight 45 kg [100 lb]

APS-503 is the sea-search radar of Canadian Sea King helicopters and is manufactured by Eaton and by Litton of Canada. The antenna is stabilized in pitch and roll and can be tilted through 8 deg up or down. The display is a B-scope.

LASR-2 is a commercial version with twice the power (100 kW peak), 2 pulse widths, 4 alternative PRFs, and 3 alternative scan rates. LASR-2 is broadly comparable to the APS-504.

◆ APS-504/APS-140

Band: X (8.9–9.4 GHz) **Beam:** 2.3×5 deg

Peak Power: 100 kW **Pulse Width:** (i) 0.5 (ii) 2.4 microsec

PRF: 1600, 1200, 400, 200 pps (range scales 20, 50, 100, 250 nm)

Scan Rate: 30 or 12 rpm (or 72 deg/sec sector scan)

Antenna Dimensions: 112×33 cm (stabilized)

Antenna Weight: under 72 kg total

APS-504 is the maritime-surveillance radar developed from APS-503 by Eaton and by Litton of Canada. The (V)3 version incorporates a scan converter so that its video can be displayed on a standard 875-line high-resolution television, and so that it can be recorded by a standard television cassette recorder. It is stabilized in pitch and roll, and it can operate in variable-width sector-scan mode.

Two Israeli Westwind 1124N maritime-reconnaissance aircraft show their APS-504(V)2 nose radars. All markings have been blacked out by the censor. (Embassy of Israel)

The basic version is (V)2; (V)3 has digital processing and a high-definition raster display. The (V)5 version is a pulse-compression radar with a TWT transmitter (8-kW peak power). Typical maximum range is 370 km. In 1987 Litton Canada received contracts for a (V)5 upgrade, which could be used on board Canadian S-2 Trackers. As of 1989, these aircraft are to be retired, but the radar is presumably a candidate to upgrade the many Trackers still in service elsewhere.

APS-504 is standard in Fokker maritime-patrol aircraft, which are operated by Angola, the Netherlands, Peru, the Philippines, Spain, and Thailand. Other users: Australia (GAF Searchmaster L), China (Harbin Y-8), Egypt (Navy Beech 1900), Iceland (Coast Guard Twin Otter), Indonesia (GAF Searchmaster L), Nigeria (Twin Otter), Thailand (Grumman S-2), and the United States (Customs Service GAF Nomad, Navy Beech 1900 for range safety).

The Litton APS-140(V) is a derivative of APS-504, incorporating coherent TWT, pulse compression, frequency agility, and scan-to-scan integration. The IRIS reconnaissance radar is a synthetic-aperture derivative; as of 1989, 6 were in service, with 3 more in production. Imagery is stored on board the aircraft, down-linked as needed. IRIS can operate in either wide-swath (18×18 -m resolution) or high-resolution (3×3 -m resolution) modes.

◆ LN-66

See shipboard radars and fire-control systems (under Antiaircraft Warfare section).

◆ ASP

Computing Devices Co. is conducting full-scale engineering development of an Airborne Signal Processor (ASP) for an SAR planned for Canadian CP-140 Aurora maritime-patrol aircraft.

FRANCE

◆ DRAA-2A

Band: X **Pulse Width:** (i) 0.5 (ii) 2 microsec

PRF: (i) 1300 (ii) 400 pps

Scan Rate: 6 or 8 rpm (provision for 30-deg sector scan)

The stabilized radar of the Alizé carrier-based ASW aircraft and of the Atlantique Mk 1 (DRAA-2B) has a maximum instrumented range of 60 or 200 nm (reflected in PRFs above). This radar is being superseded by IGUANE.

Although this radar is principally a means of detecting surface ships and snorkels, DRAA-2A can also function as a low-altitude AEW set, like the British Searchwater and the U.S. APS-20 (which, after all, was originally conceived as an AEW set). Within a French battle group, the combination of this radar and the shipboard higher-altitude sets should give effective radar early-warning out to a radius of about 100–150 nm.

Many details are not available, but the first prototype Alizés had U.S.-supplied APS-33s, which presumably approximated DRAA-2A's dimensions and performance. APS-33 was intended for large ASW aircraft such as the Neptune. APS-33 operated in X-band and had a 3.6-deg fan beam and, with 52 kW peak power (pulse widths 0.5 and 5 microsec, PRFs 800 and 200), could detect a surfaced submarine at 65 nm and a snorkel at 20 nm. Maximum range was 200 nm, minimum 200 yd.

A 1957 proposal to equip some Alizés with APS-20 radars for dedicated AEW was rejected. Presumably, a combination of separate AEW and ASW aircraft would have displaced so many strike aircraft that the small French carriers would no longer have been viable.

◆ Agave

The multimode X-band monopulse radar of the Super Étendard strike fighter is used to target Exocet antiship missiles, among other weapons. Scan limits are 140×60 deg, and the radar can detect an airplane at 18–28 km or a patrol boat at 40–55 km. In the search mode, the radar scans over 140 deg horizontally, and over 6–12 deg vertically, the position of the horizontal bar being selectable through 60 deg up or down. Typically, vertical cover is limited to a single 6-deg bar to reject low-altitude clutter; at higher elevation angles, 2 bars (12 deg) are used because the single narrow bar may miss a fast target. In the autotrack (monopulse) mode, the radar can transmit data either to a missile or to a HUD. Range gates can be set at 5–85 nm.

Agave is a 1-operator radar, and its controls (antenna elevation, bearing and range markers, lock-on for autotrack) are all

on a single hand grip. The antenna is an inverted Cassegrain. Total weight is 65 kg.

Agave was proposed in 1974, derived from the earlier RH 370 helicopter radar. Passing its trials in 1975, Agave entered service in 1978. Over 170 had been ordered by 1986. They have been installed on Jaguar, Mirage F1, and Mirage 50 aircraft. The Jaguar version uses a raster scan display rather than the usual PPI. Agave is to be replaced by the new Anemone radar on French Navy Super Étendards.

The original RH 370 had a peak power of 90 kW and used a 51-cm Cassegrain dish, stabilized in roll and pitch. RH 370 could detect a patrol boat at 35 nm, with an accuracy of 1 deg in bearing and 0.1 nm in range. RH 370 reached the initial evaluation stage in June 1971.

◆ AGRION 15/IGUANE/VARAN

Band: X (9.1 GHz) **Peak Power:** 108 kW

Pulse Width: 0.25 or 1.5 microsec **PRF:** 1200, 600, 300 pps

Scan Rate: 12, 24 rpm **Weight:** 110 kg (total)

Data above apply to Varan (TMV 118B).

These systems are X-band frequency-agile pulse-compression surface-search radars. Pulse compression is used partly to reduce peak power, thus making the radars less detectable. In 1982 Thomson-CSF claimed that pulse compression made for an effective pulse width only a tenth that of magnetron radars, with 35 times the equivalent peak power, and that VARAN was 6–8 times lighter, 3–9 times more difficult to detect, and 6 times more discrete than any other pulse-compression radar on the market.

These radars use 2 pulse lengths, long (tenths of a microsecond) for long-range detection of large targets and short (thou-

An Atlantique Nouvelle Generation (Atlantique Mk 2) displays its IGUANE radar and its ESM systems in the wingtips. Any radar pushed out into the airstream creates drag, but that offset from the main airframe is the only way a single reflector can cover anything approaching 360 deg. Offset was the solution in aircraft such as the Alizé, the P-2, and the S-2. The alternative is to use 2 reflectors (as in the P-3) or to accept 180-deg scanning (as in the S-3, which has a nose radar). The bulge under the transparent nose contains a gyro-stabilized high-resolution thermal imaging camera, Tango, with a switchable $6.45 \times 4.30/2.15 \times 1.43$ deg field of view (the turret can turn to 110 deg to either side of the airplane, and its elevation limits are $+15/-45$ deg. The output is a 625-line television signal, 50.5 frames/sec. (U.S. Naval Institute)

sandths of a microsecond) for small targets in a rough sea. The long compressed pulse provides sufficient energy for long range. The short pulse is needed in a rough sea to limit the size of the resolution cell, so that the target stands out against the surrounding noise.

The basic unit is IGUANE, the radar for the Atlantique 2 and for the modernized Alizé. The program began in 1974, and technical evaluation began in January 1979; IGUANE first flew in May 1981. Claimed performance: 28 nm on a snorkel, 60 nm on a fast attack boat, 130 nm on a medium-sized ship, all in sea-state 3 or 4. For target classification, the antenna is locked with its beam pointing sideways, functioning as a synthetic-aperture system, while a special unit (Anaconda) forms the image. The antennas used in the Alizé and Atlantique are identical to those already in use. Total weight is 75 kg in an Alizé and about 130 kg in an Atlantique.

AGRION 15, which is used to target AS 15TT missiles, adds a monopulse tracking unit and a matched boresight-stabilized 1.3-m cheese antenna. AGRION 15 has 2 scan speeds and a TWS mode. This radar is used on board the Dauphin helicopters exported to Saudi Arabia. It has also been bought by Iraq and Chile.

VARAN is an IGUANE with a smaller antenna, for medium maritime-patrol aircraft to use for sea search and OTH-T. VARAN equips French Navy Guardian maritime-surveillance aircraft.

Thomson-CSF, the manufacturer, credits all 3 radars with the ability to detect a lifeboat or a snorkel at 30 nm, a fast patrol boat at 60 nm, and a freighter at 120 nm.

The names of all 3 radars are acronyms: IGUANE is *Instrument de Guet pour Avion Navale Embarqué*; AGRION is *Appareil de Guet de Recherche et d'Identification d'Objectif Na-*

vale; VARAN is *Veille Aéroportée Anti-Navire*. Work on IGUANE began in 1975, and the first production radars were delivered in 1980.

◆ Anemone

Anemone is the replacement for Agave, to be used in French Navy Super Étendards now being modernized. Anemone is primarily an air-to-surface radar but also has useful air-to-air performance. Modes are: linear scan search, continuous track, single target track, track while search, ground map, and ranging. The manufacturer is Electronique Serge Dassault (ESD).

◆ Ocean Master

The next-generation maritime-patrol-aircraft radar now under development, Ocean Master, is derived from technology originally developed for the RDX/RDY fighter radars, both of which have programmable signal processors (for variable waveforms). It is expected to enter service in 1995-96.

Like the current French maritime-patrol-aircraft radars, Ocean Master employs pulse compression. It will also use scan-to-scan and pulse-to-pulse integration to detect periscopes in sea clutter; it will incorporate ISAR; and it will be capable of tracking numerous targets while scanning. A SAR capability is under development. The radar's RDX/RDY ancestry will provide it with significant air-to-air performance, to provide a degree of AEW. As in the fighter radars, the antenna is electronically scanned (the customer can specify either an active or a passive array).

The scan-to-scan and pulse-to-pulse integration and digital-processing features are now being tested on board an Atlantique 2 aircraft.

◆ ORB 31 (Heracles I)

Band: X (9335-9415 MHz)

Beam: (a) 4×7.5 (b) 3.2×6 (c) 4.8×7.5 deg

Peak Power: 12 or 30 kW

Gain: (a) 29.2 dB (b) 30.5 dB (c) 28 dB

Pulse Width: (i) 0.2 (ii) 0.5 (iii) 4 microsec

PRF: (i) 1600 (ii) 800 (iii) 400 pps

Antenna Dimensions: (a) 608×308 mm (b) 728×368 mm (c) 460×308 mm

Antenna Weight: (a) 1.1 (b) 1.3 (c) 0.8 kg (ORB 31D combines reflector (c) with 30-kW transmitters) (ORB 31W combines reflector (a) with 30-kW transmitters)

The Omera-Segid helicopter sea-search radar is used in its ORB 31D version on board Super Frélon helicopters to target the AM 39 Exocet. This radar also exists in an ORB 31W configuration, for French Navy Lynx helicopters, and in an ORB 31AS antisubmarine version, carried by Alouette-IIIs. These radars all scan through 180 deg in bearing.

The ORB 31D and 31W versions use 2 transceivers, one for long range and another for short range and high resolution (and for clutter rejection). Range on a ship (1000 m^2) is 80 km (ORB 31D) or 50 nm (ORB 31W), and total weight is 75 kg (ORB 31D) or 61 kg (ORB 31W).

ORB-31 was derived from ORB-3, which is a license-built Ekco weather radar.

◆ ORB 32 (Heracles II)

Band: X (8500-9600 MHz or 9100-9500 MHz)

Beam: 2.6×6.2 deg **Peak Power:** 80 kW

Gain: 32 dB **Pulse Width:** 0.25 or 2.0 microsec

PRF: 1200, 600, or 300 pps **Antenna Dimensions:** 72×36 cm

Antenna Weight: total weight 129 kg

The modular Omera radar for small maritime-patrol aircraft was announced in 1979. ORB 32 was developed from the ORB 31-series. Each radar consists of 5 main elements: an antenna (1 of 7 parabolic reflectors, with major axes 46-85 cm and minor axes 30 or 36 cm, with front or rear illumination, gains of 28.5-32 dB and beams of $2.6-4.8 \times 6.2-7.5$ deg); a pedestal (1- or 2-axis stabilization, full or sector scan at 20 and 40 rpm); a junction box; a transmitter-receiver (4 types covering both bandwidths above, all with the same peak power, PRFs, and

The TANGO IR turret of the Atlantique-2 maritime-patrol aircraft, at the Paris Air Show, 1989. (Author)

pulse widths, but fixed, tunable, coded jump, or frequency-agile); and a PPI display. Sectors are 60, 120, 180, or 240 deg; and all of these radars can scan the full 360 deg. Range is 90 km on a 500-m² target.

Data apply to the ORB 32WAS version for the SA 321 Super Frélon helicopter. This radar was adopted by China (PRC) for its SA321J helicopters. There is also a similar ORB 32WD reconnaissance and target-designation radar, capable of tracking 2 ships. The Swedish government plans to buy a combined AS/WD version, ORB 32ASD.

◆ RDX

The Thomson-CSF pulse-doppler radar for the new Rafale fighter is to be operated by both the French Air Force and the French Navy. The air force requires simultaneous air-to-air and air-to-ground operation, including terrain-following. The navy emphasizes air-to-air detection at maximum range, for fleet air defense. The air force requirement is to be met by an electronically scanned antenna, which flew in 1987 and which will be able to generate multiple beams either simultaneously or in rapid succession. Because multiple-beam forming wastes some radar energy, the ideal navy solution would have been a mechanically scanned antenna. Since both versions of Rafale will probably have to carry the same radar, RDX will instead add radar power to make up for the scanning losses. To meet the requirement for operations at a wide variety of ranges, RDX will operate at high, medium, and low PRF, the peak power being matched to PRF (and varying by a factor of up to 10). The transmitter will be a dual-peak-power TWT. RDX will also use a programmable signal processor capable of about 1 Mflop within relatively small dimensions, requiring the development of new 0.8-micron (versus the current 1.2-micron) integrated-circuit technology.

Range will exceed that of the current RDI, i.e., beyond 50 nm. Rafale is also to have an optronic air-to-air fire-control system, with a range of 30+ nm. RDX is necessarily a multimode radar, since it must be suited to fleet air defense, deep strike, and ground attack. In the air-to-surface mode, it is optimized for antiship attack, entailing long-range target search, multitarget tracking, target assessment, and control of smart weapons.

Search modes are: look-up/look-down, velocity search (VS), and range while scan (RWS). Raid assessment is automatic; the system chooses the 8 highest-priority targets, displaying their ranges and closing speeds. The pilot can change priority. Tracking modes: TWS and single target track (STT). TWS is intended for firing MICA missiles fitted with active seekers; STT is optimized for semiactive missiles. Selection among close combat modes is controlled by the pilot from the stick. In the air-ground mode, the HUD superimposes a radar map on the real landscape, in a suitable scale. The system can also automatically terrain-follow while in the air-to-air mode ("expanded visibility"). RDX can also radar-map with high resolution for navigational update, target designation, search and tracking of both fixed and moving targets, and air-to-ground ranging.

RDX will use a new Radant (RBG) antenna, developed by Thomson-CSF ($\frac{2}{3}$ share) and by ESD ($\frac{1}{3}$ share), collaborating as a GIE (*Groupeement d'Intérêt Economique*); RBG means *Radar de Bord du GIE*. It is a passive scanner because the deadline for service entry was too short for development of an active array.

RBG is a patented Thomson-CSF design; there are 2 tandem lenses, each consisting of a stack of phase-shifter channels and each polarized at right angles to the other, with a 90-deg polarizer between them. Each steers the beam in 1 dimension by phase shifting. The lenses are illuminated from behind by a flat-plane array that produces the focused beam turned by the phase shifters.

In April 1989 the French government (DGA) awarded the consortium a contract for contract definition and for development prototypes. The first prototype is to be delivered in 1991; it will fly during the second half of the year aboard a Mystère 20. It will first fly on board a Rafale in 1993, production beginning in mid-1995.

◆ RDY

This new radar for Mirage 2000 fighters incorporates an air-to-sea mode for Exocet and Kormoran missile control. They are primarily air-to-air radars and also have low-altitude penetration modes (for ground avoidance and contour mapping). As in RDX, the key to multiple operation is a programmable signal processor. Variable waveforms include multiple-range gate high PRF, medium PRF, and low PRF. The flat-plate antenna scans a 60-deg cone; it may later be replaced by an electronically scanned antenna. The transmitter has 2 alternative peak powers, corresponding to different PRFs. This radar is scheduled to enter production in 1991.

ITALY

◆ APS-705/707/APQ-706

Band: X (dual frequency)

Beam: 2×7 deg (AB 212); 1.5×10 deg (SH-3D)

Peak Power: 25 kW (option: 75 kW)

Pulse Width: (i) 0.05 (ii) 0.15 (iii) 0.5 (iv) 1.5 microsec

PRF: (i) 1600 (ii) 1300 (iii) 1300 (iv) 650 pps

Scan Rate: 20 and 40 rpm

Antenna Dimensions: 1.2-m aperture (AB 212) or 1.6-m aperture (SH-3D) **Antenna Weight:** total system weight 87 kg

The SMA TWS radar for Italian Navy AB 212 and SH-3D helicopters (surface search, periscope detection, and tracking) employs two 25-kW transceivers (1 antenna) for frequency di-

APS-705 antenna, line-of-sight stabilized in roll and pitch. This radar is also offered in a prodded version, to provide aircraft with an antiship capability, in association with the Marte missile. APS-705 operates in X-band, with peak power of 20 kW. (SMA)

APS-707 antenna, designed to operate at a peak power of 90 kW. (SMA)

APS-707 installed on board an Argentine Electra airliner converted for use in maritime patrol. The U.S.-built Orion (P-3) shares much the same airframe. (SMA)

versity. The antenna is stabilized in line of sight and can be tilted 20 deg up or down.

APS-707 is a more austere version of APS-705. 707 is a single-channel fixed-frequency lightweight set (one 20-kW transmitter). There is also a high-powered version, using a 90-kW transmitter, which has been adopted by the Argentine Navy to replace existing APS-20 radars on board SP-2H Neptune maritime-patrol aircraft. APS-707 is frequency agile and has other ECCM features.

APQ-706 is a double-antenna radar (back to back) used to guide the Marte antiship missile (carried on board Italian Navy SH-3D Sea Kings). 706 uses 2 channels, 1 of fixed frequency and 1 with frequency agility, the latter to detect small high-speed targets. The fixed-frequency channel is used for navigation and periscope detection. The transmitter is the 75-kW frequency-agile unit available as an option in APS-705. The antenna is line-of-sight stabilized.

◆ APS-784

The SMA/FIAR X-band radar for Italian EH-101 helicopters will probably serve both for surface search (including attack against surface ships) and for some degree of AEW. The antenna will scan through 360 deg. The transmitter will be a TWT, and pulses will be compressed. For antiship operation (such as missile target designation), APS-784 will be capable of TWS operation. APS-784 will be a compact radar, using only 4 line-replaceable units.

SMA has offered a scaled-down version for the NATO NH.90 helicopter.

◆ Grifetto (PA-2801) and SCP-01

Grifetto is the FIAR radar proposed for the antiship version of the Italian-Brazilian AM-X fighter; some of this technology may be incorporated in the APS-784 radar of the EH-101 helicopter. Grifetto is part of a privately developed Grifo series of X-band radars. The simplest, PA-2801, is a small (50-kg) magnetron radar limited to antiship and close-air-support missions. It is designed to detect a frigate at a range of 55 nm. Aeritalia considers Grifetto the standard radar for the antiship version of the AM-X.

The antiship version of Grifo is currently designated Grifo-ASV. It operates in the lower part of X-band, using a low-PRF 100-kW magnetron, with a 41×34 -cm flat-plate monopulse antenna. The main operating modes are air-to-sea (including TWS on seaborne targets) and air-to-air (including single-target tracking). Ground tests were completed in 1988, and late in 1989 Grifo-ASV was being tested on board a PD 808. Integration with AM-X was then scheduled to begin mid-1990.

However, a more advanced radar in the same family, Grifo X, may be adopted for Italian Air Force strike versions of the AM-X. Grifo X weighs about 70 kg (165 lb), has a 16-in antenna, and should have useful air-to-air performance.

The most advanced radar of the series, Grifo, uses a TWS transmitter and weighs about 90 kg (about 200 lb). The antenna is a 24-in flat plate, and a frigate can be detected at 80 nm in sea-state 4. This radar is intended to replace existing radars on aircraft such as Mirages and Soviet- and Chinese-built fighters.

Members of the Grifo radar family show the range of antenna sizes envisaged. The radar in the background is the antiship version (P2801); the multimode P2800 is in the foreground. (Author)

The prototype was tested in 1988. Bandwidth is up to 200 MHz, with both low- and medium-PRF waveforms. Average power is up to 120 kW (up to 4% duty cycle).

In 1988 SMA announced an alternative AM-X radar, SCP-01 (Scipio), which SMA was developing in cooperation with a Brazilian company, Tecna, using Brazilian Air Force research and development funds. SMA will be responsible for signal processing. SCP-01 will presumably equip Brazilian AM-X strike fighters. Total weight will be about 80 kg; the antenna diameter is about 16 in, and average power will be about 120 W. Estimated range on a frigate is 60 nm.

SWEDEN

◆ HERA (9HCI 100)

The BEAB-Omera frequency-agile periscope-detection and surface-search radar appeared on refurbished KV-107 ASW helicopters in 1986. HERA can detect a snorkel at 25 nm in sea-state 5, or a frigate at 100 nm, and can be used to find targets for the RBS 15 missile. A transponder allows 2 helicopters to coordinate their attacks.

9HCI 100 is the export designation (9HCI 200 with torpedo fire control included).

◆ SLAR

Ericsson's side-looking airborne radar is used by the Swedish Coast Guard and offered for export as an austere AEW unit. It has been carried aboard a Metro III airliner for coast-surveillance trials. As of 1989, it was in service with several countries.

The antenna pod is 3 m long and operates in X-band. Total weight is less than 70 kg. Radar images are displayed on a television and can be recorded. Range is up to 100 km, and the data can be filtered for moving targets.

USSR

◆ Big Bulge

The Bear-D X-band surface-search radar is used to target SS-N-3 and -12 missiles. This radar, with a smaller radome, is also fitted to Hormone-A helicopters. Reported PRFs for the Hormone version are 414–418 and 621–628 pps.

◆ Down Beat

The Blinder and Backfire missile-guidance radar appeared in 1959. Down Beat is associated with the AS-4 and AS-6 missiles, and it is frequency-agile, with variable PRF.

◆ Mushroom

This X-band surface-search radar is installed in Ka-25 ASW helicopters.

Big Bulge radar under a Bear-D bomber, 1989. (U.S. Navy)

This Hormone helicopter carries a smaller version of Big Bulge, for missile targeting. (U.S. Navy)

Down Beat nose radar on board a Badger. (U.S. Naval Institute)

◆ Puff Ball

The navigation/attack radar on Badger-C is used to target AS-2 and AS-6 missiles. Puff Ball is also carried by Badger-D, -E, -F, and -J. Puff Ball operates at X-band, with PRFs of 410 and 620 pps.

◆ Short Horn

Short Horn is a Ka-band (14–15 GHz) bombing radar and is the chin (sea-search) radar on the Bear-D. This radar is also carried

by Badger-G (AS-5 and AS-6 missiles). Short Horn is frequency-agile and has both circular and sector scan. Reported characteristics: pulse width (i) 1–1.8 (ii) 0.5–1.4 (iii) 0.4–1.3 (iv) 0.01–0.9 microsec; PRF (i) 313–316 (ii) 496–504 (iii) 624–626 (iv) 1249–1253 pps.

◆ Wet Eye

The surface-search radar of May and Bear-F ASW aircraft is associated with the BM-1 and, presumably, later sonobuoy systems.

UNITED KINGDOM

◆ ARI 5955/MAREC/MAREC II

Band: X Peak Power: 15 kW
Pulse Width: 0.5 PRF: 400 pps

The Sea King X-band search radar was introduced in 1968 and has been replaced since 1982 by the MEL Sea Searcher. ARI's effective range is 50 nm, compared to 100+ nm for the Sea

Searcher. ARI 5955 was originally a German Ekco radar. X-band was chosen because S- or C-band would have given insufficient definition, and Ka- and Ku-band would have been excessively affected by weather. This and later MEL radars are all associated with big horizontal plotting tables incorporating backlit radar displays.

MAREC (Maritime-Reconnaissance Radar) is a developed form of ARI 5955, with a higher peak power (65 kW) and antenna gain (34.5 dB), 2 pulse lengths (0.5 and 2.5 microsec), and 2 PRFs (200 and 400 pps). In a proposed installation on board the British Aerospace HS 748, MAREC used a 36-in stabilized antenna (2.5-deg beam) in an under-fuselage radome. Alternative antennas were 24–48 × 12–21 in.

MAREC was not sold successfully, but MAREC II was selected for Indian Coast Guard Do 228 aircraft and also for the Dornier Do 128 used by the Cameroons. MAREC II operates in X-band (peak power 80 kW); pulse widths are 0.4 and 2.5 microsec (PRFs, respectively, are 400 and 200). Maximum range is about 250 nm (maximum instrumented range is 219 nm). The Indian sets are being produced under license by Hindustan Aeronautics.

◆ Blue Fox

The Ferranti multimode monopulse X-band radar for Royal Navy Sea Harriers was developed from the private-venture Blue Falcon core radar of the mid-1970s. Reportedly, Blue Fox is also related to Seaspray. The antenna is a flat roll-stabilized slotted array. It incorporates an IFF interrogator.

Radar modes: (i) air-to-air/air-to-surface scanning in azimuth and/or elevation; (ii) lock-on track (1 target); (iii) visual acquisition (through the HUD); (iv) air-to-surface ranging (the radar locks on the aim point to provide range data); (v) ground mapping (for navigation).

The transmitter is a spin-tuned magnetron, hopping frequency on a pulse-to-pulse basis for ECCM, for clutter rejection (the clutter characteristics vary from frequency to frequency, hence can be reduced if successive pulses are integrated), for glint reduction (again, the reflecting characteristics of a complex target will vary with the frequency, and thus can be smoothed out by frequency hopping), and also for reduction of STA errors due to detection of large reflectors (such as land masses) at a distance.

Blue Fox was optimized for mid- to high-altitude targets; the Sea Harrier was originally intended to intercept Bear-Ds providing targeting data for ships and submarines armed with SS-N-3 missiles. As a consequence, Sea Harriers in the Falklands had no look-down capability, and pilots often had to acquire their targets visually.

This radar is to be replaced by Blue Vixen, which can look down, in Sea Harrier FRS.2.

◆ Blue Kestrel

This X(I)-band radar for British EH-101 and Sea King helicopters covers 360 deg. Blue Kestrel is a TWS radar, and its transmitter is coherent (with pulse-compression); it is also frequency-agile. This radar was derived from Seaspray (below). Scan rate is 12 or 24 rpm, and a small target can be detected at 25 nm. Blue Kestrel was first installed for tests (on board a Sea King) late in 1985, for flight trials in the spring of 1986. Development models were delivered by January 1989.

◆ Blue Vixen

Ferranti's multimode coherent pulse-doppler radar for modernized Royal Navy Sea Harrier (FRS.2) is derived from the earlier Blue Fox and from Ferranti's private venture Blue Falcon core-radar project. Blue Falcon is also the basis for Ferranti's proposals for aircraft such as EFA. Blue Vixen is a response to some of the Falklands lessons and is designed to be compatible with the AMRAAM medium-range air-to-air missile.

The radar automatically selects the appropriate air-to-air mode, from among low PRF, high PRF (velocity search or range while scan), and medium PRF. It also automatically initiates

TWS, presenting synthetic-video track histories to the pilot. On detection of a target within a specific short-range zone, the radar automatically selects single-target-track (STT) mode. There are 2 air-to-sea modes (both with TWS, Sea 2 with a decluttered display for tracking small targets in high sea-states). A real-beam-mapping (RBM) mode provides ground mapping and can incorporate TWS. The other air-to-surface modes are air-to-surface ranging (for weapons delivery), precision velocity update (for navigation), and beacon interrogation. Growth options are doppler beam sharpening (DBS) and ground moving-target indication (GMTI). Special covertness features are the ability to retain radar data after reception (transmit/freeze mode), single-sweep transmission (data update), spread-spectrum transmission, and sector search. The manufacturer also lists the narrow-sidelobe antenna and the TWS capability as covertness features.

Total weight is 141.5 kg, of which 102.5 kg is in the nose and 25 kg (the programmable signal processor) is in a rear bay, connected to the nose equipment by a 1553B bus.

The development contract for this radar was let in July 1983, and a prototype, which flew in a BAC 111, was delivered late in 1985 (flying in mid-1986). Limited finances forced deletion of provisions for JTIDS, although space and weight are still reserved for later installation.

Red Fox is a repackaged version offered for other aircraft.

◆ Sea Searcher/Super Searcher

Compared to the earlier ARI 5955, the MEL X-band search radar for Sea King helicopters is credited with twice the range. Sea Searcher is a TWS radar that can sector-scan. There are 2 alternative (selectable) pulse widths, for operation in various sea-states. The antenna is enlarged: sizes from 107–610 mm in horizontal aperture [42–240 in] are available.

Peak power is 85 kW, and scan rate is 30 rpm.

Super Searcher is a development announced in 1982 that uses a 42 × 16-in dish, or a 48 × 10-in planar array, or a 30 × 10-in planar array antenna, and has greater detection, tracking, and missile-guidance performance. All arrays are stabilized within ±20 deg. A new color CRT replaces the earlier monochrome PPI. There are 3 selectable pulse lengths, including an ultrashort pulse for high definition in bad weather, and 4 alternate PRFs. Scanning is by sector or over the full 360 deg. The 14-in raster-scan (625-line) CRT display has freeze frame and memory storage (and MTI). Range scales: 4, 8, 16, 32, 64, 128, 256 nm. This radar has TWS capability. Signal processing options are within-beam integration, scan-to-scan integration, pattern enhancement, and CFAR. Super Searcher is the radar of the Indian Navy Sea King Mk 42B helicopter and also of the RAN S-70B Seahawk; it was also selected for Brazilian EMB-111 patrol aircraft.

In 1988 MEL announced Super Searcher PC (pulse compression), which was proposed for the Canadian New Shipborne

Super Searcher PC components. (MEL)

Aircraft (NSA) helicopter. This version uses a TWT transmitter; it has 3 alternate pulse widths (2 compressed, 1 uncompressed), and 5 alternate PRFs.

The Royal Navy planned to install a new 360-deg-scan Super Searcher Skua (Triple S) in rebuilt Lynx helicopters, but this requirement was canceled because of cost in 1988.

◆ Seaspray

Band: X **Antenna Dimensions:** 27 in × 10 in (deep)
Antenna Weight: total weight 65 kg

Ferranti's sea-search radar for the Lynx helicopter uses a Philips frequency-agile (spin-tuned magnetron) transmitter. Seaspray is intended primarily to detect and track small fast craft, such as fast patrol boats, and can be used to guide Sea Skua missiles. It can also be used as a periscope detector. Tracking is monopulse. There are 4 selectable PRFs.

Ferranti announced Mk 2 and 3 in August 1982. Mk 2 had a new processor, and Mk 3 was a TWS version with a full 360-deg scan. Compared to Seaspray Mk 1, Mk 3 has full 360-deg coverage and TWS performance. The display is a television-type raster showing processed video, and the picture can be frozen if necessary. Total weight is about 140 lb.

By early 1985 over 250 Mk 1s had been ordered, users including the Royal Netherlands Navy, the Royal Danish Navy, Argentina, and Brazil. In 1984 the German Navy selected Seaspray Mk 3 for the Sea King Mk 41 helicopters, to replace their existing MEL ARI 5955 radars, which could not be used to illuminate targets for Sea Skua missile engagement. Mk 3 was also chosen for South Korean Super Lynx Mk 99 helicopters, which are being equipped with Sea Skua missiles. In November 1984 a further version, Seaspray Mk 4, was chosen to equip Bell 212 ASW helicopters for Turkey.

Seaspray antenna (686 mm wide). (Ferranti)

◆ Searchwater (ARI 5980)

Searchwater is Thorn-EMI's Nimrod MR.2 X-band pulse-compression surface-search radar; Searchwater also serves as an AEW radar on board British and Spanish Sea King helicopters. This radar was the major improvement over the MR.1 version, using both a narrow beam and a short pulse to limit the patch of sea clutter surrounding a target. Pulse-to-pulse frequency agility helps eliminate sea returns, which are frequency dependent. The radar integrates all pulses in any beamwidth during 1 scan and can also integrate from scan to scan. The detection threshold is controlled to maintain a constant false-alarm rate; the associated computer produces processed video, which is what the PPI shows. Searchwater is credited with a target-

Searchwater in its AEW form, as carried by Sea King helicopters. (Westland)

classification capability based on target size and aspect. The antenna is pitch- and roll-stabilized, with controllable tilt and automatic sector scan.

The operator has A-scope, B-scope, and raster-scanned PPI displays, the A-scope being used for what appears to be ISAR.

In 1985 Thorn-EMI was awarded a contract for a color display, with which processed video could be overlaid on raw video (in the monochrome version only processed video could be displayed). That was expected to improve anticollision performance, as well as detectability of targets.

Claimed performance: 28+ nm on a snorkel, 60+ nm on a fast attack boat, and 130+ nm on a medium-sized ship.

Searchwater development began in 1972, initial tests following in 1973; the first production Nimrod 2 was delivered in August 1979.

The associated IFF is the Cossor Jubilee Guardsman.

Thorn-EMI's helicopter-borne early-warning version of Searchwater was initially developed in response to the experience of the Falklands War. The patrol version, intended for sea search, uses a fan beam; the AEW version uses a pencil beam with circular polarization provided as an alternative to the vertical and horizontal polarization of the Nimrod (patrol) version.

The AEW version has 2 alternative scan rates (faster to track faster-moving targets, slower for better detection at longer range) and 4 range scales (i.e., PRFs; pulse widths are adjusted to match range scales, presumably to maintain the same average power output). There are alternative warning and search modes optimized, respectively, for aircraft and ship detection. The antenna can also be tilted to scan for weather features, and a separate A-scope is used to assist in target classification; presumably the blips displayed on it show some structure related to the target's shape and aspect.

Targets are detected by the operator, who manually designates them on the PPI. In the warning mode, the PPI is arranged to brighten fast-moving targets. Once designated, targets can be automatically tracked. Any position of the PPI can be displayed in expanded form on a B-scope (bearing vs. range) for more accurate positioning of the target designator, a feature presumably valuable if there are many targets close together. The associated computer provides both target track data and computed range and intercept-vector data for fighters. A Sea King equipped with Searchwater controls fighters directly (as does the much more powerful E-2C) rather than merely handing target data down to a ship (as in early U.S. and all previous British AEW aircraft).

The system can track up to 16 air targets in manual control and can direct up to 6 simultaneous interceptions. There are 2 operator stations, side by side, with the tactical coordinator (in contact with the senior warfare officer on board the carrier) on the right. The tactical coordinator can track up to 40 surface targets, the helicopter providing OTH-T support for surface ships. The officer at the left-hand display is responsible for air targets. The system is reportedly being developed to interchange data between the 2 displays so that fighters can be directed against designated surface targets. Work is also proceeding to increase computer capacity so that more air targets can be han-

dled. The system currently lacks the air-to-surface data link associated with many earlier AEW aircraft (which did not themselves control fighters); reportedly, Searchwater also suffers from clutter when tracking low-flying air targets. Introduction of a coherent transmitter (as in the related Skymaster surface-search radar) would help solve the latter problem, as target doppler would be easier to extract.

Searchwater is described as noncoherent, but its manufacturer also credits the system with the capability of extracting doppler data from its pulse-compressed signals. That capability suggests that pulses are internally coded by phase rather than by frequency.

Thorn-EMI had proposed an AEW adaptation of Searchwater before the Falklands War, but this project had been rejected on the grounds that the Royal Navy would, in the future, fight only in the North Sea and eastern North Atlantic, i.e., always under the cover of long-range shore-based aircraft such as AWACS. The Falklands War demonstrated that other contingencies were very possible, and on 5 May 1982 Thorn-EMI revived its idea. The study was officially approved on 13 May, and 2 Sea King helicopter prototypes were ordered on 24 May; the first flew on 23 July 1982, and the prototype Sea King AEW helicopters embarked on board HMS *Illustrious* on 2 August 1982. The project survived the end of the war, and production AEW helicopters became operational in 1986. British carriers now embark a flight of 3 AEW helicopters. In addition, 2 ASW Sea Kings are fitted for, but not with, the Searchwater radar, as potential spare airframes. In mid-1989 the Royal Navy ordered 2 more Searchwaters, to equip the 2 Sea Kings fitted for but not with the radar, so that each carrier will have 4 rather than 3 AEW Sea Kings. These radars will be delivered in mid-1991.

This system is also employed by the Spanish Navy.

Thorn-EMI is developing a next-generation series of radars, Skymaster (for AEW) and Searchwater 2/Searchwater NH. Skymaster is currently being offered for installation on board a Britten-Norman Defender, but the manufacturer believes that it can be carried by a Lynx frigate helicopter. Skymaster is a pulse-doppler radar capable of detecting a low-flying fighter at 140 km (77 nm) and of tracking more than 50 targets (with more than 250 held on file). Like Searchwater AEW, it normally requires 2 operators.

Searchwater 2 offers Searchwater performance at about half the weight and also provides AEW. It is intended for maritime-patrol aircraft such as the P-3, Fokker Maritime Enforcer Mk 2, and the CN235. Searchwater NH is a variant intended for the NATO frigate helicopter now under development.

◆ ANR 360 (Navigator)

Decca's maritime-surveillance radar was developed in Norway and first flew in a Cessna 337 in mid-1979. Navigator is a standard Decca X-band (3-cm) solid-state marine radar with a 25-kW transmitter. The antenna is limited to 18-cm depth to fit under the chin of a helicopter. In the Mk 1 fitted in the Cessna, the antenna is in a standard cargo pack attached to the underside of the fuselage, using a fiberglass radome. Mk 3, planned for the Sea King helicopter, will use a chin radome for 360-deg scanning. Maximum instrumented range is 95 nm, with 8 range scales from 0.5 nm up.

This radar was originally developed to meet a Norwegian requirement for a periscope detection unit, to deal with submarines in fjords. As fitted in Sea Kings, the radar will have a data link to control attacks by fast patrol boats hidden behind islands.

◆ ASR 360

Band: X (9.1 GHz) **Beam:** 3×27 deg
Peak Power: 25 kW **Gain:** 25 dB
Pulse Width: 0.05, 0.25, and 1.0 microsec
PRF: 825 pps minimum **Scan Rate:** 32 rpm
Antenna Dimensions: 30-in slotted waveguide

ASR 360 is Racal-Decca's surface-search marine radar, adapted for small maritime-patrol aircraft, such as converted

Short Skyvans (Sultan of Oman Air Force, which bought 15 in January 1984). As of 1984, ASR 360 had also been selected by British Aerospace for a modified Jetstream 31EZ. ASR 360 was originally developed for the Royal Norwegian Navy in 1979, to be flown on board a single- or twin-engined Cessna (the first installation was a Royal Norwegian Navy Cessna 337).

◆ Sea Owl (PID)

GEC-Marconi's stabilized long-range FLIR for Royal Navy Lynx helicopters is also designated Passive Identification Device (PID). The stabilized FLIR uses standard TICM II modules, and the associated signal processor automatically searches for, detects, and tracks surface targets. The turret slews at up to 60 deg/sec, over ± 120 deg in azimuth; elevation limits are $+20/-30$ deg. Magnifications are $5\times$ and $30\times$ (fields of view 12×8 and 2×1.33 deg). The IR sensor uses 8 parallel CMT SPRITE detectors and feeds a 625- or 525-line monitor. Turret weight is 66 kg. There are also a 17-kg signal processor and a 16-kg target tracker for automatic search, detection, and tracking of surface targets. The system is designed to connect to a 1553B bus.

GEC-Marconi has proposed the related multirole FLIR turret for the projected Super Lynx helicopter. This turret slews at up to 110 deg/sec and is stabilized to within 88 microrad. The telescope zooms continuously between 2.5 and 10 magnification; fields of view are 24×16 down to 6×4 deg with 625-line (50 frames/sec) video, or 19.4×13 down to 4.9×3.3 deg with 525-line (60 frames/sec) video. Resolution in the narrow field of view is typically 0.227 mrad vertical and 0.182 mrad horizontal. The TICM II module uses 8 parallel SPRITE detectors working in the 8–13 micron band. Total weight is 35 kg, and the turret is 380 mm (15 in) in diameter.

Sea Owl, on display at RNEE, 1989. (Author)

UNITED STATES

◆ AAR-42

AAR-42 is Texas Instruments's pod-mounted FLIR detector for A-7 attack aircraft. AAR-42 is gimballed and provides a night window/bombsight; as of 1988, over 100 had entered U.S. Navy service. Early in 1985 work began on an upgrade for the Air National Guard, to include a wide-field-of-view navigation mode, DC-restored video, and a capability for hands-off operation (automatic gain/level). These improvements will be available for possible navy upgrades.

The stabilized FLIR image is displayed on the pilot's HUD. Coverage: ± 20 deg in azimuth, $+5/-35$ deg in elevation. The lens zooms from wide ($1\times$ magnification) to narrow field of view ($4\times$ magnification), the former for navigation and the latter for target identification and weapons delivery. By 1985 claimed MTBF was 390 hr.

Work began in 1973, with operational evaluation in October 1976, first production delivery in September 1978, and approval for service use in March 1979. Pod dimensions: 21×193 in (720 lb). AAR-42 will ultimately be replaced by the new Low Altitude Night Attack (LANA).

◆ AAR-50/AAQ-16

Hughes's system, AAR-50 is a navigation set, TINS (thermal imaging navigation set), for the F/A-18, derived from the earlier AAQ-16. AAR-50 provides a pilot with an image (on the HUD) of the approaching terrain, in either black-is-hot or white-is-hot form (the latter looks something like a conventional television image). TINS has a fixed 20×20 -deg field of view (and thus cannot be used for target-following), occupying a pod (10×78 in, 175 lb) on a stub pod adapter on the starboard side of the airplane. Hughes claims that MTBF is greater than 410 hr (MTTR is 17 min, using standard WRA components). Five prototypes have been delivered; as of early 1989, first production deliveries were scheduled for that year.

TINS (AAR-50) mounted on an F/A-18. (Hughes)

The earlier AAQ-16 is intended for both the U.S. V-22 Osprey and the Anglo-Italian EH-101; it was deployed to the Persian Gulf on board U.S. SH-2s (see below). AAQ-16 is a turret-mounted FLIR, slewing at 130 deg/sec, with azimuth limits of ± 210 deg and elevation limits of $+85/-180$ deg. It has 2 magnifications, $1\times$ and $6\times$ (corresponding fields of view are 30×40 and 5×6.7 deg). Video is 875 or 525 lines. The turret is controlled by a joystick. The turret weighs 45 lb and is 12 in in diameter (14 in deep). Hughes claims MTBF is 400 hr.

In 1988 AAQ-16s (in production for the army and the Customs Service since 1985) were mounted on board LAMPS I helicopters operating in the Persian Gulf. On these aircraft the turret is in the nose, on the right-hand side, just forward of the radome. The AAQ-16 image can be down-linked to the ship operating the helicopter.

◆ AAS-33 (DRS)/TRAM

AAS-33 is the A-6E detection-and-ranging set (DRS), part of the airplane's TRAM (Target Recognition and Attack Multisensor) system. TRAM employs a stabilized turret carrying a FLIR, a laser rangefinder/designator, and a laser receiver (to pick up targets designated on the ground), all within a 20-in dome. The FLIR has a zoom (up to 13-power) lens. The main technical problem in development was packaging everything within the very small dome. The sensors can be slaved to the aircraft radar, and when not in use the dome rotates to protect the FLIR and laser windows. Hughes is the manufacturer.

Reportedly, pilots credit TRAM with quadrupling their capability and with increasing bombing accuracy tenfold. Because the turret can be turned 180 deg, TRAM can be used to assess bomb damage on the first run, without making a second pass.

DRS and TRAM were part of the project for an enhanced all-weather A-6A, begun in 1972. The prototype was test flown in 1976, and TRAM was approved for service use in March 1980. Conversions of existing A-6s began in 1978, and installations in new aircraft under the FY85 program.

Northrop received a contract from Grumman in May 1985 to develop an IR video automatic tracker (IRVAT) for the A-6E. The tracker could keep lock on targets while the airplane maneuvered. The FY86 program included funds to begin engineering design to integrate AV-8B/F-18 night-attack electro-optics into the A-6E. This project includes a passive night navigation system. The Naval Air Systems Command issued an RFP for a follow-on DRS in April 1987.

◆ AAS-36/37

AAS-36 is the Texas Instruments infrared detecting set (IRDS) for P-3 Orions. IRDS provides a thermal image of the target on

An AAS-36 turret under the nose of a P-3 Orion. (Naval Reserve Association)

a television set, and the detector is inertially stabilized against target motion. The passive tracker can be locked onto a target of interest. The set is carried in a small turret under the nose of the airplane.

AAS-36 is broadly similar to the AAS-33 DRS used on the A-6E. FLIR fields of view are 15×20 and 5×6.7 deg. Slew rate is 1 rad/sec (about 57 deg/sec), and azimuth limits are ± 200 deg. The turret is stabilized to within 0.125 mrad. It weighs 301 lb. MTBF is 300 hr (MTTR 30 min).

AAS-36 replaces the KA-74 camera originally installed on board P-3A and -3B aircraft. A program to replace the LLLTV originally installed on board the P-3C began about when the airplane entered production, and competitive procurement of a FLIR turret began in 1971. The navy temporarily bought 11 Hughes AAR-37 and 4 Texas Instruments AAR-40 FLIRs before awarding the AAS-36 contract to Texas Instruments in 1972 as part of the P-3C Update II. Texas Instruments began work late in 1974, the first production award following in mid-1977. AAS-37 was initially installed on board P-3C Update II aircraft, but was later extended to -3As and -3Bs.

The AAS-36 infrared receiver is incorporated in the AAQ-15 infrared detecting-and-tracking set used on board air force HH-60 helicopters and C-130 gunships. In that application 3 simultaneous fields of view are presented, and there is an automatic video tracker.

The AAS-37 IRDS (IR detecting-and-ranging set) is a derivative, used on board marine OV-10Ds. AAS-37 provides automatic target tracking and laser illumination for weapons such as Paveway. The project was originally designated OV-10D Night Observation Gunship (NOGS); it was canceled, then revived in 1978 as the Night Observation System (NOS). The IRDS development contract was awarded in June 1976, with the first flight test following in November 1977. Technical and operational evaluations were completed in July 1978, and delivery of 23 units began in February 1979 and was completed that August.

◆ AAS-40 (Seehawk)

This lightweight Northrop FLIR was developed for the U.S. Coast Guard's HH-65 Dolphin helicopters but was not adopted; it has been included in the S-2 Tracker modernization project for Taiwan. Seehawk uses standard DoD FLIR components. The 39-kg turret-mounted FLIR has 3 magnifications, $1 \times$, $2 \times$, and $6 \times$ (corresponding fields of view are 30×40 , 15×20 , and 6.5×5 deg). The turret slews at up to 180 deg/sec; azimuth limits are ± 190 deg, and elevation limits are $+30/-105$ deg.

◆ AAS-38

AAS-38 is the Texas Instruments/Ford Aerospace FLIR for F/A-18 Hornet fighter-bombers and is used primarily for attack against land targets. The system is pod-mounted and ultimately will control a laser target designator/ranger. This FLIR incorporates an automatic target tracker and automatic gain/level control for hands-off operation. The system as a whole employs 10 Weapons Replaceable Assemblies (WRAs); mean time to replace 1 is less than 12 min.

The pod is 13×72 in and weighs 347 lb. It is typically mounted on the lower left of the aircraft fuselage and provides the pilot with a 3×3 - or 12×12 -deg field of view. The pilot can move the line of sight from -150 to $+30$ deg, with 540 deg of roll freedom in either direction. Targets can be tracked at 75 deg/sec.

AAS-38 was the first navy FLIR designed for supersonic operation. This system entered service in February 1985, after more than 175 successful test flights between 1980 and 1983, a 170-flight program at NWC China Lake and NAS Patuxent River in 1984, and an operational evaluation at Patuxent River in 1985. Full-scale development of the laser tracker began in 1983, and it is scheduled for incorporation in pods delivered from 1989 onward.

Dimensions: 13×72 in; weight 370 lb (including laser

AAS-38 FLIR pod mounted on an F/A-18 (Hughes)

ranger). Ford claims an MTBF of 80 hr for the full FLIR/laser ranger (MTTR 15 min).

Three major improvements are currently in production: pod boresight G-load compensation software; filtered inertial-to-sightline coordinate transformation (CSI) for better targeting accuracy; and air-to-air automatic tracking. A multifunction autotracker and an advanced air-to-air capability are under development. The multifunction autotracker automatically selects 1 of several possible air-to-air tracking methods (algorithms) to lock onto another airplane. The autotracker can conduct a search for an airborne target, automatically detecting it and locking on; alternatively, the autotracker can track several targets simultaneously (a FLIR equivalent of radar TWS performance).

During the Gulf War an AAS-38 pod was carried on the port stores station of 1 SH-60B LAMPS III helicopter of HSL-44. The pod's 875-line video was interlaced so that it could be displayed on the 525-line monitor on board the helicopter. This image could not be data-linked down to the ship. Six more production pods will have the data-link capability, and the FLIR may be slaved to the helicopter's radar. The SH-60B cockpit could not be modified for night operations, so the crews were provided with hand-held, army-type, Texas Instruments TAS-6A FLIRs. Crews were also provided with Fujinon stabilized binoculars to identify distant surface contacts detected by the search radar. However, in the absence of a zoom-lens FLIR, such identification brings the helicopter well within the range of hand-held missiles. Hence the importance of the FLIR pod.

In all, 25 SH-60s were modified for the Persian Gulf mission (Earnest Will).

Reportedly, current production AAS-38s incorporate a laser target designator/ranger, for which space was provided in the original design. The laser can perform some radar functions when the airplane is operating in radar silence.

◆ S-3 FLIRs (OR-89/AA)

The FLIRs installed in S-3s do not have separate AN designations because the FLIRs are integral elements of a larger weapons system. The first version, OR-89/AA, was also the first FLIR to be designed simultaneously with the overall airframe. The OR-89/AA is also installed on board many P-3Bs and Canadian CP-140 Auroras (as OR-5008/AA). Existing OR-89C/AAs are now (1988) being upgraded to OR-263/AA configuration, incorporating DoD Common Modules. The OR-263 can be operated off-line as an independent FLIR.

Both OR-89 and OR-263 are manufactured by Texas Instruments.

OR-89/AA was developed from the AAD-4 and AAS-28 FLIRs used in Vietnam. Lockheed contracted with Texas Instruments directly in August 1969, and the first prototype was delivered in March 1971. The FLIR is turret-mounted under the airplane, just abaft the cockpit. The field of view is 5×6.67 or 15×20 deg, with azimuth coverage of 200 deg in either direction and elevation coverage of 0 to -84 deg. Output is an 875-line television picture. About 1982 the specified MTBF, which had been demonstrated in service, was 345 hr. Turret diameter is 20.5 in.

The AAQ-10 (Pave Low III) of the HH-53 helicopter is a derivative. This device is also installed on board Israeli Navy Westwind reconnaissance aircraft, in a special high-speed turret. The full Pave Low installation includes an APQ-158 radar.

◆ APG-65

See the Anti-aircraft Warfare section; APG-65 is a dual-purpose radar.

◆ APQ-126

Band: Ku (7 selectable frequencies, 600-MHz band)
Beam: 2.5×18.4 deg (antenna tilts to cover $45 \times +70/-30$ deg)
Peak Power: 60 kW **Gain:** 28.5 dB
Pulse Width: (i) 0.2 (ii) 1 (iii) 2 microsec
PRF: (i) 3600 (ii) 720 (iii) 360 pps
Scan Rate: 90, 120, 180 deg/sec (horizontal); 150 deg/sec (vertical)
Antenna Dimensions: 19.5×13 in
Antenna Weight: 45 lb (230 lb total)

APQ-126 is Texas Instruments's radar for the A-7E Corsair II attack bomber. Compared to the earlier APQ-116, 126 added a third pulse mode and a terrain-avoidance mode, in addition to ground ranging, ground mapping for navigation, and blind bombing. Frequency agility (over a 30-MHz range at a switching rate of 100 Hz) is used to improve ranging accuracy and to achieve long-range target detection. APQ-139 is a later version with AMTI.

◆ APQ-148/156/APS-130

Band: Ku (16–17 GHz) **Beam:** $1.4 \times 35-50$ deg
Peak Power: 100 kW **Gain:** 39.2 dB
Pulse Width: (i) 0.4 (ii) 1.25 (iii) 3.0 microsec
PRF: (i) 2400 (ii) 800 (iii) 300 pps
Scan Rate: 100, 50, or 25 deg/sec sector scan
Antenna Dimensions: 36×17 in
Antenna Weight: 138 lb

Data above apply to APQ-92, the radar superseded by APQ-148; they give an indication of its characteristics, although the details of the newer radar will be somewhat different. Total coverage in the radar described above is 120 deg in the horizontal, and vertical coverage limits are $+20/-40$ deg, depending on tilt. Total weight was 490 lb. The associated monopulse target tracker, APQ-112, used a 14-in circular parabolic dish (gain 30 dB, weight 75 lb, beam 3.8 deg). It operated in Ku-band

This diagram illustrates the principle of the APQ-148 and -156 radars. The interferometer associates an elevation angle with each combination of range and azimuth; the processor picks out the particular combinations corresponding to each point observed by the main radar, using azimuth and range gates around those points. The result is a terrain display. (Norden Systems)

(15.8–17 GHz), with a peak power of 60 kW (0.4 microsec pulses, PRF 2400 pps). The beam could scan over 90 deg in the horizontal, and between $+15$ and -45 deg in the vertical. Scan rate was 50 deg/sec in the vertical, to find the elevation of a target detected by the main APQ-92, and sector scan rate was 60 deg/sec. Total weight was 300 lb.

APQ-148 and -156 (a modified -148) are the A-6E radars. APQ-148 operates in Ku-band, with peak power about 60 kW; the antenna is 24×18 in (originally 36×18 in). Total APQ-148 weight is about 500 lb. In the APQ-156 version (total weight 450 lb) it has 3 alternate PRFs and 4 alternate pulse widths. These radars have the same video processor as APQ-92 but have new antennas (AS-2604) and frequency-agile transmitters. Both -148 and -156 have TWS capability. The manufacturer (Norden) claims that the receiver design maximizes azimuth resolution, achieving about half the value that would be calculated based on antenna size (hence the use of a significantly smaller antenna in the newer radar). That suggests that these radars use some form of monopulse processing. They are frequency-agile, primarily to reduce ground clutter and scintillation.

These semi-3D radars replace the earlier combination of the 2D APQ-92 and the pencil-beam (monopulse target tracker) APQ-88 or -112. APQ-92 used AMTI processing to detect significant moving ground targets. APQ-88 or -112 locked onto a target designated by the BN on a display generated by the main radar. It was used primarily to provide target elevation to the central computer. The target tracker also provided a supplemental terrain map, presented on the pilot's radar CRT beneath the vertical display.

The combination of 2 separate radars was a major maintenance problem. In 1969 the A-6 system was modified so that the target-tracker radar, which was essential for elevation data, could also provide some search data, in a redundant-target-tracking (RTT) mode. However, the main radar could not be

An APQ-156 antenna, showing the phase interferometer below the main reflector. (Norden Systems)

An APS-130 antenna for the EA-6B. This radar is essentially APQ-156 without the interferometer. (Norden Systems)

discarded because its fan beam was needed to achieve a sufficient search rate.

The solution was to replace the second (pencil-beam) radar with an interferometer consisting of 2 rows of 32 horns each, 24 in wide, moving with the main dish in azimuth. The difference in time of arrival of a signal in the upper and lower rows of horns measures the elevation angle to a target picked up by the 2D reflector. The interferometer produces a continuous elevation-range profile for terrain avoidance.

The combination of conventional dish and interferometer, with a single transmitter, is APQ-148.

Radar operating modes are search (basic mode), beacon, airborne moving target indicator (AMTI), and terrain clearance for low-level flight. Radar range modes include displays at up to 150 nm as well as much more detailed ones out to 75 nm. Minimum PPI range is 5 nm. Targets may be detected in the PPI mode using AMTI, which operates at short ranges (limits are 18, 22, and 27.5 nm depending on the display mode). There are also 2 special sector modes, ARE-60 (automatic range expansion—60 deg) and ARE-30, B-scans between ± 30 and ± 15 deg, primarily for attack. The depressed-center PPI mode (azimuth sector 20–110 deg) is primarily for navigation.

There are 2 displays, a 6-in direct-view radar indicator (DRVI) for the BN and a 5-in storage tube for the pilot (which can retain a radar picture when the radar scans only once, then shuts down, for stealth). The APQ-156 version has only a DRVI. In addition, terrain data are displayed for the pilot, for terrain avoidance, on the horizontal display, gray shades giving range information, and height giving elevation data. The terrain win-

dow on the vertical display is 26 deg wide (in terms of real azimuth); this is search-radar-terrain-avoidance (SRTC) data.

Norden received a contract to convert existing APQ-92 radars to TWS operation in August 1969. The first 13 APQ-148 radars were ordered in 1970 (total cost \$5.946 million, the first being delivered in 1971), with about 200 being delivered by the end of 1975. Six preproduction AMTI modification kits (MX-9736/APQ video processors) were ordered in 1976, followed by an order for 18 in 1978, and a contract for 295 more in 1980.

At that time work also began on updating the APQ-148 to -156 configuration. An analog signal-converter unit is replaced by a digital unit. The BN control box is replaced by 2 panels, an updated control box and a separate built-in test panel. The moving-target indicator is replaced by a more advanced unit. Reportedly, this modification is associated with TRAM, and the digital signal converters may be needed to process TRAM video for presentation on the radar scopes. Reportedly, Norden is developing an ISAR modification for APQ-156, and a version of this radar has been installed in B-52s as part of their offensive-avionics-system (OAS) upgrade.

Early in 1985 Norden received a Grumman order for the A-6 upgrade radar, which became APQ-173 (see below).

APS-130 was a simplified version of APQ-148 for the EA-6B Prowler, but it has been superseded by APQ-156C (first ordered in 1987), this radar now being standard in all versions of the A-6.

◆ APQ-168/174

APQ-168 is the Texas Instruments radar selected for air force and navy versions of the Bell-Vertol V-22. APQ-168 is intended primarily for navigation and terrain avoidance and is derived from a radar developed for the LANTIRN low-level attack sensor. Flight trials on board an HH-60 helicopter began in 1988.

APQ-174 is another derivative of the same LANTIRN radar, intended specifically for combat search and rescue.

◆ APQ-173

APQ-173 was the projected radar for the canceled A-6F Intruder and was intended to replace the APQ-156 of the earlier version. The contract award to Norden was announced in 1985. The future of this radar is in doubt, given the cancellation of the A-6F and uncertainty over the A-6G (which was intended to have most of the avionics planned for the -6F, but not some other improvements). This radar may have been derived from a multimode radar developed by Norden for Israel.

APQ-173 uses doppler beam sharpening for ground mapping and has an ISAR mode for ship classification. Reportedly, APQ-173 can acquire and track tactical targets at more than twice the range of the earlier APQ-156.

APQ-173 is a growth version of APQ-156 with ISAR, increased (reportedly more than doubled) range, sharper resolution (using doppler sharpening), and an air-to-air mode suitable for AMRAAM use. Increased range was considered crucial because the new generation of standoff weapons exceeds current radar range. With the cancellation of the A-6F for which it was designed, APQ-173 was to have been installed on board the new A-12. However, Norden was dropped by the A-12 systems integrator (GE), and at this writing the radar is the subject of a lawsuit.

The A-6F would have combined APQ-173 with dual AYK-14 mission computers (for redundancy), and its combat system would have been tied together by a 1553B bus. Other major features would have been the IR Video Automatic Tracking (IRVAT) system, ALQ-165, ALR-67, and NAVSTAR GPS.

◆ APQ-183

APQ-183 is Westinghouse's multifunction radar (MFR) for the A-12. The first was delivered in August 1990. APQ-183 includes elements of the B-1B and F-16 (APG-66) radars and, reportedly, also reflects some of the experience gained in developing the earlier APQ-173, canceled in April 1989. Reportedly, APQ-183 is a modular radar, including SAR and ISAR elements.

◆ APS-20

Band: S (2820 MHz) **Beam:** 3.5×8 deg
Peak Power: 2 MW **Gain:** 32 dB
Pulse Width: (i) 0.67 (ii) 2 microsec **PRF:** (i) 900 (ii) 300 pps
Scan Rate: 2, 4, 6, or 15 rpm; sector scan 20–50 deg/min
Antenna Dimensions: 8×3 ft, parabola
Antenna Weight: 180 lb

These data apply to APS-20F. This radar was originally developed late in World War II for AEW and was carried by a variety of single-engine aircraft, including the British Gannet. APS-20 also proved very effective at snorkel detection and for that reason equipped the P-2 Neptune ASW aircraft. During the Falklands War, Argentine P-2s used their APS-20 radars to target British warships for Super Étendards carrying Exocet missiles.

◆ APS-80A

Band: X (8.5–9.6 GHz)
Beam: 2.4×3.5 deg (3.6-deg pencil beam; 18-deg csc²) (coverage: $45 \times +10/-20$ deg)
Peak Power: 143 kW **Gain:** 35 dB
Pulse Width: 2.4 microsec **PRF:** 400 pps
Scan Rate: 6 rpm (sector scan 48 scans/min)
Antenna Dimensions: 42×24 in
Antenna Weight: total weight 380 lb

APS-80 is the radar installed on board P-3A and P-3B patrol aircraft, replaced in P-3C updates by APS-116.

◆ APS-88

Band: X (8.5–9.6 GHz)
Beam: 2.6×5.0 or 3.2×18.0 csc² deg (coverage: $40 \times +10/-25$ deg)
Peak Power: 45 kW **Gain:** 33.5 dB
Pulse Width: (i) 0.35 (ii) 0.8 (iii) 4.5 microsec
PRF: (i) 2000 (ii) 1025 (iii) 200 pps
Scan Rate: 6 or 28 rpm; sector scan 36 deg/sec
Antenna Dimensions: 42×20 in
Antenna Weight: 61 lb (total 228 lb)

APS-88 is the periscope-detection and surface-search radar of S-2 Trackers.

◆ APS-115

Band: X **Beam:** 2.4×3.6 deg
Peak Power: 143 kW **Gain:** 34 dB
Pulse Width: (i) 2.5 (ii) 0.5 microsec **PRF:** (i) 400 (ii) 1600 pps
Scan Rate: 6 or 12 rpm; sector scan 36 or 72 deg/sec
Antenna Dimensions: 3.5 ft
Antenna Weight: 84 lb (each); total system weight 523 lb

APS-115 is the sea-search radar of the P-3 Orion. This radar is unusual because it uses 2 antennas, 1 in the nose and 1 beneath the tail, to achieve 360-deg coverage, without disturbing overall streamlining.

◆ APS-116/134/137

Band: X (9.5–10.0 GHz) **Beam:** 2.4×4.0 deg
Peak Power: 500 kW **Gain:** 34 dB
Pulse Width: (compressed) (i) .0025 (ii) 0.5 (iii) .012 (iv) .012 microsec (all pulses are transmitted at 0.5 microsec duration) (compression ratio 250:1)
PRF: (i) 2000 (ii) 400 (iii) 400 (iv) 400/2000 pps
Scan Rate: (i) 300 (ii) 6 (iii) 60 (iv) searchlight, for ISAR
Antenna Weight: total system weight is 472 lb

These data apply to APS-137.

APS-116 is the surface-search radar of the S-3A Viking, of the German version of the Atlantic, and of the Canadian CP-140 Aurora. Manufactured by Texas Instruments, APS-116 is a coherent (MTI) high-resolution (short-pulse) radar. For periscope detection amid the clutter of rough water, or for high-altitude surveillance, this radar rejects clutter by using pulse compression and fast-scan processing. APS-116 has TWS capability but can also operate in a searchlight mode, tracking a single small target. Modes are (i) periscope and small-target detection, (ii) navigation and weather avoidance, (iii) long-range maritime surveillance, and (iv) ISAR imaging.

Performance in test: 26-nm range on a snorkel (aircraft at

APS-137(V)1. (Texas Instruments)

1500 ft), 33-nm on a fast attack craft (from 5000 ft), 75-nm on a destroyer (8000–10,000 ft). These are maximum ranges in sea-state 3/4, and mean ranges were shorter. For example, the average range on a snorkel was 15.5 nm. Minimum resolution is 1.5 ft.

APS-134 is the "international successor" to APS-116, incorporating the latter's less sensitive improvements. Peak power is 500 kW, with a fast-scan antenna. Modes are

- (i) periscope detection in clutter, with high resolution (1.5 ft): 2000 pps, 150 rpm, 32-nm display, adjustable false alarm rate;
- (ii) long-range search/navigation, with medium resolution: 500 pps, 6 rpm, 150-nm scale;
- (iii) maritime surveillance, with high resolution (short pulses): 500 pps, 40 rpm, 150-nm scale. This radar was chosen for the U.S. Coast Guard HC-130.

APS-137(V) is a modified APS-116 incorporating ISAR, for the S-3B Viking; 137(V) supports the Harpoon antiship missile. In ISAR mode, the aircraft antenna does not scan the ship but points in searchlight mode, examining the different doppler shifts as the target moves.

APS-137 will replace APS-115 on some P-3s.

In 1989 an APS-137 was mounted experimentally on board the hydrofoil *Hercules* (PHM 2), currently used primarily for anti-drug-smuggling surveillance. In the frequent surface-ducting conditions of the Caribbean, it can often see well beyond the ship's nominal radar horizon, and its ISAR feature is used

APS-137 was mounted experimentally on board the hydrofoil missile boat *Hercules*, to provide OTH ship identification, using ducting and the ISAR capability of the radar. It occupies the mast radome. (Texas Instruments)

to identify potential targets, separating them from the dense shipping traffic. In one exercise *Hercules* was able to distinguish a missile destroyer from surrounding shipping and, thus, to cue in other hydrofoils for a simulated attack.

◆ APS-120/125/138/139/145

See the Anti-aircraft Warfare section.

◆ APS-124

Band: X **Beam:** 1.2×20 deg
Peak Power: 350 kW **Pulse Width:** (i) 0.5 (ii) 2 (iii) 1 microsec
PRF: (i) 1885 (ii) 940 (iii) 470 (16-period staggered PRF) pps
Scan Rate: (i) 120 (for weather) (ii) 6 (iii) 12 rpm
Antenna Dimensions: 72×12 in planar array
Antenna Weight: total system weight is 208 lb

APS-124 is the sea-search radar of the LAMPS III (SH-60) helicopter. Small targets are detected in the midst of sea clutter by sea-clutter decorrelation (fast scanning and scan-to-scan integration). With a low profile, the antenna can be slung under the helicopter, for full 360-deg coverage. The short-pulse rapid-scan mode is for weather. Estimated range on a 1-m^2 target is 16 nm, compared to 20 nm for APS-115 or -116.

The antenna is AS-4035.

◆ APS-127

Band: X **Beam:** 5×6 deg
Peak Power: 200 kW **Pulse Width:** (i) 2 (ii) 0.5 microsec
PRF: (i) 400 (ii) 1600 pps **Antenna Dimensions:** 2×2.6 ft
Antenna Weight: total weight 295 lb

APS-127 is Texas Instruments's surface-search radar for small maritime-patrol aircraft, such as Danish Gulfstream IIIs. Estimated range on a 1-m^2 target is 18 nm. This radar is carried by U.S. Coast Guard HU-25A aircraft. APS-127 is unusual in using a stabilized antenna. It integrates successive scans by using a direct-view storage-tube display for both plot and surveillance information.

◆ APS-128

Band: X (9375 MHz) **Beam:** 2.4×9 deg
Peak Power: 100 kW **Gain:** 32 dB
Pulse Width: (i) 2.4 (ii) 0.5 microsec **PRF:** (i) 400 (ii) 1600 pps
Scan Rate: 15 or 60 rpm **Antenna Dimensions:** 42×11 in

Eaton's sea-surveillance radar is for light aircraft, particularly for antismuggling and EEZ enforcement. Users are Brazil, Chile, and Gabon on Brazilian-built Embraer EMB-111 aircraft; the

Japanese Maritime Self-Defense Agency on Beech 200Ts; the Royal Malaysian Air Force and Indonesian Air Force on C-130MPs; Spain and Uruguay on CASA C-212s; Spain on retrofitted C-130s; NASA on the Short Skyvan; and the U.S. Customs Service on an ILC Aerostat (balloon).

The flat-plate array antenna is compensated for pitch and roll up to 20 deg and can be tilted up to 15 deg up or down. The transmitter is frequency agile (85 MHz peak-to-peak). Claimed mean time between failure is 442 hr in long-term use.

Unlike most radars, this one uses a television-type (raster-scan) display. The radar signal is converted into a digital signal before display, and the bright 8-in (diagonal) tube can be shifted to display the outputs of other sensors, such as FLIRs. The display is bright enough to have signal-processing features, including target enhancement and scan-to-scan integration, so that target tracks can be generated. The radar is also fully integrated with inertial, Omega, or other navigational systems, and the display can be switched to other sensors, such as infrared.

Claimed performance: 30 nm range on a snorkel or a small fishing vessel (10 m^2) in sea-state 3; 60 nm on a trawler (150 m^2) in sea-state 5; 100 nm on a freighter (500 m^2) in sea-state 5; 120 nm on a tanker (1000 m^2) in sea-state 5.

There is a pulse-compression version for small-target detection; the manufacturer claims that resolution is 5 times better than that of standard maritime radars. Frequency is selectable between 9.2 and 9.5 GHz in 20-MHz steps, and there is 100-MHz pulse-to-pulse frequency agility. Peak power is 8 kW minimum (10 kW nominal) but equivalent to 500 kW (50:1 compression ratio), for 5-microsec pulses (compressed to 0.1 microsec). PRFs are 2000, 1500, 800, and 400 Hz.

The current manufacturer, the Telephonics Corp., offers DTACS, the Digital Tactical System, an APS-128 plus added sensor capacity, with tactical-navigation and sensor-plot data displayed on the radar screen via microprocessor control. DTACS is installed on Puerto Rican police Beech 200T aircraft and has been offered as an S-2E or helicopter system.

◆ APS-131/135/SLAMMR

These are Motorola X-band, side-looking, SAR radars. APS-131 and -135 are used by the U.S. Coast Guard to detect ships and boats as well as oil slicks. SLAMMR (side-looking airborne modular multimission radar) is a commercial version sold to Indonesia and carried on board modified Boeing 737s (the antennas are on the upper aft fuselage). APS-131 uses two 8-ft slotted arrays mounted back to back in a stabilized pod carried under the belly of an HU-25A aircraft. There are 4 range settings: 13.5, 27, 54, and 108 nm. APS-131 has a peak power of 200 kW (0.2-microsec pulses, PRF 677 or 1477 pps) and produces a 1-deg beam. APS-135 is a similar radar carried by Coast Guard HC-130s. Its two 16-ft antennas are mounted on the sides of the fuselage. The fan beam is 0.5 deg wide (csc² fan). In both cases, the output of the radar is a film image analogous to a strip map.

Eight of these radars were delivered to the U.S. Coast Guard in 1982.

Indonesia uses 16-ft antennas for the SLAMMRs in its Boeing 737 surveillance aircraft; there is also a version with 8-ft anten-

SLAMMR radar occupies the dorsal strake, aft, on this Indonesian Boeing 737. (Motorola)

APS-135 in a side pod on the fuselage of a Coast Guard HC-130 (above the landing-gear fairing). (Motorola)

nas. The 16-ft antenna gives 0.5-deg resolution in azimuth. Peak power is 200 kW (generated by a magnetron; a 0.2-microsec pulse makes for 30-m range resolution). Despite the noncoherent design, there is very good pulse-to-pulse stability for moving-target indication; the optional MTI processor uses an FFT, to detect targets simultaneously from 0 to 80 nm. Flying at 30,000 ft, SLAMMR can detect a 100-m² target out to 100 nm (for maritime surveillance), depending on ocean conditions and aircraft speed and altitude. It can detect a 1-m² target out to 35 nm. With the MTI processor, it can detect small targets moving at 5 mph at 50 nm and larger and faster targets at 80 nm. The single operator station uses either a dry film display or a color CRT. Current upgrades include a high-resolution digital recorder.

◆ APS-143

Band: X (9.2–9.5 GHz, agile over 200 MHz)
Peak Power: 8 kW **Gain:** 31–33 dB typical
Pulse Width: 5 or 17 microsec, compressed to 0.1 microsec (compression ratio 70:1, 240:1)
PRF: 2500, 1500, 800, 400 pps

This Telephonics small-aircraft sea-search radar is presumably a potential successor to APS-128. (V)1 is in coast guard service on shipboard aerostats (balloons). (V)2 has been selected by the U.S. Air Force for range surveillance and safety. (V)3 has been selected for the Sikorsky S-70C(M)1 ASW helicopter and for the NATO frigate helicopter (NH 90). All versions use a TWT transmitter and a flat-plate stabilized antenna. Claimed performance: detects a 1-m² target at 37 km in sea-state 3 from low altitude. Azimuth accuracy is 0.5 deg, and range resolution is 46 m. Total weight is 81.8 kg. The radar can be fitted for TWS and MTI and for missile guidance; it can interface with ESM or IFF. Maximum range is 370 km. The display is a digital raster-scan unit; memory is 512 × 512 × 3 pixels for video, and 512 × 512 × 1 for overlay graphics. APS-143 combines APS-128 technology with a compressive receiver similar to that in the B-1B. Telephonics describes it as the lightest, least expensive pulse-compression radar of its type in existence. Total system weight (APS-143) is 180 lb.

◆ ASQ-173

The pod-mounted F/A-18 Laser Spot-Tracker/Strike Camera (LST/SCAM) is manufactured by Martin Marietta. The stabilized laser spot-tracker occupies the forward end of the pod. The system picks up a target designated by a ground- or air-based laser, feeding digital target data into the F/A-18 fire-control system and indicating target position on the HUD. The target is acquired at maximum standoff range on the first pass, reducing aircraft vulnerability; and communication between the attack pilot and the forward air controller or ground target designator is minimized. The 35-mm strike camera at the after end of the pod is gimballed so that the target can be photographed while the attacking airplane maneuvers. Dimensions: 8 × 90 in, weight 155 lb, required MTBF at least 333 hr. This pod occupies

F/A-18 laser spot tracker/strike camera (LST/SCAM, or AN/ASQ-173). (Martin Marietta)

the space on the starboard side of the F/A-18 body otherwise occupied by a Sparrow missile.

◆ HARPSS

Texas Instruments High-Altitude Remote-Platform Surveillance System is a large-aperture IRST system to be tested on board a P-3C in 1991. It is to be tested through the end of FY91, with production scheduled for FY96. HARPSS has an 8-in aperture and shows greatly improved clutter rejection; it covers 360 deg. The same IRST system will be modified as an airborne-early-warning sensor.

◆ Integrated IR Search and Track/Laser Rangefinder Sensor Demonstration

In November 1989 Hughes received a 27-month contract to demonstrate the operation of an IR sensor and a CO₂ laser through a single aperture. Such a device would greatly reduce the surface area of the sensor; the main technical problem is to shield the IR sensor from the laser. The ground test was scheduled for August 1990 and the airborne test for late 1991.

◆ A-6E System Weapons Improvement Program (SWIP)

SWIP began in January 1988 as an interim improvement program for A-6Es, pending the production of the A-6F. With the cancellation of the A-6F and then of the more austere A-6G, it became a means of maintaining the A-6 fleet pending the introduction of enough A-12s. SWIP has encountered some funding difficulties but will presumably benefit from any slowdown in the A-12 program. It addresses the major limitations of the current A-6E: the lack of any passive night-attack capability, limited ECM, analog displays and controls, a slow (and saturated) computer, no ISAR radar, marginal engine thrust, and marginal bringback (i.e., capability to return to a carrier without dropping fuel and expensive weapons; current bringback, including fuel, is 6000 lb). The same list of defects was used to justify the A-6F; presumably, the ultimate goal of SWIP is not too far from the canceled project. However, in order to be affordable, SWIP proceeds in blocks. Block I is now underway, and Block II is being funded. Late in 1989 the Senate rejected Block III in favor of Block II for FY90. Block III is to be requested under the FY91 budget.

Block I provides Harpoon IC, HARM, and Maverick capability, as well as survivability upgrades and the new Boeing wing.

SWIP Block IA was begun under the FY90 program. It includes a new mission computer (as yet undetermined) driving a HUD, a standard central air-data computer on the 1553 bus, the new IDAP defensive package, improved navigation systems (GPS, with software installed in the ASN-139 inertial-navigation system), and a new TACAN (ARN-118 rather than ARN-84). The existing ALQ-126 countermeasure is retained, with new antennas in a modified wing fillet. The first SWIP Block IA airplane should begin flight tests in about May 1991. Eventually, a total of 110 aircraft are to be updated.

IDAP, the integrated defense avionics program for the A-6E, is being installed in conjunction with SWIP Block 1A but is separately funded. It is to be installed beginning in 1993.

Block II provides Cats Eyes/NVG for passive night attack, the AWW-13 data-link pod for the SLAM missile, weapons-control-system wiring upgrades, and safety improvements such as a better flight director (TADS, the tactical-attitude direction system).

IDAP employs an S-band active warning radar, covering both forward and rear hemispheres, which triggers chaff, IR decoys, and a new towed active decoy. It also advises the pilot to take the best possible evasive course. Grumman claims the towed decoy is the first operational one of its kind. Developed by China Lake, it has already completed flight and development tests. An A-6E carries 3 towed decoys deployed from a belly position well abaft the wing, near the chaff dispensers. IDAP also provides the pilot with night (FLIR) imagery in the main display.

◆ Harrier Night Attack (Cheap Night)/Real Night

From late 1989 on, Marine Corps Harriers (AV-8B) will be equipped with a special austere night-attack system, comprised of a narrow-field FLIR camera in the nose and a pair of NVGs for the pilot. The FLIR image, with a 22-deg field of view, is presented on the pilot's HUD (at 1:1 scale) and can also be shown on a cockpit CRT. The goggles allow the pilot to see to the side, and they expand the field of view at minimum cost (and minimum space and weight penalty). Although the view through the goggles is not as sharp as that presented by the FLIR, pilots have found no difficulty in integrating the two. The result is much simpler and less expensive than the air force's LAN-TIRN, partly because the field of view of the FLIR is fixed (pointing ahead). Pilots look into a turn with their goggles, rather than slew the FLIR, which is mounted in the nose above the angle-rate bombing system. Unit flyaway cost is estimated at \$1.2 million.

The goggle concept, code-named Cheap Night, evolved in 1984–85 from a proposal, presented at the navy/marine strike school, for an inexpensive night-vision device to expand Harrier capabilities. GEC Avionics was chosen to supply the Cat's Eye goggles. Cat's Eye was developed as part of a continuing British program, Night Bird, begun in 1978.

The U.S. Navy conducted a series of foreign weapons evaluation (FWE) projects: Cheap Night, Quick Night, Real Night, and also USN Fleet Quick Night. The Cheap Night program began in April 1984, using a TA-7C at China Lake to develop a night visual attack capability, balancing capability against cost and using existing technology. Using goggles, a pilot could fly at 450 kt at 200 ft, then pop up and bomb.

The next program, Quick Night (1985–86), used an A-6E at NATC Patuxent River. This time the crew used Cat's Eyes goggles and the navigational FLIR of the A-6E. The crew found the FLIR field of view too narrow (the airplane had no HUD), but they liked the goggles and the combination of filtered cockpit lighting and the FLIR. A 12-month Fleet Quick Night program was then conducted, using an Atlantic Fleet A-6, to further define night-system requirements.

The current A-6E program is Real Night, again using GEC equipment. This time the A-6 is equipped with a CO₂ laser-scanning and obstacle-warning pod (the British-built GEC LOCWS) to paint unseen obstacles on the HUD projecting a FLIR image. The pod scans an 8-deg box (2 deg up, 6 down, 4 across) in a near-vertical sinusoidal pattern at 50 kHz, building up a full frame every 1–1.5 sec. Once obstacles have been detected, they are stored and continue to be displayed even after they have moved out of the 8-deg box. Locus is designed to detect a 1-cm cable at 1.5 km in heavy rain. The first test flights were in 1986, using an A-6 carrying a FLIR with a thermal target-cuing device in an underwing pod.

As of May 1988, the U.S. DoD planned to buy 600 Laser Obstacle and Cable Warning Systems (LOCWS) and 2000 NVGs (part of Cheap Night).

Night attack F/A-18Cs and Ds are to receive a related system using a 20-deg HUD.

The marine order for Cat's Eyes goggles was the first major sale of the system. An operational A-6E squadron began using them in 1987, and 83 were initially ordered, with an option for 245 more. They have combiner eye pieces underneath the actual image intensifier, giving the user an unrestricted view when looking down toward the HUD or instrument panel. Other goggles require the user to view the HUD or instruments through the tubes, giving a poor view. When the pilot looks outside, a light-intensified image is projected onto the combiner eye pieces. An IR beam points up from the instrument panel, switching the goggles off automatically when the pilot looks down inside. An Integrated Night-Vision System (INVS) was begun late in 1987, to develop a lightweight, integrated, night-vision-goggle helmet that would be balanced to eliminate the torque and strain caused by unbalanced goggle weight during high-G maneuvers.

◆ ARBS (AN/ASB-19)

Hughes's Angle Rate Bombing Set was developed for the Marine Corps, to improve the accuracy of visual bombing. ARBS automatically tracks ground targets and automatically acquires spots designated by ground-based lasers. The tracker provides the bombing (weapons-delivery) computer, an IBM System 4/Pi, with both the line-of-sight angle to the target and the rate of change of that angle. The air-data computer provides true air speed and altitude; and the weapons-delivery computer solves for the ballistic path of the bombs, providing the pilot with an appropriate course displayed on the HUD and releasing the bombs at the appropriate moment. No range measurement is required (it is implicit in the combination of altitude and line-of-sight angle). Targets are tracked by a dual-mode television/laser tracker. The weapons-data computer stores all appropriate weapons ballistic data.

Nine preproduction models were built in 1975, and tests began in the summer of 1976. ARBS was initially installed in A-4M attack bombers, which had no elaborate radar system, and was also compatible with the AV-8 Harrier, which ARBS now equips. In an AV-8B, ARBS consists of a dual-mode tracker (DMT) in the nose, a weapons-delivery computer (WDC), and control units (CUs). The DMT acquires and tracks laser-designated targets; in daytime, the pilot can also designate and track using a television. Because the television camera is located next to the laser tracker, transition from mode to mode is very easy; the airplane can also acquire (and then track) targets designated by lasers on board other aircraft or on the ground. In addition, because the airplane is provided with an inertial navigation system, a target position can be predesignated, and the laser set to point it out when the airplane comes within range. The WDC computes weapon trajectory and filters DMT data, delivering them to the aircraft general-purpose computer, which actually flies the airplane and drops the bombs. Tracker slew angle and target designation are controlled from the aircraft stick (the AV-8B has a HOTAS cockpit); target data are presented on the HUD.

Typical television acquisition range is 15 km (8.2 nm) for a 3-m target with 10% contrast. A typical target designation laser 1 km from a target can be detected at 15 km under similar conditions. The optics can slew to compensate for 450 deg of rolling motion, covering +10/–70 deg in elevation and ±37 deg in azimuth. The system computer is designated CP-1278; it is an IBM System/4 Pi SP-1, with 32k 16-bit words (17 bits including parity check), operating at 440 KOPS. Total system weight is 59 kg [130 lb], and estimated cost, about 1987, was \$210,000.

This system was originally the Improved Weapon Delivery System (IWDS) for the A-4M.

◆ RDR-1300

Band: X (9305–9385 MHz) **Peak Power:** 10 kW
Pulse Width: (i) 0.5 (ii) 2.35 microsec
PRF: (i) 800 (ii) 200 pps
Scan Rate: 12 or 36 looks/min (scan angle 120 or 40 deg)
Antenna Dimensions: 10, 12, or 18 in flat plate

This Bendix radar, also made by FIAR, is standard in the Hughes/McDonnell 500 Defender, which many navies use as a lightweight ASW helicopter. The U.S. Army designates it APN-215 (V). It is also widely used commercially. RDR-1300 can be used both in the radar mode and in a beacon reception mode (9310 MHz).

The antenna is stabilized in line-of-sight within 1 deg. Range accuracy is 1%, and minimum tracking range is 600 yd. Data are held digitally in the radar memory, and the display is a 4.34×3.33 -in high-contrast CRT. Range marks (for, respectively, the long/short range modes) are 2.5/0.5, 5/1, 10/2, 20/4, 40/10, 80/20, 160/40, and 240/60 nm.

RDR-1400 is a related helicopter navigation and beacon radar, used on the Italian navy's utility version of the Sea King helicopter. The 1400C version incorporates a sea-surveillance mode, with clutter rejection to detect small boats, buoys, etc.

The RTR-1401B receiver-transmitter operates at the same peak power but with different PRFs, 720 and 240 pps. Maximum range: 185 nm with the 10-in antenna, 240 nm with the 12-in, and 322 nm with the 18-in.

◆ RDR-1500

Band: X (9370–9380 MHz; 9305–9315 MHz for beacon)

Beam: 2.6 or 3.4×10.5 deg **Peak Power:** 10 kW

Pulse Width: (i) 0.1 (ii) 2.35 microsec

PRF: (i) 800 (ii) 200 pps

Antenna Dimensions: 99.06 or 73.66 $\times$ 22.86 cm flat plate [39.0 or 29.0 $\times$ 9.0 in]

This Bendix-FIAR radar is derived from the RDR-1300C and carried on board coast guard HH-65A Dauphins. It has a high-resolution mode for sea search and terrain mapping and a long-range mode for weather avoidance. Maximum range is 300 km [164 nm].

◆ TNR

Texas Instruments' Ku-band pulse-compression Tornado Nose Radar equips German naval strike Tornado aircraft (the British nonnaval air-defense version uses a different radar). There is no official designation; TNR is commonly used. The Tornado system might be imagined as a more elaborate and more automated version of the A-6E described in the Surveillance and Control section, using a 64k central computer, with TNR as its main sensor. The main navigational sensors are an inertial platform and a doppler radar. The main computer can store planned targets for preset attack (using dive or loft bombing, air-to-surface missiles, or guns). Bombs can also be dropped on targets of opportunity, using a continuously computed impact line (CCIL) displayed on the HUD, or using laser target marking.

TNR consists of 2 separate elements sharing a common mounting, power supply, and computer/processor, the TFR (terrain-following radar) and the GMR (ground-mapping radar). The former is used for high-speed approach and escape, the latter for weapons control. TFR is limited to a terrain-following mode. GMR has mapping, air-to-surface ranging, air-to-air tracking, land/sea target lock-on, and beacon-homing modes. There is also a home-on-jam mode. The radar image is digitally scan converted for HUD display. ECCM features include PRF jitter and frequency agility. The main GMR display is the combined display (CRT) in front of the rear seat; radar data can also be displayed on the pilot's HUD. GMR employs a conventional, stabilized dish antenna and operates at moderate PRF. It has a fairly narrow beam in both azimuth and elevation since it can be maneuvered in azimuth and in elevation for the air-to-surface ranging mode, the outputs from which are slant range, range rate, and pointing angles to the target.

The TFR antenna is a 2-lobe, monopulse, phased array mounted below the GMR antenna; the central system computer integrates its output with other navigational sensor data. In straight flight it performs a 2-bar box scan (± 8 deg in azimuth, $+10$ to -20 deg in elevation); when the airplane turns, those parameters open up, the scan being steered into the turn. At a

high rate of turn, the scan becomes a figure-8 (total scan about 15 deg in azimuth; the antenna is steered as much as 7 deg into the turn). The antenna thus looks ahead into the direction the airplane is about to take. The associated computer lays down a "ski-toe" contour ahead of the airplane, the rise in the toe being set for a given level of pilot comfort (maximum push-over varied in minus 0.95-G increments for the hard ride, and minus 0.5-G in soft ride). The system climbs the airplane whenever a terrain feature is detected penetrating the set contour. TFR operates at high PRF.

TNR has a height-finding mode in which the angle to an identified surface target is measured as a datum.

The radar is built under license by Ferranti/GEC Avionics, AEG/Telefunken/Siemens, and FIAR. A Phase I improvement (1985) went into production in 1987; it provides the radar with a faster computer.

TNS was chosen about 1970, winning out over a proposal for a 3-part radar, using X-band for ground mapping, Ku-band for operation near the target, and a laser for final ranging. There was also an unsuccessful Autonetics proposal for a single phased array.

AIR-LAUNCHED MISSILES AND GUIDED BOMBS

ARGENTINA

◆ Martin Pescador

Dimensions: 21.85 m $\times$ 2.95 m (span 73 cm) [8.6 $\times$ 116.1 $\times$ 28.7 in]

Weight: 140 kg [309 lb] **Warhead:** 40 kg [88 lb]

Propulsion: rocket **Speed:** Mach 2.3 (impacts at Mach 1.1)

Range: 2.5–9 km [2700–9800 yd]

Martin Pescador, as displayed in Argentina, 1982. (Dr. R. S. Scheina)

This radio-command-guided antiship missile was developed by the *Instituto de Investigaciones Científicas y Técnicas de las Fuerzas Armadas* (CITEFA); the name means Kingfisher (which suggests its role). It is sometimes described as a Bullpup derivative. The guidance operator follows the missile, using the tail flare. Martin Pescador can be launched from an airplane at up to Mach 0.5, or from a low-speed helicopter (in which case its effective range is 4.3 km).

Development was completed in 1979, and the missile entered service in 1982. Two or three were used, unsuccessfully, during the Falklands War. A total of 68 were reportedly manufactured between 1981 and 1984, to replace AS 11 and AS 12 missiles in Argentine service.

CHINA (PRC)

◆ HY-4, C601

See Silkworm (ship-launched version).

FRANCE

◆ Exocet (AM 39)

See ship-launched versions.

Exocet AM 39. (Author)

◆ ANL

ANL is the projected Aerospatiale-MBB aircraft- and helicopter-launched antiship missile (*anti-navire légère*): 200 kg (50-kg warhead), with solid-fuel ramjet propulsion (for speed greater than Mach 2) and 30-km range. Guidance will be mid-course inertial and terminal active radar.

This weapon began with a German Navy requirement for a missile for helicopters, combat aircraft, maritime-patrol aircraft, and even ships operating in narrow waters. However, ANL would also fill a potential French requirement for an AS-15TT replacement. MBB will probably collaborate with Aerospatiale on this project.

◆ ANS

See ship- and ground-launched antiship missiles.

◆ ARMAT

Dimensions: 40 cm × 4.15 m (span 120 cm) [15.8 × 163.4 × 47.2 in]

Weight: 550 kg [1213 lb] **Warhead:** 160 kg [353 lb]

Propulsion: solid-fuel rocket

Speed: Mach 0.9 (supersonic in a dive)

Range: 40–120 km [43,700–131,200 yd]

This antiradar missile, carried by the Atlantique maritime-patrol aircraft, replaces AS 37 (and uses much the same airframe). ARMAT has much the same configuration as AS 37; but the motor has a much greater impulse, and ARMAT has a new seeker. This missile has been used by the Iraqi Air Force in the Gulf War (reportedly in 1984). ARMAT will be replaced by the lighter-weight STAR.

◆ AS 12

This wire-guided missile is carried by French Navy and Royal Navy WG-13 (Lynx) helicopters. See also the surface-to-surface version, SS 12M.

◆ AS 15TT

Dimensions: 18.4 cm × 2.16 m (53 cm wing span) [7.2 × 85.0 × 21 in]

Weight: 96 kg [211.6 lb] **Warhead:** 29.7 kg [65.5 lb]

Propulsion: rocket (boost-sustain; burn time 45.2 sec)

Speed: 280 m/sec [919 ft/sec] **Range:** 15+ km [8+ nm]

This helicopter-fired missile first appeared in the mid-1970s as a replacement for the existing AS 11/12. AS 15TT is a sea-skimmer (altitude about 15 m, radio altimeter equipped) and radar-beam command-guidance replaces the wire guidance of the earlier missiles. The manufacturer claims that AS 15TT is difficult to jam because it receives signals by means of a rear-facing antenna. The guidance radar, a Thomson-CSF AGRION 15 (X-band, pulse-compression), tracks both target and missile

AS 15 TT, as carried by a Dauphin 2 helicopter, with AGRION 15 radar. (Aerospatiale)

and computes the error in range and bearing between missile and target.

The impact-fuzed warhead is derived from that of the AS 12.

Current users: French navy, Bahreini navy (from a helicopter on board the Lurssen fast patrol boat), Saudi Arabia (helicopters flying from *Al Madinah*-class frigates). The development program was financed as part of the Saudi program; first deliveries were in March 1985.

In 1989 Iraq became the second customer for the Dauphin/AS 15TT antiship system, Saudi Arabia having been the first.

Reportedly, the system suffers from very short effective range (2–3 nm); the missile-guidance link cannot function at the design range of about 7 or 8 nm. Reportedly, the explosive launch technique thrusts many missiles out of the capture beam.

AS 15TT is the end result of a series of missiles beginning with the AS 12 developed in 1955–57 by Nord. AS 12/SS 12 (see SS 12M, below) was a version of the earlier SS-10/11 antitank missile with a warhead 4 times as heavy, for use against ships or fortifications. Like the earlier missiles, it is wire-guided, the operator tracking the tail flare and applying course corrections manually. Thus AS 12, whose trials began in 1960, is a daylight system. The next version, AM 10 Lasso (Léger Air/Surface Semi-Automatique Optique), used semiautomatic IR guidance similar in principle to that of the TOW missile, the operator tracking the target and the system tracking the flare in the tail of the missile. The warhead was the same as that of AS 12. The program was announced in 1977, but it was soon superseded by AS 15, which was originally to have had radio command guidance in place of the wire guidance of the earlier missiles. Compared to AM 10, AS 15 has a slimmer body with flip-out tail fins. The TT suffix in AS 15TT indicates *tous-temps* (all weather), the missile being tracked by radar rather than by a tail flare.

A surface version, MM 15, was proposed for coast defense in 1979 and was shown as a ship-launched weapon in September 1984. No sales had been announced as of late 1988.

◆ AS 30

Dimensions: 34.2 cm × 3.65 m; 1.0 m span [13.5 × 143.7 × 39.4 in]

Weight: 520 kg [1146 lb] **Warhead:** 240 kg [529 lb]

Propulsion: solid-fuel rocket (boost-sustain)

Speed: 450 m/sec on sustainer, after 2-sec boost [1476 ft/sec]

Range: 10 km; flight time to impact approx. 21 sec; minimum range about 3 km [10,900/3,300 yd]

Data apply to the AS 30L laser-guided version of the basic weapon. The original AS 30 (semiautomatic-command line-of-sight guidance) was begun in 1958 and was delivered in 1964. Work on the laser-guided version began in 1974, the ATLIS designator running its trials in 1977. The laser-guided missile first

An AS 30L is fired; the laser illumination pod is outboard on the same wing. (Aerospatiale)

flew on 4 April 1980, production beginning in 1984 (first delivered June 1984). The target is designated on the basis of a television image, the laser and television being slaved together so that the pilot can drop the weapon and break away at 4 Gs. The television automatically tracks the target during and after the break.

This weapon is in service on board French Navy Super Étendards and on board French Air Force Jaguars equipped with a Thomson-CSF laser designator pod, for use against both ships and fixed land targets. AS 30 has also been exported to Egypt and to Iraq; Iraq reports having used it during the Gulf War.

Production: 538 were on order by early 1987, 223 having been delivered. Reportedly more AS 30Ls have been manufactured for export than for French service. Over 4000 of the earlier AS 30 were manufactured, for at least 7 countries. Estimated unit price in 1986 was \$275,000.

◆ AS 37 Martel

Dimensions: 40 cm × 4.122 m (span 1.192 m) [15.8 × 162.3 × 46.9 in]

Weight: 550 kg [1212 lb] **Warhead:** 150 kg [331 lb]

Propulsion: dual-thrust solid-fuel rocket

Speed: about Mach 1

Range: 30–60 km [32,800–65,600 yd]

This Missile Anti-Radar Television was an Anglo-French project, originally an antiradar weapon. Separate studies conducted by Hawker Siddely Dynamics and by Matra during 1960–63 were merged in 1964. Matra was responsible for the antiradar Martel (AS 37). Hawker Siddely developed a television-guided version to meet RAF Staff Requirement AJ.168. Only the antiradar version remains in service, with the French Navy (Atlantique Mk 1) and with RAF antishipping Buccaneers.

AS 37 Martel television-guided missiles carried by an RAF Buccaneer maritime-attack bomber. [U.S. Naval Institute]

The airframe is similar to that of AS 30. The antiradar seeker is steerable.

In 1982 Martel was considered for action against Argentine radar in the Falklands, but the U.S. Shrike was chosen instead, reportedly because of skepticism that the missile could survive the very long flight from Ascension to the target. The missile was used by the French Air Force in Chad in 1987.

◆ STAR

In 1986 Engins Matra announced that it was working on a new antiradar missile, STAR (*Supersonique Tactique Anti-Radiation*). STAR is described as a 250-kg [551-lb] ramjet with a range of 150 km [164,000 yd], designed to open penetration corridors for naval attack aircraft and also to attack heavily defended targets such as high-value warships. STAR will incorporate experience with Martel and also with the ARMAT missile, manufactured since 1984. The latter is too heavy to be carried by anything short of an Atlantique maritime-patrol bomber, whereas a Super Étendard would be able to carry 4 STARs.

At the Bourget Navale show in 1988 Matra described STAR as the first of a family of lightweight Mach 2.3 air-to-surface missiles, the second of which would be an antiship missile, a competitor to the Aerospatiale ANL.

Germany (West)

◆ Kormoran (AS 34)

Dimensions: 34.4 cm × 4.4 m; 100 cm span [13.6 × 173.2; 39.4 in]

Weight: 600 kg [1320 lb]

Warhead: 160 kg; 55-kg HE [353/121 lb]

Propulsion: boost-sustain rocket

Speed: M 0.9 **Range:** 30+ km [33,000+ yd]

Kormoran was conceived as an antiship missile that could be fired by a low-flying aircraft, popping up briefly to fire, against ships moving at up to 40 kt. Kormoran, therefore, uses inertial mid-course guidance and an active terminal seeker, approaching the target at a height of 2–5 m. Guidance modes are radar lock-on (RLO), radar acquisition (ACQ), and visual (VIS). In the RLO and ACQ modes, the missile is fired either without any use of the aircraft's radar or with a brief pop-up for acquisition. The visual mode allows firing even if the fighter's radar fails, but this mode entails considerably greater danger to the launching pilot.

The missile uses a delayed-action fuze to penetrate the target, the warhead consisting of 55 kg of high explosive surrounded by 16 projectile charges, each of which can penetrate 70–90 mm of steel. The explosive is formulated to provide an especially rapid explosion, so that the pressure wave is particularly destructive.

Kormoran firings began in 1967 with a series of booster tests from F-104G fighters. Test firings were completed in 1974 with approval for service use. At that time MBB was awarded a contract for 10 preseries and 350 production weapons. Of 7 test shots July–September 1977, all were hits. The first production missiles were delivered in December 1977.

Kormoran 2 has an improved (220-kg) warhead, increased range (55+ km), and improved ECM resistance and is designed for better target selection and for multiple launches. The missile weighs 630 kg and flies at Mach 0.95.

Kormoran began with an MBB study in 1962, a development contract following in October 1967. The design was reportedly influenced by experience in several abortive Franco-German missile projects of the 1960s; development was by Nord (now Aerospatiale) and Bolkow (now part of MBB). Drop tests were made in 1969, and a 50-round test program was completed in 1973. The production contract, for 356 missiles and 56 installations, was let in November 1976. The missile made 7 hits out of 7 shots during German naval tests in December 1977. Italy ordered Kormoran to arm its antiship Tornados in 1980, and about 450 have been delivered to date.

The Kormoran 2 program began with a 1983 development contract, and deliveries to the German Navy (*Marineflieger*)

Kormoran missiles carried by a German Navy Tornado. (Messerschmitt-Bölkow-Blohm GmbH)

were expected in 1988–89. Late in 1987 Kormoran 2 was successful in its second test flight (Sardinia range). Total production will probably be about 180, excluding export sales.

In 1987 estimated unit cost was \$450,000 for Kormoran 1 and \$575,000 for Kormoran 2.

INDIA

Hindustan Aeronautics Ltd. is reportedly developing a Mach 4 air-to-surface missile for air force and navy use, with a 100-km (109,000-yd) range and a 35-kg [77-lb] payload. The missile is to be launchable from 30,000-ft altitude.

INTERNATIONAL

◆ MSOW

The MSOW program collapsed in mid-September 1989 when the U.S. Air Force withdrew in favor of a hitherto-secret competing system, probably the Have Slick described below. Northrop was reportedly tasked to resurrect a standoff weapon proposal, originally formulated under the U.S. Air Force–Army JTACMS program, to compete with MSOW-B (the long-range version). The United States also withdrew from a program to develop ISAS (Intelligent Shelter Attack Submunition), a smart KE penetrator using IR, mm-wave, or dual-mode seeker, which was to have been carried by the MSOW bus.

The Rockwell team was selected shortly before the program collapsed.

MSOW details can be found in the previous edition of this book.

JAPAN

◆ ASM-1

Dimensions: 35 cm × 3.95 m; 120 cm span [13.8 × 156.8; 47 in]
Weight: 610 kg [1344 lb] **Warhead:** 250 kg [550 lb]
Propulsion: solid-fuel rocket **Speed:** Mach 0.9
Range: 50 km [54,680 yd]

ASM-1. (*Ships of the World*)

Mitsubishi is the prime contractor, selected in November 1973, for this Japanese Type 80 antiship missile. The missile was tested in 1977–79 (first unguided flights were December 1977), and production began in 1980. ASM-1 was announced for coastal defense in 1981 and entered service in 1982 (F-1 fighter). This missile employs inertial mid-course guidance and an active terminal seeker and approaches the target at low altitude.

Platforms: F-1, F-4EJ, F-15, F-16, and P-3; all but the F-16 (2 missiles) carry 4 each. In the case of the F-1, a J/ASQ-1 fire-control system is required. Estimated unit price (1987) is \$425,000. An ASM-1C version for P-3 Orions is being bought under the 1987–90 Four-Year Defense Plan.

The Japanese FY88 budget included funds for a successor ASM-2 using an imaging infrared seeker and powered by a turbojet. The ASM-2 will be the primary antiship weapon of the new FS-X (F-16 derivative). ASM-2, based on the Type 87 surface-to-surface missile, has a range of more than 150 km. The first prototype is scheduled for completion in the fall of 1990.

Reportedly, a new version of ASM-1 (perhaps ASM-2) incorporates ferrite-based, radar-absorbing-material (RAM) wing surfaces in place of the light alloy surfaces of ASM-1.

The SSM-1 surface-to-surface missile is a turbojet-powered version. In 1988 it was reported that Mitsubishi was beginning development of a new long-range antiradar missile specially intended to attack ships.

XGCS-1 is Mitsubishi's strap-on, passive-IR guidance system for 225-kg and 340-kg bombs. Flight tests (for initial use by F-1 fighters) began in mid-1988.

SWEDEN

◆ Rb 04E

Dimensions: 50 cm × 4.45 m × 200 cm span [19.7 × 175.2 × 78.7 in]
Weight: 600 kg [1322 lb] **Warhead:** 300-kg HE [661 lb]
Propulsion: single-stage solid rocket
Speed: about Mach 0.9 **Range:** up to 32 km [35,000 yd]

Guidance for this missile is by active terminal radar following an autopilot-controlled flight. This weapon, the first Swedish air-launched antiship missile, is manufactured by Saab-Scania. Rb 04 was originally designed to meet a 1949 requirement for an antiship standoff missile, the prototype being launched on 11 February 1955; Rb 04 became operational in 1959. Rb 04D became operational in 1972 and was followed by the current Rb 04E, which has a reduced wingspan, modernized structure, better guidance, and a new rocket motor. The contract for its development was signed in 1969. Rb 04E can be launched at

A Viggen attack fighter with 2 Rb 04E missiles underwing. (Swedish Navy)

near-sonic speed and is carried by the AJ 37 Viggen fighter. The missile attacks at low altitude, after a programmed descent. Production ended in 1977. Rb 04E experience was exploited in the RBS 15 program (see ship-launched missiles).

◆ Rb 05A

Dimensions: 30 cm × 3.6 m × 80 cm span [11.8 × 141.7 × 31.5 in]
Weight: 305 kg [672 lb] **Propulsion:** liquid-propellant rocket
Speed: supersonic **Range:** 9 km [9800 yd]

The Rb 05A antiship missile, as carried by a Viggen attack fighter. (Swedish Navy)

This missile is radio-command guided, the operator using a joystick to line up a tracking flare in the missile's tail with the target. The Rb 05A development contract was let in 1960, followed by a production contract in 1970; production ended in 1977.

◆ Rb 15

See ship- and ground-launched antiship missiles.

USSR

Details of guidance are given for many of the Soviet air- and surface-launched missiles. The reader is cautioned that these are old data (from about 1973). The Soviets may well have re-

placed some or all of their conical-scan radars with monopulse units much more resistant to countermeasures (as the PRC did with its Styx derivatives). The demise of the British masthead repeater conical-scan countermeasure suggests that this development occurred in the early 1980s.

◆ AS-1/SS-C-2 Kennel/Salish (Komet)

Dimensions: 115 cm × 7.9 m; span 4.9 m [45.3 in × 25.9 ft; span 16.1 ft]
Weight: 3100 kg [6800 lb] **Propulsion:** RD-500K turbojet
Speed: 510 kt **Range:** 55 nm [13.5 nm for coast defense]

AS-1 being moved to its Badger bomber. (U.S. Navy)

AS-1 was the earliest Soviet air-to-surface antiship missile; SS-C-2 is the coast-defense version. The Soviet name is Samlet. SS-C-2 has been widely exported. It was initially deployed only in concrete bunkers on the Black Sea coast; in the mid-1960s a mobile system was tested. In the early 1970s these weapons were replaced, in Soviet service, by SS-C-3 (the coast-defense version of the SS-N-2). Reportedly, SS-C-2 is still used by Bulgaria, Cuba, Egypt, Poland, Romania, and North Korea. The air-to-surface version is no longer in Soviet service, but a few may remain in Egypt and Indonesia, for launching from Tu-16 bombers.

The Soviet Navy initially experimented with ex-German V-1 cruise missiles, but in 1947 the MiG fighter design bureau was ordered to begin work on a new antiship missile, Komet, using a combination of beam-riding mid-course guidance and semiactive terminal guidance. The radar was a modified RPB-1 X-band bombing/navigation radar, Komet III (NATO code name Mushroom). This weapon became operational in 1958. It was limited in effective range because the bomber had to provide sufficient terminal illumination. Moreover, because the bomber had to remain near the target throughout the flight of the missile, the attack could be disrupted up to the time of impact by the destruction of the bomber. The combination of tail bulb (to receive the guidance beam) and nose radome (for semiactive terminal homing) provided evidence that the system had both beam-riding and semiactive guidance. AS-1 was typically dropped at 16,000 ft at 250 kt, to dive at about 3 deg.

The normal warhead weight was 600 kg, but reportedly it could be increased to as much as 1000 kg.

The missile generally resembles (and reportedly is based on) the MiG-15 jet fighter, and reportedly AS-1 used MiG-15 jet engines with more than 5 hr of running time remaining (so that the engine could be run up and tested annually without exhausting its lifetime before operational use). Running time was 6 min before flight, with a flying endurance of 15 min.

The beam-riding guidance technique limits surface-to-surface range to line of sight. This missile was installed on board the

cruiser *Admiral Nakhimov* in 1956–57, and several missiles were launched successfully. However, the system was abandoned because of the size and inefficiency of the weapon. Several Komets were reportedly test fired before Marshal Tito on the Soviet naval test range at Cape Feolent in 1958.

A coast-defense (land-based) version entered development in 1952, differing from the air-launched version by having a smaller rearward-pointing antenna. Presumably that decrease was acceptable because the range was quite limited, to about 25 km, so that the missile needed less gain to receive the guidance beam at extreme range. Tests began in 1956 at Cape Feolent, and the first missiles were deployed at Balaklava, and then at Kildin Island, in 1958 as a replacement for the existing 130-mm coast-defense gun. Missiles were fired from semifixed rails in reinforced underground bunkers, the missile rising to a preprogrammed cruise altitude of 400 m before coming under radar control. The bunkers were expensive, and they were soon replaced by a mobile launcher, a truck-borne rail. This device in turn was derived from a zero-length launcher that the MiG bureau had developed in 1956 for the SM-30 (MiG-19 derivative) interceptor. The Soviets deployed their first mobile launchers at Poti in the early 1960s. Ultimately, the Soviet Navy deployed about 19 missile battalions (3 Northern Fleet, 6 Pacific Fleet, 5 Black Sea Fleet, and 5 Pacific Fleet), but these figures probably include SS-C-1 (land-based SS-N-3) missiles. A typical mobile battalion consisted of 3 batteries, each with 6 launchers. The earlier fixed battalions had been only about half as large, with 2 or 3 launchers per battery.

Exports began in the early 1960s. The Polish Navy received 3 battalions, the East Germans 1, and the Rumanians and Bulgarians 1 or more batteries each; the missile is still in service in the latter 2 countries. This missile was also exported to Cuba, Egypt, and Syria, with Cuba receiving about 50 launchers.

There was also an army version.

In the late 1970s the Soviets began to replace SS-C-2 with a land-based version of SS-N-2 (Styx).

The Soviet designation of the air-launched version is KS-1 (industrial number 4K87, popular name Komet). The designation of the coast-defense version is S-2 (Sopka).

◆ AS-2 Kipper (K-10)

Dimensions: 35 in × 31 ft, span 16 ft **Weight:** 9250 lb
Warhead: 1000-kg [2200-lb] HE or nuclear
Propulsion: turbojet **Speed:** Mach 1.4–1.6
Range: 115 nm high trajectory; 54 nm low trajectory

Kipper is a turbojet antiship missile with active radar seeker or inertial guidance (nuclear version); one missile is carried by a Badger-C. Kipper entered service in 1961. Like the later AS-4 and AS-6, AS-2 locks its radar on before launch: hence the need to fly at relatively high altitude until fairly close to the target. This method of operation is ultimately limited by the launch platform's altitude; at 40,000 ft the radar horizon is about 300 nm. A missile that can lock on after launch can be fired to a greater distance. For example, if the missile climbs to 80,000 ft and then scans (and locks on by data link), the radar horizon is about 480 nm.

AS-2 is typically launched at about 36,000 ft at 400 kt, cruising level for the first 40 nm, then diving at 8–10 deg until it reaches a point about 75 nm from the expected target position. The missile then flies level or dives at an angle of less than 3 deg. Minimum range is about 30 nm. The seeker (I-band, conical scan on receive only at a scan rate of 60–80 Hz) is activated 60–40 nm from the expected target position. Total flight time from a range of 100 nm is 7.5 min. The missile carries a beacon, so the launching bomber can track it in flight, and its inertial mid-course guidance has provision for command override. These tactical data date from late 1973.

AS-3 (Soviet designation: K-20), a fighter-sized missile carrying a large thermonuclear bomb, is almost certainly limited to strategic attack and so is not described here. AS-3 is being replaced by the slower (but much longer-ranged) AS-15, an air-launched version of SS-N-21.

◆ AS-4

Dimensions: 35 in × 37 ft, span 11 ft **Weight:** 14,300 lb
Warhead: 2200-lb HE or nuclear
Propulsion: liquid-fuel rocket
Speed: Mach 2.5–3.5 [1850–2590 mph]
Range: 250 nm high flight profile; 150 nm low altitude

This weapon was apparently designed specifically for the Blinder bomber, itself intended as the successor to the Badger. Kitchen was first seen in 1961 under a Soviet Air Force Blinder-B, during the Tushino air display, and was later adapted for strategic bombers (Backfire-B and Bear-B and -C). AS-4 has not been seen under Soviet naval Blinders but is carried by Backfire-Bs, entering service in 1967.

AS-4 is launched at about 36,000 ft but climbs after launch to an operational altitude of about 80,000 ft. Its J-band terminal seeker is activated about 80 nm from the expected target position, and it begins its 3-deg dive shortly afterward. Terminal velocity is Mach 1.1 (cruise velocity is about Mach 3.5). Minimum range is 70 nm. Time of flight from a typical operational range of 150 nm is 9.4 min. Mid-course guidance is by a pre-programmed autopilot. These tactical data date from late 1973, when it was not known whether the missile had a mid-course command-override feature.

The associated radar is Down Beat.

AS-4 is a very difficult target to engage because, thanks to its rocket motor, it cruises at extreme altitude before diving steeply at its target. The antiship version uses active radar guidance, but nuclear-armed versions probably are inertially guided; in this latter form AS-4 may replace the huge AS-3 (which is essentially a jet fighter's body carrying a large thermonuclear bomb). In the nuclear antiship version, AS-4 presents a particularly difficult problem: because the missile may be intercepted only as it dives, a conventional missile kill may leave the tumbling bomb intact. This problem has made for considerable U.S. Navy interest in defensive nuclear SAMs in recent years.

There is also an antiradar version, reported in 1981.

The Soviet name is Burya.

◆ AS-5 Kelt

Dimensions: 35 in × 28 ft, span 15.7 ft **Weight:** 10,350 lb
Warhead: 2200-lb HE **Propulsion:** liquid-fuel rocket
Speed: Mach 0.9–1.2
Range: 175 nm high-altitude flight profile; 90 nm low-altitude flight profile

AS-5 is a faster, one-for-one replacement for AS-1 (the Soviet Komet) and was introduced in 1965. Two can be carried underwing by Badger-C and -G bombers. J-band terminal-phase active radar homing replaces the beam-riding guidance of the earlier missile, and AS-5 has about twice the range of the AS-1. The warhead is 1000 kg [2204 lb] of HE. Wings and tail surfaces resemble those of AS-1; the nose is similar to that of Styx (SS-N-2).

AS-5 probably has a minimum range of 60 nm and an operational range of 60–80 nm. Minimum range is the range at which the seeker must be turned on to control the missile effectively. Typically, then, the missile would be launched at about 70 nm at 36,000 ft, locked on immediately, and set into a 6-deg dive. At this range the radar horizon is at 10,000 ft, and a launch at this altitude would reduce the dive angle to less than 3 deg. Total flight time would be 6.7 min. Alternatively, the missile can be launched at extreme range and its terminal homer activated when its estimated range to the target is about 60 nm; at that point it begins to dive. The initial dive, to about 8000 ft at 40 nm from the target, is steep, followed by a shallower (less than 3 deg) dive into the target. Total flight time in this case is about 11 min. These tactical data date from late 1973.

The associated radars are Short Horn and Puff Ball.

Antiradar AS-5s were fired at Israeli targets during the 1973 October War. Of 25 missiles fired, 20 were shot down by fighters or by ground antiaircraft guns. The remaining 5 destroyed 2

radars and a supply depot, demonstrating the antiradar capability of the seeker.

◆ AS-6 Kingfish

Dimensions: (approx) 35 in × 34.4 ft; span 8 ft
Weight: 10,800 lb
Warhead: 1000-kg [2200-lb] conventional or 350-kT nuclear
Propulsion: liquid-fuel rocket **Speed:** Mach 2.5–3.5 (at 60,000 ft)
Range: 350 nm high-altitude profile; 160 nm low-altitude

Carried by Badger and Backfire bombers, AS-6 probably embodies some AS-4 technology. Guidance is reportedly similar. AS-6 probably has a considerably higher speed but a similar flight profile (high-altitude cruise, reportedly at about 18,000 m [59,000 ft], and a steep terminal dive). First reported about 1972, Kingfish entered service about 1977.

The long range quoted recently and unofficially for the high-altitude profile would suggest that this missile can lock on after launch (LOAL). Whether Soviet air-launched weapons have this capability has long been the subject of debate, as LOAL would greatly change Soviet antiship tactics. For example, a bomber carrying a LOAL missile could approach at relatively low level before firing its weapon in a pop-up trajectory, basing the launch point on data supplied externally (e.g., by satellite). Maximum range may actually be closer to 250 nm if this weapon is not locked-on after launch.

AS-6 carried by a Badger bomber. Note the absence of a big targeting radome: this missile is probably an inertially guided land-attack version. (U.S. Navy)

◆ AS-7 Kerry

Dimensions: 275 × 3525 mm; span 785 mm [10.8 × 139; 30.9 in]
Weight: 287 kg at launch, 222 kg at burn-out [633/489 lb]
Warhead: 111 kg [245 lb] **Propulsion:** solid-fuel rocket
Speed: 600–750 m/sec [1165–1456 kt]
Range: 2–10 km [2200–10,900 yd]

AS-7 is a standard Soviet tactical missile, carried by Forger VTOL fighters and also presumably by other aircraft, including naval Fitters. Introduced in the late 1970s, it is roughly equivalent to the U.S. Bullpup. The missile is manufactured under license by Rumania, under the designation A921; the data above and the notes below apply to this version as displayed at Baghdad in 1989. Yugoslavia also manufactures a version of AS-7. The missile shown in 1989 is about twice as fast as originally described, somewhat slimmer (11 rather than 12 in in diameter), and with a shorter wingspan (30.9 rather than 37.4 in); the earlier data apparently referred to an earlier test version.

The missile is manually guided to line of sight (via a radio command link), 3 radio correction points being provided in its flight pattern. In the version shown at Baghdad, it had an HE antitank warhead with an impact fuze.

AS-7 can be launched at 80–5000 m [750–16,400 ft] altitude. Minimum launching altitude at a diving speed of 600–1000 km/hr [330–550 kt] is 3–5 km [10,000–16,400 ft]. Maximum G-load at launch is 4.6.

The Soviet name is Grom. Other users are Bulgaria, India, Iraq, and Poland.

AS-8 was the designation temporarily applied to the AT-6 helicopter-borne antitank missile.

◆ AS-9 Kyle

Dimensions: 50 cm × 6.0 m; span 2.0 m [19.7 × 236; 78.8 in]
Weight: 750 kg [1653 lb]
Warhead: 200 kg [440 lb]; also reported as 150 kg
Propulsion: liquid-fuel rocket **Speed:** Mach 3.0
Range: 90 km [49 nm; also given as 60 nm]

This defense suppression (antiradar) missile, carried by Badger, Backfire, Fencer, and Fitter-C and -D, was introduced in the mid 1970s. AS-9 may be the antiradar missile supplied by the Soviets to the Iraqis during the Gulf War under the designation X23. An Iraqi version displayed at Baghdad in 1989 was designated Nissan-28 and was reported to have 3 different seeker heads, for 3 different bands (for ground and naval radars).

Configuration is similar to that of the much larger AS-6.

◆ AS-10 Karen

Dimensions: 305 mm × 3.5 m [12 × 137.8 in]
Weight: about 400 kg [882 lb] **Warhead:** 100 kg [220 lb]
Propulsion: solid-fuel rocket
Speed: Mach 0.9 **Range:** 6 nm

The AS-10 is an electro-optically guided tactical missile, derived from AS-7. Karen is carried by land-based naval Fitter-D fighter bombers. It is broadly comparable to the U.S. Maverick.

◆ AS-11 Kilter

Dimensions: 42 cm × 4.9 m; span 1.45 m [16.5 × 193; 57 in]
Weight: 780 kg [1719 lb] **Warhead:** 170 kg [375 lb]
Propulsion: solid-fuel rocket **Range:** 55 km [30 nm]

AS-11 is an antiradar missile carried by defense-suppression aircraft such as the Su-24 Fencer and MiG-25 Foxbat F; presumably it could also be carried by the large carrier-based fighters.

◆ AS-12 Kegler

Dimensions: length 3.8 m; span 90 m [150; 35.4 in]
Weight: 350 kg [771 lb] **Range:** 34 km [37,000 yd]

Reportedly, this antiradiation missile is a lighter weight successor to AS-9, for the Su-24 Fencer, Su-25 Frogfoot, and Tu-22M Backfire.

During 1989 there was increased interest in the threat of Soviet antiradar missiles, some members of Congress asking whether the Aegis system could contend with the threat. This interest was apparently caused by a CIA study of Soviet ARM potential, perhaps involving one or more new air-to-surface missiles.

◆ AS-13 Kingbolt

This is an air-to-surface missile carried by the Su-24; no other information has been released.

◆ AS-14 Kedge

Dimensions: 40 cm × 3.9 m; span 1.0 m [15.9 × 154; 39.4 in]
Weight: 630 kg [1389 lb] **Warhead:** 250 kg [551 lb]
Propulsion: solid-fuel rocket **Range:** 6–8 km [6600–8700 yd]

AS-14 is a laser- or electro-optically guided missile, with 4 fixed rear fins and 4 canards. Kedge-A is the laser-guided version, to which the range above applies. Kedge-B is an electro-optically guided version equivalent to the U.S. Maverick. Aerodynamic range is variously reported as 30 or even 40 km [44,000 yd], and the disparity with effective range given here suggests that the missile can be used in an alternative ground-designated mode, the airplane dropping it beyond defensive range. AS-14 is similar to AS-10 and can be used against shipping.

AS-14 is carried by the Fencer-D (Su-24), Fitter (Su-20/22), Flogger (MiG-23/27), and Frogfoot (Su-25) in Soviet service. At least with the Flogger, AS-14 is controlled by a laser designation pod. The Soviet designation is X-29L. The industrial designation 9M721 has also been reported.

AS-14 has been exported to Iraq; a Mirage F1EQ-5 carries 2

underwing and uses a French Thomson-CSF ATLIS laser designator pod in place of the Soviet equipment. ATLIS was developed for the 10-km AS-30L and can guide AS-14 out to a range of 12–15 km, compared to the normal range of 6–8 km.

AS-15 is a strategic missile, the air-launched equivalent of SS-N-21 (RK-55); AS-16 is a short-range strategic ballistic missile equivalent to the U.S. SRAM. AS-19 is reportedly a long-range strategic cruise missile. Presumably, AS-17 and -18 are next-generation tactical weapons.

The Soviets have laser-guided versions of their standard 500-, 750-, and 1000-kg bombs; it is not certain whether these versions are in naval service.

UNITED KINGDOM

◆ ALARM

Dimensions: approx 23 cm × 4.24 m; span 73 cm [9 × 166.9 × 28.8 in]

Weight: about 200 kg [441 lb]

ALARM antiradar missiles carried by an RAF Tornado. (British Aerospace)

ALARM (Air-Launched Antiradar Missile) is currently being developed for the RAF; ALARM, should it enter service, will probably also be carried by Royal Navy Sea Harrier fighters. The manufacturer, British Aerospace, claims that maritime use on board RAF antiship Buccaneers is currently (1988) being studied.

ALARM differs from earlier antiradar missiles in that it can loiter above a radar, forcing its operator to shut down. The missile uses a boost-sustain motor, flying to a preset altitude and then diving or gliding. In theory, because the motor is shut down well away from the target, ALARM should not provide much of an infrared signature. The seeker is turned on soon after launch; the missile is guided toward an emitter if one is found. Published sketches of ALARM's trajectory suggest that it follows a ballistic (up and over) path rather than a direct homing path and, therefore, that the missile can function despite emitter shut-down (after launch). If the preselected target does not emit when the missile is fired, the missile hangs from a parachute over the target area, deterring an enemy operator from turning on his or her set.

Unfortunately, trials in the United States had to be canceled because of failures of the Nuthatch motor, and in November 1987 a new motor, developed by Bayern Chemie of West Germany, was selected. Early in 1988 there were reports that the British Ministry of Defence was considering buying U.S. HARM missiles and canceling ALARM. However, the missile flew successfully at China Lake in November 1988.

◆ Sea Eagle (P3T)

Dimensions: 40 cm × 4.14 m; span 1.2 m [15.8 × 163 × 47.3 in]

Weight: 600 kg [1325 lb]

Warhead: approx 230 kg, aluminized RDX-TNT [about 500 lb]

Propulsion: Microturbo/Toulouse TRI-60-1-607 turbojet engine

Speed: Mach 0.85 (cruise) **Range:** 110+ km [120,000 yd]

Sea Eagle was developed to meet British Air Staff Requirement 1226 for a replacement for both the television-guided AJ 168 and the antiradar AS 37 versions of Martel. Sea Eagle is essentially a Martel with a turbojet and a new seeker.

Sea Eagle uses inertial mid-course and active terminal-phase radar guidance and can distinguish a preferred target from

Sea Eagles on board an Advanced Sea King helicopter, 1985. (Westland)

A Sea Eagle missile, with a French cluster bomb (Belouga) in the foreground. (Author)

among a target array (e.g., a task force or convoy). Selected target-signature data are stored in the missile's computer before flight. Reportedly, the seeker head is capable of homing on jam or homing on a specific radar emitter. The manufacturer is British Aerospace Dynamics.

The missile is designed to hit a target at or just below the waterline. The front face of the warhead is specially dished to ensure penetration at shallow grazing angles, recalling dished faces fitted to World War II air-dropped depth charges so that they would not skid on hitting the water. This warhead was developed at RARDE (Royal Armaments Research and Development Establishment) for the abortive Under-Sea Guided Weapon development of Martel.

Sea Eagle is carried by British Sea Harrier, Tornado, and Buccaneer aircraft, and it is operational with both the Royal Navy and the Royal Air Force; the missile has also been sold to the Indian Navy (to be carried by Sea King helicopters). Reportedly, Sea Eagle will also be exported to Saudi Arabia, to be carried by Saudi Tornado strike aircraft. There are reports that India may buy Sea Eagle for Jaguar fighter-bombers. Sea Eagle has been tested on board the Chilean CASA/Embraer T-36 trainer (2 can be carried by the A-36 attack version) and on board the Tornado.

Sea Eagle was first fired in 1981. Development of a projected Mk 2 was abandoned.

A ship-launched version, P5T, was proposed in 1981. British Aerospace claimed that 3 could be carried for every 2 MM 40

Exocets. However, the Royal Navy chose the U.S. Harpoon in place of both for the Type 22 Batch 3 and the Type 23 frigates. At that time, the major development item was the strap-on booster. However, British Aerospace had to develop the booster anyway so that Sea Eagle could be fired by Indian Navy Sea King helicopters. Thus, British Aerospace was able to develop the surface-launched version of the missile with very little additional effort. P5T was first launched in March 1987. As of 1988 no sales had been reported.

◆ Sea Skua (CL 834)

Dimensions: 25 m × 2.5 m; 0.72 m span [9.8 × 98.5 × 28.5 in]

Weight: 145 kg [325 lb] **Warhead:** 30 kg (9 kg RDX) [66/19 lb]

Propulsion: boost-sustain solid-propellant rocket (boost burn-time 2 sec)

Speed: Mach 0.8 **Range:** 15 km [16,400 yd]

Sea Skuas carried by a Lynx helicopter, 1984. (Westland)

Sea Skua is a helicopter-launched antiship missile, conceived primarily as a counter to fast missile-armed patrol boats. The range was chosen so that Sea Skua could be fired from outside the lethal envelope of a Soviet SA-N-4 anti-aircraft missile (located, e.g., on board a *Nanuchka*).

Guidance is by semiactive radar, typically using emissions by a surface-search set such as the Seaspray on board Lynx helicopters. The flight path is preprogrammed, with a choice of 4 approach altitudes (choice based on sea-state and type of target). Approach height is maintained by a radar altimeter. Typically, a Lynx shipboard helicopter carries 2 or 4 Sea Skuas.

Sea Skua replaces the French AS 12 in British service and is broadly equivalent to the French AS 15TT. AS 12 had been bought as an interim weapon that could be fired by a Wasp helicopter, and Sea Skua was inspired by evidence, e.g., in Exercise Northern Merger (1974), that such a helicopter could easily locate and attack surface ships. The Lynx, then in development, was expected to locate and identify hostile ships by both Seaspray radar and ESM. Missile weight was fixed by the requirement that 3 missiles and their associated equipment (but not the Seaspray radar) weigh no more than 580 kg. Frigates' space constraints limited the length of the stowage frame to 2.65 m, and wings and fins had to be detachable. The intended target set the type of warhead (30-kg SAP, for penetration).

Project definition for Sea Skua began in April 1972, and BAC formally proposed the missile in 1974. British government funds were provided in 1975 to complete the program and produce missiles. The first airborne firing of a fully guided round came in November 1979. This missile was ordered by the West German Navy in May 1984 for use on board Sea King helicopters, which are being equipped with Ferranti Seaspray 3 radars in dorsal radomes. This program is being completed in 1989. Turkey has adopted Sea Skua for use on board its projected fleet of

Sea Eagle compared to Sea Skua, at RNEE 1989. (Author)

The Sea Skua boat now under construction; this model was displayed at RNEE in 1989. (Author)

Agusta-Bell AB.212 helicopters, using a radar mounted above their cockpits; and Brazil plans to deploy the missile on board its Lynx helicopters.

Current work concentrates on the ship-launched (SL) version. Reportedly, several Southeast Asian and Latin American navies have shown interest, although no orders had been announced as of the fall of 1988. British Aerospace installed Sea Skua on board a Hymatic 21 fast patrol boat, for demonstration firings (the first was on 25 June 1990). It carries 8 missiles and a Seaspray Mk 3 radar. There is also a proposed coast-defense version, using a 4-missile box launcher. British Aerospace carried out the first successful firing of the SL version in December 1988.

The first Sea Skua fired from the boat (*Verifier*) off Aberporth at a range of 12 km [6 nm] missed a buoy target by 0.4 m. The guidance radar is a 360-deg scanning Seaspray Mk 3 radar, normally mounted on board a helicopter. The missile can engage targets 15–20 deg to each side of the axis of the launch canister and can be programmed to fly at any 1 of 4 heights. Missiles can be ripple-fired and can fly at preset vertical as well as lateral separations. The ship-launched version is nearly identical to the air-launched type, but the signal processor in the radar is more sophisticated.

UNITED STATES

◆ AIWS

AIWS is a navy program for a short-range Advanced Interdiction Weapon System, to engage land targets and to replace laser-guided weapons such as Paveway, Skipper, and Maverick. These 3 subject the launching airplane to too great a threat; AIWS will be fire-and-forget. AIWS was 1 of 2 new air-weapon starts of the FY87 program; the other was SLAM. The program also envisaged an additional new weapon, ASWS, for use at greater ranges. ASWS and AIWS were formally proposed in February 1985 as future affordable ("bronze bullet") standoff weapons; the interim SLAM will be extremely expensive.

AIWS was conceived as a low-cost weapon with a range of somewhat over 5 nm and with a maximum weight of 2250 lb, to carry 3 alternative warheads: 1000- or 2000-lb unitary warheads or a cluster of bomblets. Guidance will initially be inertial (see IAM below), although satellite navigation (GPS) may later be incorporated. Reportedly, the required baseline navigational performance is a drift of no more than 10 deg/hr, but the new ring laser gyro technology may make 1 deg/hr practicable. Press releases suggest that the "bronze bullet" concept may later be relaxed to allow for such exotica as an Israeli-developed fire-and-forget IR-imaging (as in Popeye 2) or millimeter-wave guidance, and fiber-optic-wire guidance by the launching airplane. The baseline remains a fire-and-forget weapon.

AIWS resulted from the Naval Strike Warfare Master Plan of 1985, and the RFP, originally scheduled for December 1986, was

Boeing's version of AIWS. (Boeing)

McDonnell Douglas's version of AIWS. (McDonnell Douglas)

approved in March 1987 after a long study of performance vs. cost. Then Secretary of the Navy John Lehman ordered the cost limit of \$50,000 just before he left office; the original expected unit cost had been \$70,000 to \$120,000. The production decision will probably be made about 1992, AIWS entering service about 2000.

The AIWS program was approved by the Deputy Secretary of Defense in December 1985, to make up for the lack of any true standoff naval attack weapon other than the obsolescent Wall-eye. The only other general-purpose naval attack weapons are general-purpose bombs (including such laser-guided variants as Skipper) and cluster weapons (Rockeye and APAM). Even guided weapons such as Skipper must be launched by a pilot who has the target in view and who is, therefore, vulnerable to anti-aircraft fire.

AIWS's characteristics were developed at a May 1986 conference at NSWC. They were much affected by lessons learned both in Lebanon and in the Libyan raid. The conferees wanted a low-altitude standoff range greater than that possible with Walleye, Skipper, and LGBs; the launch itself should not reveal the aircraft's location; the weapon should be difficult to detect en route to its target; the weapon should make multiple kills per pass; and the aircrew should be provided with "last frame assurance" that the intended target had been neutralized or destroyed, so that subsequent attackers could be assured that the target was no longer a threat, and so could avoid wasting weapons on it.

The key requirement was the demand that the pilot not have to lock the missile onto the target before firing. Pilots cannot stand off at low (safe) altitude if they must have the target in sight at the moment of missile launch. The usual solution has been to provide the missile with a data link to the airplane, locking on only after the target has been detected, while the pilot looks on from a safe distance. However, long-range antijam data links are expensive, and a pilot loitering, even at a distance, to decide which of several targets in the seeker's field of view to attack may be in danger.

The Texas Instruments/LTV version of AIWS, which they call Shadow. (Texas Instruments)

The AIWS solution is to allow the pilot to specify the precise location of a target during a brief pop-up at a safe distance. Target location is fed into the memory of the missile, which can, in theory, navigate to the designated target after popping up at much shorter range. "Last frame assurance" required a combination of some kind of imaging sensor and a data link, but that link would be needed for only a short time, just before the missile hit. The link could, therefore, be simpler than that used in earlier missiles, for which pilots had to use their imaging sensors to find the targets in the first place.

Quiet launch required aerodynamic performance superior to that of existing weapons, so that even when launched at low altitude the missile could coast for a time before its motor ignited (if power was required at all). Multiple kills per pass required a cluster munition. The missile could provide CEPs, at 5-nm range, of 5–7 ft. Long range suggested GPS-aided inertial guidance. The system could be either completely prebriefed, the missile flying to a predetermined target position; or the missile could be flown to a target located by the airplane. In either case, accuracy would depend on the accuracy of the aircraft's navigation. In the second case, the aircraft's survivability would depend upon how quickly the target could be located once the airplane was nearby. It would have to pop up to sight the target, and pop-up altitude would depend on terrain features.

Unfortunately, studies soon showed that within the \$50,000 ceiling the weapon could not have a terminal seeker, data link, or propulsion. AIWS characteristics were, therefore, revised; the weapon would achieve a minimum operationally acceptable standoff range, a low-cost inertial guidance system (estimated guidance costs were \$14,000–\$21,000), a cluster payload, and capacity for future growth to meet the initial requirements.

There were still some design problems, particularly in providing an unusually high lift-to-drag ratio (as much as 13:1). In 1988 it was estimated that the airframe would probably cost \$12,000–\$20,000 (perhaps as little as \$10,000 in a future automated factory). AIWS is reportedly conceived as a stealthy weapon. That characteristic is probably important for 2 reasons. First, unless the missile is stealthy, its appearance near the target will give away the presence of the launching airplane. Second, AIWS will enter service at about the same time as the new stealthy naval attack aircraft, the A-12 (the Advanced Tactical Aircraft). In theory, a stealthy missile could be slung from a stealthy airplane without compromising the latter's low observability, whereas conventional munitions would add enormously to the overall radar cross section of such an airplane.

Development of AIWS began in mid-April 1987. The competitors are Boeing, Grumman, McDonnell Douglas/Hughes Aircraft, and Texas Instruments/LTV. Boeing is already under contract to build 10 Recoverable Test Vehicles (RTVs), which will be used to test elements that may be integrated into AIWS; the first RTV was delivered to the Naval Weapons Center in January 1988. Grumman was dropped from the program early in 1989.

Current plans (1990) are for 16,000 units ("bronze bullets") for delivery through 2002, to replace Walleye, Skipper, and Laser Maverick. They will initially be armed with a cluster warhead and later will have a unitary warhead from the advanced bomb series now under development for the navy, or with an air force earth penetrator.

◆ ASWS

The navy's Advanced Stand-off Weapons System was conceived as the long-range complement to AIWS (SLAM successor). No details have been released.

◆ Bullpup (AGM-12)

Dimensions: 18 × 163 in; span 48 in **Weight:** 1785 lb
Warhead: 1000 lb **Propulsion:** storable liquid-fuel rocket
Speed: Mach 1.8 **Range:** 10 nm

Data are for Bullpup B (AGM-12C), typical of most versions.

Bullpup is radio-command guided into its target, the operator visually tracking a flare in the missile's tail. The original Bull-

Bullpups carried by a P-3B Orion, 1970. This missile was carried to attack surfaced submarines; it has now been superseded by Harpoon. (U.S. Navy)

pup A was designed in the early 1950s, entering fleet service in 1959. Bullpup B and later versions carried the heavier warhead listed above. Huge numbers of Bullpup were built, both in the United States and in Europe, and they were carried by ASW aircraft (such as the P-3) as a means of dealing with surfaced submarines (e.g., providing mid-course guidance to missiles) and with small warships. In French service Bullpup was replaced by AS-12.

Although this weapon has been superseded in U.S. service by "smart" (i.e., self-guided) standoff weapons, Bullpup is probably still in large-scale service elsewhere. The Bullpup warhead is incorporated in the Tomahawk missile and in the Norwegian Penguin and was also used in an abortive surface-to-surface derivative of Tartar developed for (but not used by) the West German Navy.

◆ Electro-Optic Bombs

The current standard U.S. Navy electro-optic weapon is Walleye. However, as stocks of Walleye are expended, the service can also use the standard series of electro-optically guided air force glide bombs described below. The original version was Pavé Strike (HOBOS, the homing bomb system), developed for the Vietnam War. The primary type, GBU-8/B, was a Mk 84 bomb fitted with a seeker, body strakes, and controllable fins. The data link connected it to the weapons-system operator (WSO) in the back seat of the attacking airplane. The successor weapon is the Rockwell GBU-15 cruciform wing weapon (CWW), for a Mk 84 or M118 (3000-lb) unitary bomb or an SUU-54 cluster weapon. The seeker can use television or an imaging IR camera. CWW can be steered toward a target area at low altitude, then made to climb and dive in. It can be steered all the way or else locked on. Development began in 1973 and tests in 1978, including over 60 launches. GBU-15 entered service in 1980. Unit cost at that time was \$127,000, including the data-link pod.

AGM-130 is a powered version, deleted from the FY88 and FY89 budgets in favor of the SLAM missile. However, the air force plans to start a production line under the FY90 budget and to begin procurement under the FY91 budget. AGM-130A is a modified Mk 84 bomb; AGM-130B is an SUU-54/B carrying BLU-106B runway-cratering munitions and HB876 area-denial munitions.

The guided bomb series (laser and electro-optic) consists of:

- | | |
|-------|---|
| GBU-1 | Rockeye II cluster bomb with KMU-420 guidance kit |
| GBU-2 | Pave Storm I, CBU-75 with KMU-351 guidance kit |
| GBU-3 | CBU-74 with KMU-422 guidance kit |
| GBU-4 | BLU-89 blast-fragmentation bomb with KMU-353 kit |
| GBU-5 | BLU-90 penetration bomb with KMU-353A kit |
| GBU-6 | Pave Storm I, CBU-79 with KMU-351 kit |

GBU-7	Pave Storm I, CBU-80 with KMU-351 kit
GBU-8	EOGB-1, Mk 84 bomb with KMU-353A kit (HOBOS). Also KMU-390 image-contrast, and KMU-359 IR. Both KMU-353 and -359 can be used with Mk 84; only KMU-390 can be used with the M118 3000-lb bomb. CEP is 20 ft.
GBU-9	M118E1 bomb with KMU-390C kit
GBU-10A	Paveway I, Mk 84 bomb with KMU-351B kit
GBU-10D	Paveway II, Mk 84 bomb with KMU-351E kit
GBU-10E	Paveway II, Mk 84 bomb
GBU-10F	Paveway II, Mk 84 bomb
GBU-11	M118 bomb
GBU-12	Paveway II, Mk 82 with KMU-388 kit
GBU-13	SUU-51 dispenser
GBU-15	Current guided bomb (modular guided weapon). Versions: GBU-15(V)1 day only, with AXQ-14 data link GBU-15(V)2 all weather, with IIR seeker
GBU-16	Paveway II (LGB-83), Mk 83 bomb with KMU-455 kit
GBU-17	hard-structure munition
GBU-20	Planar Wing Weapon, canceled 1980 in favor of GBU-15
GBU-22	Paveway III penetrator
GBU-24	Paveway III with Mk 84 bomb

♦ HARM (AGM-88)

Dimensions: 10 in × 13 ft 7 in × 44 in wingspan
Weight: 798 lb **Warhead:** 146 lb
Range: depends on launch speed/altitude
Propulsion: dual-thrust rocket motor (Mach 2+)

A HARM (AGM-88A) missile. (U.S. Navy)

HARM, the High-Speed Anti-Radar Missile, is the current standard U.S. antiradar missile. It is supersonic (as its name implies) and enjoys a very long range and, it is claimed, low detectability. Performance objectives were a broad frequency range, an increased sensitivity, a countermeasures resistance, and a smokeless motor (for low detectability). HARM is important both as a strike-protection weapon and as an antiship weapon; HARMs could be launched as precursors of an antiship-missile attack, forcing an enemy to turn off its defensive radars before the heavier (and slower) Harpoons or Tomahawks arrive.

The missile can be fired in any 1 of 3 modes: prebriefed, self-protection, or target-of-opportunity. In the prebriefed mode, the target can be acquired by the missile after it is launched (the missile seeks out an expected signature), and the attack can be conducted from very long range. Alternatively, an attacking aircraft can fire HARM automatically on the basis of information processed by an RWR. Finally, HARM can be fired at targets of opportunity, using the missile itself as the radar-search receiver, the weapon being fired manually.

The guidance system incorporates a strapdown inertial system; reportedly HARM can continue to fly toward a threat radar even after the radar has shut down. This capability predates the missile, having been introduced in Standard ARM during the Vietnam War.

Current tactics reportedly require that the missile be programmed with target range, bearing, and frequency before being fired. Given a preset range, the missile seeker can be set to activate 7–10 nm from the expected target position, to protect

the missile from distraction by other emitters resembling the target. Current HARMs must be pointed to within 15 deg of the direction of the target (i.e., the airplane must be pointed to within 7.5 deg of the target at the moment of firing).

Missile range is generally described as greater than 25 nm. In 1974, when HARM was first being developed, the desired maximum range was given as 100 nm. In 1988 it was reported that maximum range is 80 nm. Missiles are usually fired at 35–55 nm to ensure that their seekers acquire the targets.

HARM originated in the navy's Tactical Air Armament Study of 1969, which outlined the limitations of the existing Shrike and Standard ARM. Studies began in FY70, and a Proposed Technical Approach was published in FY71. After FY72 tests, Decision Coordinating Paper 92 of June 1972 approved development. Texas Instruments was selected on 24 May 1974. The air force joined the program in 1975. However, development proved difficult. Although 25 advanced-development missiles were tested, a DSARC II review in January 1977 ordered that the weapon stay in advanced development until demonstrating expanded frequency coverage and sufficient maneuverability. After that demonstration, full-scale engineering development was authorized in February 1978; and in November 1980 a navy SAR recommended low-rate production (80 weapons) for FY81. Operational evaluation, using 40 missiles, was begun in November 1981. It was successful, and full-scale production was approved on 20 April 1983. HARM was first deployed on board the carrier *Kitty Hawk* (carried by A-7s) on 13 January 1984 and first saw combat during the April 1986 Libyan raids, when 40 HARMs, some of which had been on hand for up to 3½ yr, very successfully destroyed Libyan radars.

HARM is manufactured by Texas Instruments and is employed on board U.S. naval aircraft: the A-7 Corsair II, the F/A-18 Hornet, the A-6 Intruder, and the EA-6B Prowler (first deployed August 1986). The missile would also be compatible with F-14 Tomcat fighters, although they do not currently carry it.

HARM platforms vary widely in capability. An A-7 or F/A-18 pilot will generally respond only to a preprogrammed threat. The pilot can manually reprogram the missile, but without a sophisticated threat receiver such as the ALQ-99 of the EA-6B, the pilot cannot expect to detect an unexpected threat. Until the mid-1980s, however, installation of HARM on board EA-6Bs was resisted, partly for fear that the missile might home on the airplane's active jammers. Installation became necessary when the navy experimented with all-Grumman (F-14, A-6, and EA-6B) air wings, since the new air wings did not include the usual HARM platforms, the A-7 and the F/A-18. It turned out that the missile could not home on the host airplane because the seeker was not turned on until well clear.

The great advantage of the EA-6B is that, using its ALQ-99, it can detect, locate, and verify a threat, reprogramming its missile to suit. A Block 86 upgrade to the EA-6B will remove the requirement that the aircraft point at the target and will also add a range-unknown firing mode. The first improvement is important for the EA-6B because otherwise it must interrupt jamming to fly toward the target before firing. Block 86 also allows the EA-6B to reprogram HARM in flight for threats not included in its preset threat library (prepared before flight by TEAMS, the Tactical EA-6B Mission Planning System). TEAMS prepares mission tapes for the ALQ-99, telling it which signals to seek. Using TEAMS, the airplane can be quickly reprogrammed on the ground to meet unexpected threats.

As of late 1988, only 5 EA-6B squadrons (in the all-Grumman air wings) have deployed with HARM. The navy expects to extend HARM capability to all other EA-6Bs. The bottleneck is missile-control panels, only 16 of which were available as of late 1988. Texas Instruments was to have begun delivery of 129 new panels (6 per month) beginning in November 1988.

Production of AGM-88A will continue through FY 89/90, to meet a requirement for about 15,500 missiles (7672 for the U.S. Navy and 7821 for the U.S. Air Force, down from 8054 and 9006 as stated in 1985). Procurement: FY83, 160; FY84, 381; FY85,

813; FY86, 904; FY87, 766 (total 1078 for both services, against a request for 1177); FY88, 766; FY89 (request), 1307; FY90 (plan) 200; FY91 (plan), 400. As of 1987, unit cost was about \$285,000. The thousandth missile was delivered on 26 August 1986, and the 5000th missile was delivered in September 1988.

A low-cost seeker (LCS) was developed by China Lake (1986). There are 2 alternatives. One is a seeker developed originally for the army's advanced radar projectile (ARP) (which would have to be modified to match the frequency coverage of the China Lake seeker). Because the seeker accounts for about half the overall cost of the missile, there is some hope that the new seeker will cut cost by about 20%. The LCS may also be installed in an alternative airframe, perhaps a Sparrow; the Senate Armed Services Committee has asked that the seeker be made generic rather than specialized for HARM. For a time, the navy was considering a low-cost ARM seeker for Skipper, the bombs to be used to saturate enemy radars. Congress has required that at least 800 of the FY89 HARMs, and at least 1200 of the FY90 missiles, incorporate low-cost seekers. HARMs with the low-cost seeker will be designated AGM-88B. Ford Instrument delivered the first 6 production low-cost seekers in 1987 for evaluation. The low-cost seeker was expected to be the basis of a projected joint-service advanced ARM. However, the program was terminated as part of the 1989 budget cuts.

A proposed dual-role ARM (DRARM) would have used LCS (ARP) technology and a gimbal seeker for both air-to-air and air-to-surface attack, using a Sparrow or AMRAAM airframe. DRARM was a new start scheduled for FY89, based on brass-board work under the earlier ERASE program (with initial planning in FY86).

AGM-88B shows several major improvements. It has a programmable memory (using EPROM, electrically programmable and erasable memory chips) so that the missile can easily be adapted to changing threats, even in the air. The new warhead contains thousands of 3/16-in tungsten-alloy cubes, 3 times the density of the replaced steel cubes. This warhead can now do substantial structural damage to a radar station, not merely to the radar antenna proper, cutting through half-inch mild steel or quarter-inch armor. The current flyaway cost, about \$200,000, is less than one-fifth the price of the original FY81 missiles, and MTBF greatly exceeds the original requirement of 200 hr. The next major hardware change, scheduled for FY89, is an engine that can better withstand flight-deck fires. It will be painted with a thermal insulation layer except for a narrow stripe. When the missile cooks off, only the stripe will ignite, and the motor will fall apart instead of exploding.

The next version, AGM-88C, will have a new seeker to deal with more sophisticated radars. Originally a new LCS was to have been developed as an alternative to the Texas Instruments seeker. Instead, both Texas Instruments and the alternate contractor, Ford Aerospace, are developing functionally equivalent high-end seekers for missiles designated AGM-88C-1 and -88C-2. Development of the Block IV (AGM-88C-1) missile was completed in 1989, and the missile entered service early in 1990.

The LCS was a response to congressional criticism made early in 1985; at that time early production missiles were failing (7 of 8 misses in 1984-85), and even so were expected to be quite expensive. Ford Aerospace and Raytheon were selected as LCS competitors. Texas Instruments responded by proposing partial redesign to cut cost and improve capability. DoD refused to pay \$30M for this Block-4 design, having committed \$350M for the LCS. Eventually the services agreed to pay \$17M for 13 new seekers; Texas Instruments invested \$38M. In the new C-1 design, a single antenna replaces the 2 previously used to cover the missile's wide spectrum (0.5-20 GHz), and the new signal processor is several times more powerful than its predecessor. Even so, more than half of the new missile's plug-in boards are identical to earlier ones.

In September 1989 Ford was expected to conduct pilot production under the FY90 program, with an option for limited production in FY91, and with the production contract evenly

divided with Texas Instruments in FY92. Missiles produced from FY90 on will have a more lethal warhead, to enable the missile to damage a ship's bridge as well as destroy its radar (the steel cubes now used will be replaced with high-density tungsten that can penetrate 0.5-in armor).

The current MTBF is 300 hr, compared to 125 specified. HARM is now so reliable that the airplane carrying it can use its seeker for electronic intelligence, its guidance system detecting emissions from shipboard radars and identifying the ships based on their signature. The 1989 unit price was slightly over \$200k, about 10% less than 1988.

As of 1989, the next-generation ARM was visualized as a dual mode weapon to frustrate countermeasures, e.g., passive radar plus IIR; radar emissions would be used to enable the IIR to locate its target in the background scene, and the IIR would provide guidance if the radar shuts down. Active mm-wave radar is an alternative to the IIR.

AGM-88B is being sold to Germany. The first letter of offer (5 April 1984) was for 866 missiles; the offer was revised in September 1985, for 944. Reportedly, West Germany wants to license-produce the weapon, requiring as many as 9000, to be carried by Tornados. A sale to Japan was announced in January 1987, and a sale to Spain is expected. Australia and Italy have also expressed interest, partly inspired by the missile's performance in the Libyan raids.

The U.S. budget request, as of January 1989, was for 1307 missiles in FY89, 1162 in FY90, and 1400 in FY91.

◆ Harpoon (AGM-84)

See ship-launched version.

◆ Have Slick

This is an air force program to develop a new generation of stealthy bomblet dispensers for the next generation of tactical aircraft. It will presumably be used by the navy's A-12, and it was probably the occasion for the U.S. withdrawal from the MSOW program. Flight tests are scheduled for 1990.

Have Slick is intended to blend into an airplane's shape during flight and, thus, is a direct descendant of work on conformal stores, such as fuel tanks, designed for aircraft such as the F-15. The current 2000-lb low-drag bomb contributes 25% to F-15 drag, but the goal of Have Slick is 2.5%, to be achieved by eliminating the blunt shape and the pylon. Two can be carried by an F-16, or 4 by an F-15. Individual weapons are to be launched by pistons. Because there are no pylons, the weapon has to be pushed clear of the air stream around the airplane; piston launch is preferable to explosive launch because it imposes a lesser load on the weapon and thus requires a less robust (lighter) structure, which can be made out of radar-absorbing or radar-transparent material.

Have Slick is a 2 × 14-ft "complex shape" with four 7-in fins. It has a composite (presumably radar-absorbing) skin and carries about 1200 lb of munitions (50% more than current cluster bombs and dispensers). This capacity is possible because the epoxy structure of the weapon is so light; only the spine (10% of the structure) is metal, to take the shock of piston launch. Examples of loads: 306 antipersonnel bomblets, 45 antitank weapons, or 24 antirunway devices. These munitions would be ejected from the weapon's tail. Have Slick would run in toward its target area at supersonic speed, over a distance of about 20 miles. It would then slow to plant munitions, making several high-speed passes around a battlefield. A mock-up has been installed on an F-111, and it is expected to fly at Mach 1.2, beginning in March 1990. Current estimated airframe cost is \$30,000, and the program goal is \$27,000 (which does not include payload or electronics, by far the major costs).

◆ IAM

Inertially Aided Munitions, a generic U.S. program for a new type of guided bomb, was revealed in 1988. IAM began about 1984-85. A low-cost inertial sensor (strapdown gyroscope and accelerometers) is used to provide the bomb with a precise

measurement of its path through space so that, even if lofted by an airplane below the radar horizon, the bomb can guide itself into a target designated by the attacking pilot. The inertial system cancels the usual delivery errors and is expected to improve CEP by at least an order of magnitude. The bomb trajectory can be tailored to conditions, such as terminal defenses, and the sensor should be immune to countermeasures. Moreover, each of several bombs dropped simultaneously by an airplane can be aimed at a different objective. Because IAM does not emit any signals, it would seem to be an ideal complement to future stealthy attack aircraft.

The IAM communicates with and receives alignment data from the aircraft inertial-navigation system through the standard bomb data bus (MIL-STD 1760 architecture). Predesigned target coordinates are stored in the bomb's inertial reference unit (IRU), the unit being updated via the data bus during flight. The IRU in turn controls the bomb's tail fins. In this form, bombs must be pretargeted before the airplane takes off. However, an airplane equipped with a mapping radar or a laser range-finder could presumably compute target coordinates just before the moment of release, and IAM could attack targets of opportunity, as long as they did not move very much during the bomb's flight. On the other hand, a bomb aimed at a set of coordinates cannot be jammed or fooled by camouflage, as long as the airplane can bring the target within the footprint of the bomb's fall. Similarly, an IAM weapon can attack targets that are virtually invisible, such as bridges or command posts, or very small targets such as aircraft in revetments.

Captive-carry tests have demonstrated a 12–14-ft CEP for 20-sec time of flight (low-altitude delivery) and 40-ft CEP for high-altitude delivery (50,000 ft, 60-sec flight). There is some expectation that these figures can be improved by adding satellite (GPS) navigation to the airplane and, perhaps, to the bomb. Analysis suggests that kill probability may be improved by a factor of 5 or 10 because of the much improved IAM CEP. Of course, a great deal depends on just how accurately target position has been determined before attack.

Northrop (Precision Products Division) and Boeing are the contractors. As of April 1988, Northrop had built 22 Mk 82 IAM bombs.

The technology-demonstration phase of the IAM program should have been completed by December 1988. The navy included an IAM full-scale engineering-development line in its FY89 program; the air force plans to begin such development in FY90.

◆ Maverick

Dimensions: 12 in × 98 in × 28.5 in (span)

Weight: 635 lb **Warhead:** 300 lb

Propulsion: Thiokol TX-481 dual-thrust solid-fuel rocket

Speed: supersonic **Range:** about 14 nm

Data are for the AGM-65F navy IIR version.

The Hughes Maverick is now the standard U.S. short-range tactical standoff missile; AIWS is the planned successor. Reported average CEP is less than 4 ft; and of 100 known combat launches to date (AGM-65D version), 87 hits have been achieved. This missile has been very widely exported, combat use including both South Vietnam and the Iran-Iraq War (by Iran). By the end of 1977 a total of 5666 had been exported to 7 countries: Iran (2500), Israel (600), Turkey (100), Sweden (500), Saudi Arabia (1666), South Korea (200), and Greece (100). Mav-

erick has since been exported to Egypt, Germany (West), Jordan, Morocco, Pakistan, Singapore, Taiwan (GRC), and Yugoslavia. A European consortium, led by Selenia, manufactures the missile for Belgium, Denmark, Italy, the Netherlands, and Turkey.

Development began in 1965, the prime contractor (Hughes) being selected in 1968. The missile first flew in 1969, and procurement began in 1971; Maverick entered service with the air force in January 1973. The IIR version was approved (DSARC II) in September 1976, the first successful firing being on 18 November 1975.

Versions are: AGM-65A, the original television-guided missile; -65B, the extended-range television version with scene magnification; -65C, a laser-guided version (-65E produced instead); -65D, the air force IIR version, with a 125-lb warhead; -65E, the Marine Corps laser-guided version with a 300-lb blast/penetrating warhead and a reduced-smoke motor; -65F, the navy IIR version with the -65E warhead and motor, for day/night attack against ship or shore targets; and -65G, the air force IIR version with the 300-lb warhead. AGM-65G has an improved seeker that the attacking pilot can use to aim the missile at a specific portion of a large target. The A- and B-versions weigh 462 lb; the D-version, 485 lb; and the E-version, 645 lb.

The navy's purchase of laser Maverick in FY88 will keep the production line open through 1990. The FY89 budget includes only IIR Maverick.

Procurement to date: over 30,000 AGM-65A/B; 60,697 AGM-65D; 5306 AGM-65E; 7000 AGM-65F; 1800 AGM-65G.

Unit cost: AGM-65A/B, \$50,000 in FY80 dollars (production ended May 1978); AGM-65D, \$124,000 in FY85, \$119,700 in FY86, \$88,343 with competition in FY88; AGM-65E, \$140,000 in FY84. Recent procurement:

	FY84	FY85	FY86	FY87	FY88	FY89
Air Force IIR	1980	2600	2240	3224	2700	2931
Navy IIR	—	—	195	248	425	731
Navy Laser	185	600	1500	—	1300	(732 requested)

Rapid cost escalation explains the reduction in procurement, costs later falling because of dual-sourcing and also because of the implicit threat to cut Maverick further by substituting Skipper. Navy laser-Maverick production was suspended in FY87 so

MAVERICK LAUNCH ENVELOPE
(MACH = 0.9)

Maverick launch envelope. (Hughes)

Maverick (AGM-65F) internal profile. (Raytheon)

AGM-65F Mavericks under the wing of an A-6. (Grumman Aerospace)

that a new fuze could be incorporated. In September 1987 the total U.S. objective was stated as 60,697 missiles.

Other versions have been suggested. Hughes and the air force proposed Have Wedge, a dual-mode weapon (ARM in AGM-65A television missiles). The television would have allowed the weapon to remain on course to the target even if the radar transmitter shut down. An August 1984 test produced a direct hit, but the program was not carried through to production. This concept might be applicable to SLAM, which uses a Maverick IIR seeker.

In April 1988 Hughes announced a new IR Maverick fire-control system, Rapid Fire. It automatically scans a target area and chooses likely targets, displaying them in the cockpit (and aiming up to 6 missiles for engagements). The pilot can, therefore, engage several targets during a first pass, which is all that is likely before defensive guns are engaged. Rapid Fire uses 1 of the Maverick IR seekers as a sensor, so no additional aircraft sensor is needed; the system selects targets on the basis of their shape and size. The pilot can override the system's target selections. Hughes claims that Rapid Fire can fire 4 Mavericks in less time than 1 can be fired manually. Although the program is administered by the air force, Rapid Fire is applicable to navy and marine aircraft carrying this weapon. The target discriminating logic may also be applicable to other imaging IR weapons.

As of March 1989, Hughes and Raytheon, the 2 Maverick manufacturers, were competing for a contract to develop an Improved Maverick missile. An award was expected in the summer of 1989, leading to an 18-month demonstration-validation phase. The weapon, which is intended as a gap-filler pending the appearance of AIWS, would enter service in FY93 (the baseline AIWS, expected to enter service in FY95, will not match Improved Maverick capabilities). Improved Maverick is a short-range standoff weapon incorporating a data link (for lock-on after launch) and a new motor with more sustainer thrust (the current missile is boosted for the first half second, then the sustainer fires for 3½ sec, the missile reaching Mach 1.3 before coasting). The range is expected to double, perhaps even to triple.

This program was inspired by the demonstrated ability of the missile sensor to lock onto a target beyond the missile's flight range, e.g., an F/A-18 was able to lock onto a Septar target boat at a range of about 18 nm. Plans called for the sacrifice of 1400 of about 6600 newly built Mavericks in the FY91-92 program, the money going into a few extended-range prototypes for a demonstration/validation program. Existing missiles would later be retrofitted. The future of this program is now in question because Maverick production was eliminated from the FY91 defense program.

There is also an experimental mm-wave-seeker program, initially for the air force, paid for out of the balanced technology initiative (BTI). Four prototypes are to be built and test fired. The seeker is that originally built for the earlier Wasp missile, enlarged to 9-in diameter and otherwise improved, to find "special targets" (presumably command/control posts).

As of early 1990, Maverick has been test fired by a P-3, and a current operational evaluation is determining whether P-3 Maverick capability is worthwhile. Illustrations of the new P-7 maritime-patrol airplane sometimes show Mavericks at the wing tips.

As of March 1989, Hughes is proposing a helicopter-launched version for LAMPS helicopters, with a shaped-charge warhead, as a shorter-range alternative to Penguin at about a sixth the cost. With an IIR seeker and a shaped-charge (125-lb) warhead, Maverick could reach about 6 nm from a 100-kt helicopter, and 4.5-5 nm from a hover. Use of the heavy 300-lb warhead would roughly halve these figures. Hughes argues that the shaped charge will suffice against most ships; in static tests, it cut through 45 ft of hull when exploded at a 70-deg oblique angle, generating a 4-atmosphere overpressure (and temperatures of 700 deg C) in the area adjacent to the trajectory.

Hughes also expects to propose a Maverick using a fiber-optic

data link, similar to that in the army's FOG-M lightweight missile. As of early 1989, China Lake was testing a fiber-optic guided Walleye, and the second firing, conducted while the launch airplane maneuvered freely, had been successful. Hughes uses a dual payout system (1 reel in the missile, 1 in the airplane) analogous to that of a wire-guided torpedo. This method has been demonstrated at supersonic speed at ranges as great as 100 km and is complemented by a new proprietary method of high-speed fiber-optic inspection (by laser) for quick and inexpensive fiber winding.

The Israeli Popeye 2, which is to be carried by U.S. Air Force B-52 bombers, is reportedly derived from Maverick.

The U.S. budget request, as of January 1989, was for 731 missiles in FY89, 560 in FY90, and 2135 in FY91.

◆ Paveway

Paveway is the standard U.S. laser-guided bomb, manufactured by Texas Instruments. Paveway I was the original version. Paveway II is now in service. Paveway III is a new development, intended for low-level delivery, that will use a mid-course autopilot and a very sensitive seeker. Paveway is also designated LLLGB (low-level laser-guided bomb) and is a generic seeker/wing combination, applicable to all of the Mk 80 series bombs. All of the Paveway-series bombs use a NdYAG laser operating at 1.064 microns (as in the U.S. Pave Knife or Pave Tack). The standard NATO laser designator operates at this wavelength using a 10-20 pps code.

The original Paveway was selected for accelerated development in 1965 by the U.S. Air Force Armament Development and Test Center as the laser-guided system of choice. Feasibility demonstration, using an M117 bomb with a KMU-342 guidance kit, began in December 1965, and development began in July 1967. Paveway entered service in December 1968. Texas Instruments beat out North American Autonetics for the contract (1966).

Paveway I uses a 4-quadrant silicon detector array, which drives the 4 control fins to keep the bomb pointed at the target laser spot. The kits fitted to the U.S. Mk 82, 83, and 84 bombs are designated KMU-388, 421, and 351. Paveway I has been exported to 17 countries; the United Kingdom uses it with 1000-lb bombs (designated Mk 13 or Mk 17). Pave Storm was Paveway I applied to an SUU-54B cluster bomb. Paveway I lacked standoff range and had limited performance in mist and fog. Early bombs were controlled entirely by their forward fins.

Paveway I development began in May 1969, and the weapon entered service in December 1970.

The Paveway II engineering prototype was ordered in December 1974, and the weapon entered production in 1977 (FY76 program). It has upgraded electronics and more sensitive airfoils, and is less expensive (it uses some plastic parts). The Paveway II bombs are GBU-10E/B (Mk 84), GBU-12D/B (Mk 82), and GBU-16B/B (Mk 83); Skipper is a powered version of GBU-16B/B. Britain uses a version applied to its Mk 13/18 1000-lb bomb family, with KMU-351E guidance kits.

Unit prices: FY81, \$8372; FY83, \$17,643; FY85, \$30,139; FY86, (air force) \$40,262, (navy) \$33,972.

Naval procurement: FY84, 350; FY85, 2752; FY86, 2109; FY87, 243; FY88, 222; FY89, none.

Paveway III has a rocket booster. It incorporates microprocessor control, a digital autopilot, and flip-out wings; and it can be delivered in a dive, from level flight, or by toss-bombing. The seeker has an enlarged field of view and greater sensitivity for laser acquisition in poor (e.g., European) weather. Warheads were primarily Mk 82 and 84, although it could also accommodate Mk 83 and the Hard-Structure Munition warhead. The laser seeker could be replaced by an mm-wave or passive IR seeker. All of this turned out to be far too expensive. By about 1985, moreover, the air force, the program sponsor, was more interested in an autonomous weapon to attack high-value (and hotly defended) targets; the laser-designation mission was becoming far too dangerous. Hence the shift to projects like MSOW and Have Slick.

Paveway III began full-scale engineering development in 1980. By 1985 the air force planned to continue to buy Paveway II and III through FY92. It awarded Texas Instruments a contract for 2448 Paveway III bombs (with Mk 84 warheads) in December 1984, only to cancel the contract the following February because the unit price had escalated to \$34,900. Texas Instruments then offered a 5-year program at a unit price of \$25,100. In fact, the air force bought 1407 Paveway III in September 1985 but had to pay \$40,000 each. The service then withdrew its request for further production for FY86. However, testing and development continued. In September 1986 Texas Instruments announced new software to control the angle of attack and of bomb impact, which would be important for a hard target penetrator. Paveway III was tested through 1986.

Paveway III's standoff range is probably about 3–5 nm, compared to 1–3 nm for Paveway II.

In 1988 Texas Instruments claimed that 2 Paveway III bombs were equivalent to 7 Paveway II and to 1014 unguided bombs of the same type, so that destruction of a given target would cost \$470,000 using Paveway III, \$2.08 million using Paveway II, or \$171 million using conventional weapons. It is not clear to what extent these figures included estimated aircraft losses.

The advantage of Paveway III is that it can be delivered below the flight envelopes of most surface-to-air missiles and outside anti-aircraft-gun range. Texas Instruments claims that the bomb automatically compensates for varying release conditions, so that the pilot has merely to place the target in the middle of the HUD, minimizing exposure to enemy fire. The mid-course guidance allows for considerable offset from the airplane's flight path, and the bomb is designed for steep terminal trajectory. Inertial control is required for mid-course guidance, the bomb homing on a laser spot only at the end of the trajectory. Guidance is by 4 short wings attached to the seeker on the nose of the bomb; 4 big wings at the tail make for a 5:1 glide ratio to the target.

◆ Shrike (AGM-45)

Dimensions: 8 × 120 in; wingspan 36 in
Weight: 400 lb **Warhead:** 145-lb blast-fragmentation
Propulsion: solid-fuel rocket
Speed: Mach 2 **Range:** 25 nm

The first U.S. antiradar missile, Shrike is obsolescent but remains in service (1990). Based on the Sparrow air-to-air missile airframe, Shrike was developed by the Naval Weapons Station at China Lake. The main design limitations are that the seeker must be pretuned to a set frequency (a total of 13 different seekers have reportedly been produced) and that the seeker is rigidly mounted in the missile, so that the carrying aircraft must dive at the target, warning the radar operators to shut down. The missile then goes ballistic, as it has no memory circuits. Even so, Shrike has been widely used, in Vietnam, in the Middle East, in the Falklands, and probably in the Libyan raids of 1986, always as an interim weapon pending provision of sufficient HARMs.

A series of accidental Shrike attacks on ships in Vietnam in 1972 (most notably USS *Worden*) demonstrated that small weapons could destroy combat capability by wrecking topside antennas. Antiradar missiles were thereafter considered effective antiship weapons, with the potential for "cheap kills." Partial protection, in the form of Kevlar wrapped around some waveguides, was later provided, at least in the U.S. Navy.

Development of Shrike began in 1958, and production in 1963. About 18,500 were made. Variants included AGM-45A-1, A-1A, and A-2 (1963–66, G- to lower J-bands); A-3, A-3A, A-3B (1963–68, wider-band seekers); A-7 (lower frequencies; May 1967); A-9 and A-10 (USAF only); and AGM-45C (Shrike currently carried by air force F-4Gs, to suppress SA-6 guidance radars).

As of 1989, Shrike antiradar missiles are reportedly no longer carried aboard aircraft carriers. They presumably survive as war reserves.

◆ Sidearm (AGM-122A)

Dimensions: 5 × 113 in; span 24.8 in **Weight:** 195 lb
Warhead: 10-lb blast-fragmentation
Propulsion: single-stage rocket **Speed:** Mach 2.3
Range: about 18,000 yd (high-altitude delivery)

Sidearm carried by an attack helicopter. (U.S. Navy)

Sidearm is a low-cost self-protection antiradar missile, to be carried by Marine Corps helicopters and Harriers. A converted AIM-9C (semiautonomous radar-homing version of Sidewinder), Sidearm was developed by the Naval Weapons Center (China Lake), which modified the original narrow-band passive seeker to broader-band purely passive operation and also modified the original target detection device for air-to-ground operation. The original rocket motor and wings were retained, but the canard fins were modified. Sidearm executes a programmed pitch-up shortly after launch, so that the missile can be carried by a very low-flying airplane.

Procurement: FY86, 885; FY87, 256; FY88, 276; none in FY89 (although continued production had been requested). As of September 1988, Sidearm was being operationally evaluated, and a production decision was expected early in 1989. On 25 April 1988 a Sidearm successfully attacked an armored vehicle.

As of 1989, the navy was seeking funding to extend frequency coverage up from surface radars to those used by airborne types, and also to extend the seeker antenna's field of view. This projected AGM-122B version was canceled because of a lack of funds.

◆ Skipper II (AGM-123A)

Dimensions: 14 × 169 in; span 63 in
Weight: 1280 lb **Warhead:** Mk 83-5 1000-lb bomb
Propulsion: Shrike solid-fuel rocket (Mk 78-0; WPU-5/B)
Speed: transonic **Range:** 7–9 nm

Skipper II. (U.S. Navy)

Skipper and Paveway attack trajectories. (Emerson Electric)

Skipper II was conceived as an inexpensive air-to-surface standoff missile, consisting of a Paveway II (GBU-16) laser-guided bomb with a Shrike rocket motor. Skipper, although it could not match Maverick performance, cost only about a quarter or half as much. Therefore, Skipper could be deployed in large numbers very quickly; it was certainly superior to an unguided bomb or a laser glide bomb. Because Skipper was a viable alternative to Maverick, the navy could effectively pressure the Maverick manufacturer to reduce its costs. (Cost reduction was also the effect of opening a second-source Maverick production line [Raytheon].) Skipper is much slower, unable to duplicate Maverick's performance. Even so, Skipper can still follow a moving target.

Skipper was conceived in the late 1970s at the Naval Weapons Station, China Lake, but did not attract official attention until 1981. An airfoil-motor trade-off study was conducted in FY82. Prototypes were operationally evaluated in January 1983 (over 25 were launched), and FY84 funds were reprogrammed to support the weapon. The production RFP was issued on 7 December 1983. Aerojet was awarded the motor contract on 24 July 1984, and Emerson received the missile contract on 5 March 1985; first deliveries followed in July 1985. Unit cost was \$24,324 (FY88). Procurement: 500 in FY85, 995 in FY86, 1600 in FY87, and 1334 (2556 requested) in FY88. The FY89 POM included 1550, but the budget request deleted this weapon. The stated navy requirement had been 12,000 missiles and 15,000 bomb-modification kits (\$10,000 each, for Paveway II bombs; the motor costs \$5000).

There were reportedly some problems with the quality control of the Emerson guidance-and-control package, and the navy asked Texas Instruments to improve the Skipper seeker.

The navy proposed conversion of the entire air force Paveway III stock, to replace the projected Paveway III bomb (unit cost \$142,000 when canceled), but the air force did not consider any of its bombs surplus for conversion.

A Skipper with a low-cost antiradar seeker was suggested by the navy as an alternative to, or complement to, HARM. A cluster-bomb version has also been suggested.

In FY86 Congress directed development of 2 Skipper versions, a low-cost laser-guided training bomb and a fiber-optic technology demonstration (FOG-S; see the account of Fiber-Optic Weapons, below).

◆ SLAM

See Harpoon (ship-launched).

◆ Standard ARM (AGM-78)

Dimensions: 13.5 × 180 in; wingspan 42 in
Weight: 1356 lb **Warhead:** 219-lb blast-fragmentation
Propulsion: dual-thrust rocket
Speed: Mach 2.5 **Range:** 60+ nm

Standard ARM is an antiradar derivative of the Standard Missile surface-to-air weapon and is designed for greater versatility than Shrike. Standard ARM can continue to home on a radar that has shut down during the missile's approach. No longer in production, Standard ARM remains in service (1988).

Standard ARM was ordered in September 1966 as an emergency replacement for Shrike, initially using the Shrike AGM-45A-3A seeker (Mod 0) but then being fitted with a Maxson broad-band seeker (Mod 1: AGM-78B) that did not have to be retuned and that was gimballed to allow for a wider range of airplane maneuvers. There was also an impact marker, to permit follow-up attacks on a concealed target. Major variants: AGM-78A-2 (red phosphorous smoke marker), A-4 (improved seeker to counter specific early-warning and GCI radars), B (seekers for E-G- and I-bands), B-2 (unified seeker covering all bands), C-2 (more sensitive seeker, modified fuze, and rocket motor), D (General Dynamics seeker), and D-2 (final production).

Production of AGM-78A began in FY68, and the last AGM-78D-2s were delivered in August 1976, about 3000 missiles having been manufactured. General Dynamics proposed a further

The 2 ARMs developed during the Vietnam War, and still in service: Standard ARM (foreground) and Shrike (background). (U.S. Navy)

lightweight version, as an interim HARM, but it was rejected. In July 1986 the Israel Defence Forces released a photograph of a Purple Fist antiradar missile very similar in configuration to Standard ARM but with a reshaped nose.

◆ Tacit Rainbow (AGM-136A)

Dimensions: 27 × 100 in; span 61.4 in
Weight: about 1270 lb **Warhead:** 40 lb (WDU-30B)
Propulsion: Williams International WR36-1 turbofan
Range: reported about 100,000 yd (endurance at least 80 min)

Tacit Rainbow fired by an A-7. (Northrop)

Tacit Rainbow. (Northrop)

A new type of antiradar missile developed by the Northrop Ventura Division, Tacit Rainbow can loiter in the area of a suspected (but shut-down) radar, waiting for it to be turned on. Tacit Rainbow should, then, deter the operator and, thus, turn off enemy air defenses. Conventional antiradar missiles, such as HARM, cannot loiter, and thus a radar turned off to avoid them can come back up after they have passed. Some current

missiles, such as HARM, are credited with a capability to hit a threat radar even if it is turned off during their flight, but they are probably unable to deal with multiple threats. Because the operators of the several radars could not know which one(s) Tacit Rainbow had targeted, the operators would be less likely to turn their sets back on when the missile was in their area. Details have not been released, but presumably the missile can select any of a variety of threat radars for attack, automatically setting priorities, and it would appear that flight path and loiter time are preset. The missile was developed as a classified program, first revealed in 1987.

Full-scale development began in November 1981 with an Air Force contract to Northrop; Tacit Rainbow was selected by the DRB (Defense Resources Board) as a triservice program in November 1984.

The first successful flight against an emitter was made on 10 December 1984. The first successful launch from a navy A-7 (against an emitter) was on 27 November 1985. It appears that the first successful full-up flight, in which the missile loitered, then automatically sought out and identified an emitter (which had been shut down when the missile appeared), and then attacked and destroyed that emitter, was made on 12 April 1988. It is not clear whether some of the 1984-85 flights were made with preprototypes since recent press releases refer to flight tests beginning in 1987.

The missile is stowed with its surfaces folded, the 61.5-in wing swinging out shortly after launch.

Tacit Rainbow suffered from severe cost escalation. In 1986 a 300% cost overrun forced the air force to cap the development contract. Because of test problems, the House Armed Services Committee recommended a \$60M cut in FY89 funding, leaving \$55M (including \$11.9M to start second-source production).

In June 1989 a delay of at least a year (to June 1990) in completion of the 25 developmental/operational test flights was announced, the program already running 18 months late. In August 1989 the House Appropriations Committee tried to terminate the program, claiming a 253% overrun. The air force successfully protested that the cost data were misleading, comparing estimates for a large buy to a much smaller purchase planned for FY90. FY90 production was eliminated, but Tacit Rainbow remained in the FY91 budget. Thus the program survived, but at so high a unit cost that in December 1989 the navy

was forced to withdraw from production. The service did remain in the full-scale development program and thus can later deploy the missile on board A-6s. At present only air force B-52Gs are scheduled to carry it. Clearly the missile was still needed, but by that time the overall budget was too tight to accommodate it. The Senate was particularly anxious to keep the navy in, transferring funds from the SLBM Warning System to Tacit Rainbow.

It seems likely that navy withdrawal from Tacit Rainbow was justified in part on the theory that stealthy A-12 attack aircraft would need less in the way of penetration aids. Should budget cuts and high unit costs slow or kill the A-12 program, leaving the A-6E Intruder or some successor version as the only principal attack bomber for much longer, the Tacit Rainbow decision will probably be reversed.

At this writing, work is proceeding on a ground-launched version for the army.

◆ Tomahawk

See the Strategic Strike Systems section.

◆ Walleye I and II (AGM-62)

Dimensions: 18 × 159 in; span 51 in

Weight: 2340 lb **Warhead:** 2000 lb

Speed: glide bomb **Range:** maximum 20 nm (minimum 1 nm)

Walleye. Note the television nose (covered until flight) and the wind-mill generator at the tail. (U.S. Navy)

Walleye. (U.S. Navy)

Ground Launch Version

Air Launch Version

Air- and ground-launched versions of Tacit Rainbow, the latter still under development. (McDonnell Douglas)

Data are for Walleye II. Walleye I, 1100 lb, is 12.5 × 136 in (span 45.5 in), with a maximum range of 16 nm.

This electro-optical (television) homing glide bomb by Martin Marietta was employed during the Vietnam War. No longer in production, Walleyes remain in storage.

The specific operational requirement for this homing glide bomb was issued in August 1962, and Walleye I entered production in 1966 and service in 1967 (production ended in 1970, 4531 having been built). Walleye I could be carried at up to Mach 1.9, and from 35,000 ft it could glide 10 nm. This version carried an 825-lb linear shaped-charge warhead. Hughes converted 1481 Walleye I to Walleye II, with a heavier warhead and a more accurate seeker, and reportedly built 529 new Walleye IIs. Walleye II enjoyed a much greater glide range. To exploit it, a better data link (extended-range data link, ERDL) was developed, so that the bomb could be locked on after launch. Most or all remaining Walleyes have been converted to Walleye II.

There was also a nuclear version, but it was acquired only by the air force.

Walleye versions were designated guided weapons of various Marks. Many were practice or exercise versions. Mk 5 was Walleye II, with the large warhead. EX-10 was the experimental data-link version. Mk 12 was Walleye II with a new 2-band link. Mk 13 was Walleye II with a 5-channel command data link (for retargeting after launch) and with larger wings for extended glide range. Mk 21 (1977) was Walleye I ERDL (extended-range data link) using Channel A; Mk 22 was similar (using Channel C in Mod 2, Channel E in Mod 4). Mk 23 was Walleye II ERDL (1975). Mk 24 (1974) was Walleye II, but its guidance lacked a ground bore-sight adjustment, cager retainer, or narrow field of view. Mk 25 was similar. EX-29 (1979) was an experimental Walleye I ERDL with a new differential-phase-shift-keyed (DPSK) data link, presumably jam resistant. These features were implemented in Mk 30 (1983). Mk 34 (1986) was Walleye I with a Phase II (antijam) data link (Mod 2 had an improved television camera tube). Mk 35 (1987) was a CRAB (caging, retaining, and bore sighting) version of Walleye I, without any data link. Mk 36 (1987) was an ERDL version of Walleye I. The last weapon version, Mk 37, was a 2080-lb ERDL missile with the Phase II antijam data link (Mk 38 was a captive practice round).

SHIP- AND GROUND-LAUNCHED ANTISHIP MISSILES

BRAZIL

◆ Barracuda

Dimensions: 32 cm × 5.2 m; 1.2 m span [12.6 × 205; 47.2 in]
Speed: Mach 0.9 **Propulsion:** rocket sustainer
Range: 70 km [77,000 yd]

This missile is under development by Avibras Industria Aeronautica in both ship-mounted (MM-70) and truck-mounted (SM-70) forms; MM means Mar-Mar, SM means Superficie-Mar, and the number is the range in km. An air-launched version is also projected. Barracuda was to have equipped the projected 7th–16th Brazilian ocean-patrol frigates to be built by Verolme do Brasil at Puerto Alegre, replacing Exocet MM 40. Work began in 1986, and the project was reported canceled in the 1987 Brazilian defense cuts. However, an artist's sketch was displayed at the 1989 Paris Air Show, and the missile was reported once more under development, with a first flight expected in mid-1991. At that time work effort was concentrated on the coastal-defense version. A battery would include 3 launcher vehicles, each with four 580-kg launch containers. The target-acquisition radar might be the Swedish Giraffe or the Italian Pluto. The shipboard version is now proposed to replace Exocets on board existing Brazilian frigates, using the same launch containers.

The missile itself has a cruciform tail and low-aspect wings. Development of the Avibras SIS strapdown inertial mid-course-guidance sensor is complete, but as of mid-1989 work was only beginning on the active-radar seeker, and the warhead was only 20% developed.

Barracuda is also known as Astros II/Ms. Astros II is an unguided bombardment rocket (Artillery Saturation Rocket System), using SS-30 (127 mm, 30 km), SS-40 (180 mm, 35 km), or SS-60 (300 mm, 60 km) rockets. Presumably, SS-70 denoted a guided weapon with a 70-km range, launchable from the standard Astros truck. The existing rockets are all derived from space sounding (research) vehicles, and the launcher is modular so that rockets can be interchanged very easily.

CHINA (PRC)

CATIC (FL and SY) and CPMIEC (HY) market similar missiles under different designations, presumably indicating different design bureaus; the manufacturer (the Nanchang Aircraft Factory) may be the same. However, FL-4 is described as a ship-launched version of HY-4.

◆ HY-1

A modified Styx, HY-1 was initially developed by the Nanchang Aircraft Factory as a coast-defense weapon. Work began about 1963, the factory submitting a development plan in December 1964; the preliminary design was reviewed in April 1965. Small-scale production began in 1966, but the shock of booster ignition apparently caused 3 failures, that year and the next. Acceptance tests finally succeeded in May 1972, and the missile was certified in 1974.

Work on a shipboard version began in 1967. Unlike Styx/SY-1, which is fired from a launcher fixed to the deck of a ship or attack boat, HY-1 was intended for a trainable launcher; it would be fired across the deck. Presumably, such firing makes very different demands on the guidance system's gyros. Two simulation launches late in 1968 showed that it could be launched transversely from a moving ship, and 2 dummy missiles were successfully fired from a Chinese missile destroyer in September 1971. The same ship made the first successful live firings in September 1973 (4 hits out of 4 shots). The missile was certified for production in January 1976. Batch production had already begun in 1975.

Initially the shipboard and coast-defense versions differed; they operated in different environments, and the shipboard version required some modifications to its radar and autopilot. However, a common version was developed, production beginning in 1978. HY-1 is carried on board Chinese Luda-class destroyers, and Jianghu- and Riga-class frigates. It may have replaced SY-1 on board fast missile attack boats.

Work on a modified HY-1A began in 1983; the main changes were better ECCM, lower flight altitude, and longer range. Flight tests were conducted July–September 1985 (4 hits out of 4 shots), and production began in October 1986 (deliveries began in 1987).

The HY designation stands for Hai Ying, meaning Sea Hawk.

Both this missile and HY-2 are described as Silkworm (CSS-N-2).

◆ Silkworm (HY-2, HY-4, C601, C201)

	HY-2	HY-4	C601
Diameter	—	0.76 m [29.9 in]	—
Length	7.36 m [290 in]	7.36 m [290 in]	7.38 m [291 in]
Span	2.75 m [108 in]	—	2.4 m [95 in]
Weight	2998 kg [6608 lb]	2000 kg ^a [4408/3834 lb]	2440 kg [5378 lb]
Warhead	513 kg [1131 lb]	500 kg [1102 lb]	513 kg [1131 lb]
Speed	M 0.9	M 0.8–0.85	—
Range ^b	95 km [104 kyd]	150 km [164 kyd]	95–100 km [104–109 kyd]

a. 1740 kg, air-to-surface.

b. Effective range 35–135 km [38–138 kyd].

Silkworm (CSS-N-2) is derived from the Soviet Styx, via SY-1 and, probably, HY-1. The official history of the Chinese aircraft industry, which describes SY-1 and HY-1 evolution in some detail, does not mention HY-2 at all, but the designation appears in numerous Chinese brochures.

HY-2 is produced by the China Precision Machinery Import and Export Co. (CPMIEC) and probably first appeared in the early 1980s. Egypt was the first recipient of FL-1 and HY-2 missiles (1984–85). These weapons may also have been exported to Bangladesh, North Korea, and Pakistan, although in each case it is not certain which missiles have been transferred (e.g., Pakistan has missile boats, but they may be armed with SY-1, HY-1, or FL-1, all of which use much the same airframe).

HY-2 is apparently exclusively a coast-defense missile. HY-4 exists in both surface- and air-launched versions, the latter being lighter (as shown above). C601 is an air-launched version carried by Chinese-built Badger bombers (1 or 2 per airplane).

Chinese missiles manufactured by CPMIEC on display at ASIINDEX 1988. From the top, they are M-1B, C301, C101, C802, C201, M-1, and HQ-61 (SAM). M-1 and M-1B are army artillery rockets fired from multiple launchers; -1B is heavier and achieves a greater range. (CPMIEC)

The HY-2 warhead is somewhat smaller than that of Styx, so Silkworm can carry more fuel for greater range. HY-2 and -4 use active-radar seekers; C601 has an active monopulse seeker. HY-2A uses an IR seeker. HY-2G has a more precise radar altimeter, so it can cruise at a lower altitude.

HY-4 flies at 200 m (330 ft) during cruise and at 70 m (230 ft) while homing; the missile dives steeply into its target. HY-2G flies at lower altitude, 30 or 50 m [98 or 164 ft], using a precision radar altimeter. The other weapons in this series cruise at 100 m [330 ft] height.

Chinese HY-2 (Silkworm) coast-defense missiles. (U.S. Naval Institute)

Silkworm being launched by a Chinese Osa-class attack boat. (Naval & Merchant Ships Publishing House)

HY-2 is powered by a liquid-fuel rocket, with a solid-fuel booster. A modified HY-2, HY-4 uses a turbojet power plant, with its intake under the fuselage (rather than a liquid-fuel rocket), with a solid booster for launch, C601, which is slightly more powerful than HY-2, uses a liquid-fuel rocket.

C201 is a revised HY-4 with better electronics. It was first displayed at ASIINDEX 1988 (November 1988).

Reportedly, this missile is manufactured under license in North Korea, using Chinese- rather than Soviet-supplied technology. Reported exports: Albania, Egypt, and Pakistan. Reportedly, the Silkworms fired by Iran in the Persian Gulf (from April 1987 on) had been manufactured in North Korea; the PRC denied having provided them and announced that sales would be stopped. Reportedly, Zaire may use HY-2 as a coast-defense missile.

◆ HY-3/C101/C301

Dimensions: 54 cm × 5.6 m [21.3 × 220 in]

Propulsion: 2 ramjets (and 2 solid-fuel boosters)

Speed: supersonic **Range:** 50 km [27 nm]

C101, which resembles the British Bloodhound surface-to-air missile in configuration, was announced in 1985 and will probably enter service about 1990. C101A is a proposed air-launched version. The manufacturer is CPMIEC. Length is also sometimes listed as 7.2 m [283 in] and range as 70–80 km.

HY-3 (C301) is a heavier and longer-range version of C101, launched using 4 boosters. Approximate dimensions are 76-cm diameter and 9-m length [29.9 × 354 in], and range is 100 km [109,000 yd]. This missile was first displayed as C301 at ASIINDEX 1988 in Beijing (November 1988).

Both missiles attain a speed of about Mach 2, running in to the target at a preset altitude of 7–50 m. A photograph displayed at the Paris Air Show in 1989 shows a missile hitting at a height of about 3 m [10 ft]. Both use active radar guidance, and each can be preset to execute a single terminal maneuver to evade close-in defenses.

C101 antiship missile, showing ramjets and boosters. (CPMIEC)

◆ FL-1/SY-1

FL-1 is a winged missile similar in configuration to HY-2. After launch, FL-1 rises to 100–300 m [328–984 ft], but then it descends to 30 m [98 ft], maintaining altitude with a radar altimeter. The missile has a new monopulse radar seeker, apparently operating at a higher frequency than that of the HY-2 series, and carries a 513-kg warhead. The seeker was probably derived from that of the SY-2 (C801); it is considerably smaller than that of the HY-2.

The FL designation stands for Feilung, meaning Flying Dragon.

◆ FL-2

Dimensions: 54 cm × 6 m; span 1.705 m [21.3 × 236 × 67.1 in]

Weight: 1300 kg without booster [2865 lb]

Warhead: 365-kg shaped-charge [804 lb]

Propulsion: solid-fuel rocket

Speed: Mach 0.9 **Range:** 50 km [55,000 yd]

This ground-launched sea-skimming antiship missile was first shown at the 1987 Paris Air Show. Externally, FL-2 broadly resembles Silkworm, but FL-2 uses solid propergol fuel; there is also a jettisonable booster.

The manufacturer describes the seeker as an antijam type, and the radio altimeter is said to be accurate to within 0.6 m, for sea-skimming flight.

◆ FL-4

FL-4 is the ship-launched version of HY-4.

◆ FL-7

Dimensions: 54 cm × 6.6 m [21.3 × 259.8 in]

Weight: approx 1800 kg [3967 lb]

Warhead: shaped-charge

Propulsion: liquid-fuel sustainer; solid booster

Speed: Mach 1.4 **Range:** 32 km [35,000 yd]

The manufacturer is CATIC. Externally, FL-7 appears to be a stretched FL-1/HY-2. FL-7 is described as an alternative to C801. Cruise height is 50–100 m [164–328 ft]. CATIC claims a hit probability of 75% and states that the guidance system has ECCM features. Reportedly, this missile is intended to replace FL-1/HY-2 (Styx).

In 1988 it was reported that Iran had received about 100 FL-7s.

◆ SY-1

SY-1 was a direct copy of the Soviet SS-N-2A Styx (NATO designation CSS-N-1). SY means Strive Upstream, and the missile is used both on shipboard and for coast defense.

The Chinese acquired a manufacturing license in 1959. Preparation for production began in March 1960. The first 3 ground-launched missiles were tested in November–December 1964, with shipboard simulation missiles following August–November 1965. Presumably, these were all ballistic shots since a Chinese account states that telemetry tests occurred only April–July 1966. The certification test was completed in November 1966, with 8 missiles hitting out of 9 fired (the requirement was that 6 out of 9 hit). Refitted SY-1s, tested July–August 1982, achieved the same results. Missiles were manufactured by the Nanchang Aircraft Factory. Some minor improvements, such as a better radome, were introduced.

The Chinese considered the missile defective because it used an aneroid barometer (hence could not fly at low level, since response would be too coarse and too slow) and because it used a conical-scan (on receive only) seeker, which was relatively easy to counter. The missile was initially modified to fly at a preset altitude before diving into the target; 3 hits were achieved out of 3 shots (probably about 1970).

In 1974 the Defense Industry Office of the State Council formally ordered modifications: a solid-state microwave monopulse seeker and a vertical speed sensor with a radio altimeter; the new version was designated SY-1A. Low-altitude tests using the new height controller (3 hits out of 5 shots) were successful in 1975, but 3 design certification tests (1977–80) failed, and the new version was not certified until December 1983, after a successful test in the fourth quarter of 1982.

Meanwhile, the manufacturer developed an additional improvement, the "second lowering height"; in this version the missile descends from its normal relatively low altitude to sea-skimming height near the target. This modification was successfully tested in 1980.

In its coast-defense role, SY-1 has been seen on the chassis of a T-63 amphibious tank.

◆ C801/C802/SY-2

Dimensions: 0.36 × 5.814 m; span 1.18 m [14.2 × 228.9 × 46.5 in]

Weight: 815 kg [1794 lb]

Warhead: 165 kg, semi-armor piercing [364 lb]

Propulsion: boost-sustain rocket (2 motors) **Speed:** Mach 0.9

Range: 8–40 km ship to ship; 10–50 km air to ship [8700–44,000 yd/10,900–55,000 yd]

SY-2 is an indigenous Chinese development, as compared to the earlier Soviet-derived antiship missiles. The design requirements were light weight, supersonic speed, and countermeasures resistance. Work on a liquid-fueled version began in 1970;

C801 being launched by a submarine. (CPMIEC)

C801 antiship missile, with booster. (CPMIEC)

the Chinese have written that development was badly delayed by the Cultural Revolution. The first ground test was completed only in 1975, and the test of the ground telemetry missile in 1980. Meanwhile, the liquid-fuel project was canceled in 1976 in favor of a solid-fuel alternative, at the navy's request. The Chinese account states that "results were gained from scientific research in this respect" by 1986, which presumably means that the missile had been test flown by that time.

SY-2 is also designated C801.

This weapon is also called "Yinji" (Hawk Attack). It is similar in configuration to Exocet and uses a similar box launcher, but these missiles probably are not related. The missile climbs after launch then dives to cruise altitude (20 or 30 m). Diving again to 5 or 7 m, C801 turns on its active monopulse radar seeker and then dives into the target.

C801 is carried by at least one E5SG-class submarine (6 missiles in tubes, fired on the surface) and Jianghu-III-class frigates. C801 has been offered for export on board a modified Hoku class missile boat (4 C801 in place of 2 HY-2; the boat is a steel-hulled version of the Soviet Komar). At least 1 Luda-class destroyer is reportedly being refitted with C801 missiles (but reports may actually reflect a Chinese proposal to build ships so armed for export), and this weapon is also being placed on board existing Chinese fast attack boats. An A-5 attack aircraft can carry 2 underwing.

C802 is an upgraded C801, first displayed at the Asiadex exhibition in the fall of 1988. Propulsion is by turbojet (with a rocket booster), for a speed of Mach 0.8–0.9, a maximum range of 120 km [65.6 nm] and a minimum range of 15 km [8.2 nm]. Cruising altitude is 20–30 m, and the missile descends to 5–7 m for terminal homing. Dimensions: 360 mm × 6.392 m [14.2 × 252 in]; weight is 715 kg [1576 lb]. The missile is manufactured by CPMIEC.

C801 has reportedly been supplied to several Middle Eastern countries, including Iran. C801 was supplied to Thailand on board new Jianghu-V-class frigates. Reported unit price (1990) was \$780,000. It was reported in mid-1990 that some PRC Luda-class destroyers would be rearmed with quadruple C801 launchers in place of their current FL-2s.

Perhaps the best-known Western ship-launched antiship missile, the Aerospatiale Exocet sank the British destroyer *Sheffield* and the container ship *Atlantic Conveyor* in the Falklands. Exocet has also been used by Iraq in the Gulf War, severely damaging the U.S. frigate *Stark* and hitting numerous tankers. Exocet exists in ship-launched (MM 38 and MM 40), air-launched (AM 39), and submarine-launched (SM 39) versions, all of them fueled by a solid rocket, and all sea-skimmers with active-radar homing. The ANS is the projected replacement.

The operational requirement was to disable the target, the designers arguing that to guarantee sinking they would have to provide so heavy a weapon as to preclude carrying it on board anything but a large ship. They also argued that even a relatively small (700–800-kg) missile penetrating a ship at Mach 0.9 or more while carrying a 160-kg warhead would have a devastating effect on a large ship. Some have compared this missile to a 13.5-in semi-armor-piercing (i.e., battleship) shell. In practice, when Exocets have failed to explode after impact, their unexpected solid fuel has started major fires. Because the fuel includes its own oxidizer, such fires can be impossible to smother, and the extreme temperatures generated can start fires in nearby compartments. This incendiary effect seems to have been entirely unexpected. A substantial number of duds was reported during both the Falklands War (for example, the *Sheffield* succumbed to the effects of the rocket-fuel fire, the warhead never exploding) and the Gulf War; but this problem has apparently been cured.

Range is relatively short, the designers arguing that a missile launched at very great range has to search a relatively large area of uncertainty around the target, and that the radiation of the seeker is likely to be the first warning of the missile's approach.

Exocet MM 38, the original version. (U.S. Naval Institute)

Exocet AM 39 carried by a Mirage 50 fighter. (Aerospatiale)

On this basis, the original MM 38 was designed for a range of only 40 km [44,000 yd], corresponding to the radar horizon of the medium-sized warship that would be firing the missile. At so short a range, flight time is very limited, and the target cannot move very far while the weapon is in flight, i.e., there is little uncertainty. However, a shipborne helicopter can do better, and the current MM 40 has a range of 70 km. The helicopter links its data to the launch ship; the missile still operates on a fire-and-forget basis. The air-launched AM 39 has a range of 50–70 km, depending on platform speed.

Rocket propulsion makes for shorter range than a turbojet, but the designers claim that it is unnecessary to boost an Exocet to anything like the initial altitude of a turbojet missile such as a Harpoon. The surface-launched version is fired from a fixed launcher (elevated to 12 deg), and the 2-sec boost brings the missile to a maximum altitude of 30–70 m [98–229 ft]. The missile then cruises at 9–15 m [30–49 ft] in altitude. At a distance of 12–15 km [13–16 kyd] from the predicted target position, the missile descends to attack altitude (normally 8 m [26 ft], but as low as 2.5 m [8.2 ft] in a calm sea). The seeker is turned on at this point, and altitude is maintained by radar altimeter.

System reaction time is about 60 sec (time required to warm up the seeker radar's magnetron). Prefiring information is target range and bearing, own-ship heading, own-ship speed, and vertical reference, plus manual inputs for seeker angle search, seeker turn-on range, terminal altitude, and proximity function selection (impact or pseudoproximity). There is no proximity fuze as such, but the radar altimeter can be set to burst the missile as it passes over a target. The pseudoproximity fuze works through the seeker, which calculates a "should-hit" time from the range, and detonates the weapon about 0.015 sec after it should have hit. The missile is, therefore, vulnerable to chaff: the pseudoproximity fuze can be activated by the chaff, causing the missile to explode after entering a chaff cloud, instead of seeking a real target after passing through the cloud. Missiles can also be set to begin a target-search routine after passing through a chaff cloud without detonating and without detecting an object above the sea's surface. Aerospatiale now offers a Super ADAC seeker (with better ECCM) for backfit.

AM 39 has modified control surfaces so that it can be carried at supersonic speeds, and it has a light-steel rather than an alloy motor casing. The motor provides more thrust for greater range. The SM 39 version, which is carried by French attack and strategic submarines, is launched via a buoyant capsule (fired from the tube by a gas generator and powered underwater by a solid-fuel motor, which boosts the missile clear of the water). This version uses a waterproofed MM 40 digital computerized seeker. The capsule is powered so that it can break the surface some distance from the launching submarine, reducing the risk of detection for the submarine. Boosting from underwater also reduces the maximum altitude the missile reaches and, thus, its detectability (50 m rather than the reported 600 m of Sub-Harpoon).

MM 40 is a longer-range version in a more compact canister (possible because the wings fold; total weight is 1150 rather than the 1750 kg of MM 38, and typically 2 MM40s can be carried for every MM 38). MM 40 is suitable for coast defense because this version can take a gyro angle as great as 90 deg (MM 38 can turn only 30 deg).

Exocet was first announced in October 1968, with an order from the French Navy. Greece followed in December (first firing July 1970), then Germany (West) in December 1970 (first firing June 1971), and the Royal Navy in June 1971 (trials, HMS *Norfolk*, April 1974). AM 39 was first tested in 1972. SM 39 was announced in 1979 and first fired by the submarine *Agosta* in mid-1981. Series production of MM 40 began in January 1981. The thousandth Exocet was delivered in October 1980. First reports of combat use in the Persian Gulf were in 1984.

Britain uses the MM 38 version of this missile, in a British system called Excalibur, to defend Gibraltar. The associated radar is Type 1006. The British naval designation for the Exocet

system is GWS.50. Qatar uses the MM 40 version for coast defense.

Estimated unit costs as of 1986 (export price in parentheses): MM 38, \$350,000 (\$450,000); AM 39, \$525,000 (\$650,000); SM 39, \$850,000 (this weapon is not available for export); MM 40, \$490,000 (\$600,000).

Production: total deliveries as of 1986 (total orders in parentheses): MM 38, 1262 (1575); AM 39, 714 (809); SM 39, 24 (62); MM 40, 399 (470). Orders in 1986 amounted to MM 38, 2; AM 39, 3; SM 39, 11; and MM 40, 31.

China (PRC) reportedly obtained some of these missiles in April 1985 via a third party, possibly using Exocet as a basis for its own C801 missile, and there have been reports of Brazilian production under license. A torpedo-carrying version (as a future French ASW standoff missile) was proposed, but the MILAS missile was adopted instead.

◆ ANS (Anti-Navire Supersonique)

Dimensions: 35 cm × 5.7 m [13.8 × 224 in]

Weight: estimated 850 kg [1873 lb]

Warhead: about 180-kg SAP [397-lb] **Propulsion:** rocket-ramjet

Speed: Mach 2 cruise, Mach 2.5 at high altitude

Range: 180 km [97 nm]

- AIR LAUNCH MISSILE

- SHIP LAUNCH AMMUNITION

ANS. (Aerospatiale)

An ANS prototype in flight. (Aerospatiale)

This projected replacement for the Exocet is currently under development by a consortium of Aerospatiale and MBB (Messerschmidt-Bolkow-Blohm). ANS is designed to make maximum use of existing Exocet fire-control (fire-and-forget) and

launch facilities and will be compatible with MM 40 launchers. However, ANS is intended to reach supersonic speed (Mach 2.0) and should be able to go as far as 180 nm by flying at high altitude. Normally, ANS will fly most of the way to the target at high altitude (hence at high speed, without excessive fuel consumption), descending to sea-skimming altitude about 30 km from the predicted target position and weaving at high speed (up to 10 Gs) to avoid defensive measures. The surface-launched version will have a rocket booster; the air-launched version will use no booster at all and thus may avoid detection (at the moment of launch) by passive IR scanners.

ANS was conceived about 1974 as an Exocet replacement, MM 100, which was intended to fly its entire flight path at sea-skimming altitude. The project then became the French/British/German ASSM/ASEM. That project collapsed in 1981, the British having withdrawn. ANS was announced in May 1981. ANS incorporates many projected ASSM features, including the ramjet with solid booster, the inertial navigation system, and the active-radar (Serge Dassault Super ADAC) seeker. There are 2 alternative power plants: a liquid-fuel ramjet with solid booster derived from that of the ASMP strategic missile (see the Strategic Warfare section), tested in 1985; or a boron solid-propellant rocket-ramjet proposed by MBB. In 1988 it was reported that the boron-hydride motor had been chosen.

The French-German MoU was signed in 1983, and development was completed in 1986, with the first ballistic test flight at the CEM test center in the Mediterranean on 21 May 1987. At that time the choice of propulsion had not yet been made. In 1988 it was expected that series production would begin in 1992-93 and that missiles would enter service in 1994 on board ships and from 1997 on board aircraft. However, funding cuts in 1989 stretched out this schedule, so that expected service introduction was delayed to 1998 in the French Navy and 1999 in the German. Unit price will probably be about \$1-\$1.5 million.

◆ SS 12M

Dimensions: 7.1 × 73.7 × 25.6 in **Weight:** 165 lb

Warhead: 62.5 lb. Several types, including OP3C, an SAP with a bulbous shape to aid fragmentation (actuates about 6 ft after penetration), containing about 13 lb of TNT/RDX mixture.

Range: 6580 yd (670 yd minimum)

Speed: 580 ft/sec (flight time 34 sec maximum)

SS 12M missiles on board the French patrol boat *La Combattante*, on the side of the turreted launcher amidships (the much larger launcher aft carries flares). These missiles are no longer carried by French patrol craft but survive in small numbers in some other navies. (U.S. Naval Institute)

SS 12M is a naval version of a widely used army missile; the naval users are Greece (*Kelefstis Stamou* class), Libya (*Susa*-class fast attack boats), and Tunisia (P 48-class patrol boats). The launching system was developed by Vosper (the Libyan boats' builder) and Nord Aviation. The launcher fires up to 8 prepackaged missiles in succession, all the missiles occupying forward-facing fixed racks. The attack boat, therefore, has to turn toward the target at the moment of firing. The missile aimer occupies a turret with a gyro-stabilized APX.260 sight.

The operator uses a joy-stick to guide the missiles in flight, this optical control limiting their use to visible targets. This system is extremely difficult to use from a moving ship or boat.

Trials began in 1958, and SS 12 production began in 1959, AS 12 following in 1960. SS 12M was first demonstrated in 1966.

Sweden used the earlier SS 11 (as RB 52) in coast defense; it is now being replaced by the U.S.-supplied Rockwell Hellfire (see RBS 17, below). See the last edition for details.

ISRAEL

◆ Gabriel

Gabriel was developed by IAI in 1966–68 as a direct counter to the Styx missiles supplied to the Arab states; and Gabriel entered service in 1972, proving successful during the October 1973 Mid-East war. Although having a much shorter range than Styx, Gabriel could lock onto a smaller target (i.e., a missile boat) and apparently could be fired much more easily.

Gabriel in flight. The 2 dipoles visible below the missile are presumably part of its radar altimeter. (U.S. Navy)

The original concept was to use semiactive guidance, the firing boat providing illumination. In theory, such guidance uses the intelligence of the shipboard operator to overcome jamming and sea clutter. Gabriel I also has a backup pure radio-command mode, in which the missile is steered with the aid of an optical sight, the operator tracking 4 tail flares. Gabriel II uses semiactive guidance, though in a more sophisticated form, and has an upgraded sustainer motor. During the 1973 war several missiles broke lock on their relatively small targets after picking up

larger commercial ships. In 1980, therefore, work began on an active seeker (incorporated in Gabriel III) for better discrimination. Current Israeli tactics reportedly favor fire-and-update and mixed attacks (e.g., 1 active-seeker Harpoon and 2 semiactive Gabriels) to complicate target ECM.

Gabriel I climbs to about 100 m [328 ft] after launch, then at an estimated range (from the target) of 7.5 km [8200 yd], descends slowly to 20 m [66 ft]. The missile can then be command-guided in azimuth. At a range of 1.2 km [1300 yd] from the target, Gabriel I descends to 3 m [9.8 ft], using either radio-command or semiactive-radar guidance. Later versions rise to only about 35 m [115 ft], and cruise at 17–20 m [56–66 ft].

The associated fire control is the Selenia Orion 250 (RTN-10), later replaced in at least some cases by the Israeli-built EL/M 2221.

Gabriel III has a new frequency-agile active seeker (for greater operational range) and an updated guidance computer. The missile can be fired either in fire-and-forget or in fire-and-update (mid-course data-link update) mode. The aircraft-launched III A/S version has no booster. Typically, the aircraft TWS radar is used to aim III A/S; the TWS radar can cut search area by as much as 40:1, and the missile seeker can be turned on much closer to the target. This missile can be launched at 300–30,000 ft altitude by F-4, Mirage, Kfir, or A-4 aircraft. Gabriel III was announced in 1979, and development was completed in March 1980.

Gabriel IV is a new swept-wing missile, powered by an 810-lb thrust Bet Shemesh Sorec 4 turbojet. Its operational status remained uncertain as of 1990.

After the 1973 Middle East war Gabriel I was widely exported, in characteristic sealed shipping/launching containers with a shelf life reported as 2 yr. Known customers include Taiwan (1978), Kenya (37.5-m boats, 1979), Ecuador (1980), Chile, Singapore, Thailand, and South Africa. Brazilian plans to acquire Gabriel (1982) were canceled to avoid problems with the Arab states buying Brazilian weapons. Reportedly, about 2500–3000 Gabriels have been manufactured. Estimated unit prices (1987) were Gabriel I/II, \$400,000; Gabriel III, \$450,000; Gabriel III A/S, \$550,000; Gabriel IV, \$675,000. In 1971 the quoted Gabriel I price was \$85,000–\$95,000 or a total of \$2.5 million for 6 missiles plus radar and fire control.

The South African Skorpioen is a Gabriel II derivative, built under license. However, the Taiwanese (GRC) Hsiung Feng I is an unlicensed copy.

ITALY

◆ Otomat

Dimensions: 46 cm × 4.46 m; 1.35-m span [18.1 × 189.8 × 49.1 in]

Weight: 770 kg at launch; 660 kg in flight [1697/1455 lb]

Warhead: 210-kg [463-lb] Herotol blast [132-lb explosive]

Propulsion: Turbomeca Arbizon III turbojet and 2 solid-fuel boosters **Speed:** Mach 0.9

Range: 6–60 km, Mk 1; 100–180 km, Mk 2 [6.6–66 kyd/109–197 kyd]. Minimum range for Mk 1 is 6600 yd; maximum effective range is 64 kyd; maximum flight range is 88 kyd.

Otomat missile. (Matra)

Otomat. (Matra)

Otomat is a collaborative French-Italian project (OTO Melara and Matra); missiles are manufactured in both countries. Otomat uses inertial mid-course guidance and an X-band active terminal seeker. The launcher is fixed at an elevation of 12 or 18 deg. The rocket booster carries Otomat to an altitude of 80 m [262 ft] and a sustainable speed of Mach 0.9. The missile switches on its seeker at an expected range of about 12 km [13.1 kyd]. The missile climbs to 175 m [574 ft] at a range of 4 km [4400 yd] from the target then, at 2-km [2200-yd] range, dives at 7 deg. That dive increases the chance of penetrating deep into a target ship but exposes the missile to hostile fire for an estimated 12 sec. Otomat Mk 2 is, therefore, designed to sea-skim throughout its flight.

Mk 1 receives its launch data (true target bearing, own-ship heading, time of flight, and vertical reference) from the launch ship. The initial missile course can be as much as 200 deg away from the angle of the launcher. Warm-up time is 30 sec (gyro spin-up time). It appears that the original missile could not accept mid-course updates, but that limitation does not apply to production Mk 1s.

The French version of Mk 1 (which was apparently not successfully exported) uses the Clio fire-control system, and all Mk 1s use a 3-axis Thomson-CSF Col Vert terminal seeker that scans in elevation and to 20 deg to either side of the missile. Italian-made Mk 2s have an Italian-made SMA single-axis active seeker.

Mk 2 is designed to accept mid-course guidance from a helicopter closer to the target. There are 2 forms. In the Italian Tesco system, the helicopter orders the turn toward the target, so the missile is initially directed toward the helicopter. Thus, the missile flies at low altitude all the way to the target, not needing to be high enough to receive mid-course guidance from a ship. However, because the missile must fly directly to the helicopter, the system as a whole cannot engage more than 1 target (or a few targets very close together) at a time. Moreover, the effect of the system is to increase flight time, as the missile must follow an angled path. For example, a missile fired by a Venezuelan *Lupo*-class frigate hit a target 131.5 km [144 kyd] away, but that engagement entailed a flight leg of 85.8 km [93.8 kyd] to the helicopter, and another of 51.9 km [56.8 kyd] to the target. Typical mid-course guidance platforms are AB 212 and Sea King helicopters.

In the French ERATO (Extended Range Targeting of Otomat), mid-course corrections are transmitted directly by the launching ship. The missile must, therefore, climb to 900 m [2952 ft] altitude to remain within range of the shipboard data link. The ship tracks the helicopter, which in turn detects and tracks the target. The missile descends to 20 m [66 ft] cruise altitude after receiving final instructions by ship data link, at a maximum range of about 80–100 km (the ship's radar horizon for the helicopter). A final pop-up maneuver is possible. Maximum total range is 166 km. The helicopter need not fly near the missile's flight path, and the system as a whole can engage several targets simultaneously (up to 16 missiles at 6 targets with 6 simultaneous mid-course updates). This flexibility makes it possible for the missiles to approach 1 target from several different directions more or less simultaneously. Typically, this system employs an ORB 31 or 32 or AGRION helicopter-borne radar.

Mk 2 is also designated Otomat Compact; it has folding wings for more compact stowage. The original box was 1.36 m in diameter and 4.7 m long, with a weight of 850 kg empty. Otomat Compact uses an elliptical-section container with the same width, but only 0.84 m high and weighing only 595 kg. As in the case of Exocet (MM 38/MM 40), the change in launcher allows 2 missiles to be carried in the space (and very nearly with the weight) formerly allowed for 1.

OTO Melara and Engins Matra conceived Otomat as a private venture and began studies in 1967 and development in 1969. The first unguided launching was in 1971, the first successful guided flight following in February 1972. Mark 2 trials began in January 1974. A proposed air-to-surface version was abandoned in 1976.

Otomat is in Italian Navy service and has been exported to Egypt, Iraq, Kenya (on board 2 Vosper-Thornycroft 56-m attack boats), Libya, Nigeria, Peru, Saudi Arabia, and Venezuela. About 830 Otomats had been ordered by the end of 1986, and unit cost was about \$350,000–\$400,000. As of January 1982, 402 Otomats had been reported deployed on board 83 ships.

Egypt and Saudi Arabia use Otomat for coast defense. As of 1988, Otomat production was to continue, to be followed by a successor, the supersonic Otomach. Because the Otomach program has encountered difficulties, as of 1990, an Otomat improvement program is planned, including replacement of existing analog circuitry by digital alternatives, better ECCM, greater stealth, and provision for a terminal maneuver (not previously available). An ASW version (see the Antisubmarine Warfare section) was announced in October 1986: MILAS.

◆ Sea Killer/Marte

Dimensions: Marte Mk 2: 31.6 cm in diameter; Mk 2: 20.6 cm in diameter [12.5 and 8 in, respectively]. Marte Mk 2: 4.84 m in overall length, including 1.09-m booster [191/43 in]; Mk 2: 4.7 m in overall length, or 3.64 m without booster [185/155 in]. Marte Mk 2, 98.4 cm in span [38.7 in]; Mk 2: 99.9 cm in span [39.3 in]

Weight: Marte: 330 kg [727 lb]; Mk 2: 300 kg [661 lb]. Marte in shipping container: 1056 lb. Marte Mk 2 weighs 345 kg [760 lb].

Warhead: Sea Killer Mk 2: 70-kg [154 -lb] Tritolal blast SAP with impact fuze; Mk 1: 75-lb HE-fragmentation, including 35-lb HE

Propulsion: boost: 1.7-sec burn, to 250 m/sec [820 ft/sec]; sustain: 75-sec burn

Speed: Marte: 300 m/sec [984 ft/sec]; Mk 2: Mach 1.9

Range: Marte and Mk 2: 20–25 km [22–27 kyd; minimum range 6 kyd; Mk 1: minimum range 3250 yd, maximum 11 kyd]

The missile is Sea Killer, the ship system is Mariner, and the helicopter system is Marte. Sea Killer can also be carried by a fixed-wing airplane, in which case the missile needs no booster (and is, therefore, 84 kg lighter). These missiles were manufactured by Sistel.

Mark 1 (Nettuno) is a surface-to-surface version of the Contraves Sea Indigo surface-to-air missile (slightly longer, with a larger diameter and greater weight). Sea Indigo was never placed in service by any navy, but Sea Killer Mk 1 was bought by Italy for fast patrol boats (installed only in the now-stricken *Saetta*). Mk 1 is no longer in service. Work was begun by Contraves Italiana SpA in 1963, the first prototype flying in 1966, and the weapon entering service in 1969; that year the missile was taken over by Sistel SpA (which was formed around the Contraves missile division).

Nettuno was designed for use with the Contraves Sea Hunter Mk 2 fire-control system. It is command guided, either beam riding or by direct radar command based on optical target tracking. In either case, the missile maintains sea-skimming altitude (6.5–33 ft) by means of a radio altimeter. This missile was fired from a trainable quintuple launcher (total weight about 10,000 lb).

Sea Killer Mk 2 (Vulcano) is an entirely new 2-stage missile designed to use the same guidance and construction techniques as its predecessor. The associated fire-control system is Sea Hunter 4. The missile is commanded into the line of sight of the fire-control system, then rides a radar beam. Corrections, a reference signal, and event commands (e.g., warhead arming signal) are sent via a command link at a frequency well removed from that of the guidance radar. Initial launch information includes roll, pitch, and own-ship speed. Flight time is input either manually or through the fire-control computer, and maximum range corresponds to about 120 sec. The system's reaction time is about 30 sec (to warm up the radio altimeter). The missile flies a sea-skimming (3-m altitude) course by radio altimeter; altitude can be adjusted in flight by command from the launching ship or from a helicopter. Like Mk 1, Mk 2 can also be radio-command guided (via the command link mentioned above) using an optical target tracker; the missile is made to fly down the optical axis of the tracker.

In a typical ship installation, the target-tracking radar is a Selenia RTN or a radome-mounted SPQ-711 (part of the Contraves Sea Hunter system). The bridge carries an optical tracker.

Sea Killer Mk 2 was bought by Iran (in a trainable quintuple launcher on board Vosper Mk 5 frigates). In these ships the fire-control radar is the Contraves Sea Hunter.

The first 2 successful Mk 2 launches were reported in October 1971.

In the Marte Mk 1 system, a Sea King helicopter with SMA APQ-706 radar carries 2 Sea Killer Mk 2 missiles. The APQ-706 radar uses 2 back-to-back antennas and 2 radar transceivers: a frequency-agile unit and a unit linked to a PPI. When the radar locks onto the target, the missile can be fired. Like Sea Killer, it is a beam-rider flying at a set altitude (3.4–5 m) above the sea.

Marte Mk 2 has a larger-diameter nose containing an Otomat active seeker for fire-and-forget operation. Reports indicate that the warhead is no heavier than that of Sea Killer Mk 2 or Marte Mk 1. The airframe and booster aft of the nose section duplicate those of Marte Mk 1. There is also a version of Marte Mk 2 intended for use by fast aircraft; it has no booster and weighs 260 kg [573 lb].

The corresponding ship system, which has not found any buyers, would carry 6 missiles in tubes good for 6 months without maintenance.

Sea Killer began as a private-venture project in 1965, the first tests coming in 1969, and the first operational installation, on board Iranian Navy frigates, in 1971/72. The first Marte Mk 1 was delivered to the Italian Navy in 1977, and the Italian Navy selected the Mariner system in July 1979. However, no ship installations were made. Marte Mk 2 was announced in mid-1983, and the first Marte Mk 2 test was a shot from a ground launcher against a trawler at a range of 18.8 km, 23 March 1984. Marte Mk 2 entered Italian Navy service in 1987.

In 1988 AerMacchi announced plans to integrate Marte with the MB339 trainer/light attack aircraft, and this missile will probably be carried by the Italian/Brazilian AMX fighter/attack airplane (using an FIAR/ECTA Pointer radar or an SMA/Tech-nasa Scipio for the Brazilian version, or the FIAR Grifo for the dedicated antiship version).

JAPAN

◆ SSM-1

Dimensions: 35 cm × 5 m; 116 cm span [13.8 × 197 × 45.7 in]

Weight: 661 kg [1457 lb] **Warhead:** 225 kg [496 lb]

Propulsion: Mitsubishi TJM-2 turbojet, 2 boosters

Speed: subsonic **Range:** 150 km [164 kyd]

SSM-1. (Sea Power)

Marte Mk 2 at the Paris Air Show, 1989. (Author)

At present SSM-1 is a truck-mounted antiship missile, for coastal defense. However, the missile is probably suitable for ship mounting. The Japanese FY88 budget included the first six 6-tube truck-mounted launchers for the Ground Self-Defense Force, out of a planned total of 56 (total 384 missiles). SSM-1 is derived from the ASM-1 (see Air-Launched Missiles), with a turbojet instead of a rocket power plant. Reportedly, the ASM-2 air-launched missile will be derived from SSM-1.

SSM-1 was proposed in 1981, and development began in 1982. The prototype was completed in 1983. Japan has no test range of its own, so the first prototype SSM-1 was dropped by a T-2 over the Sea of Japan in July 1986; missiles were also test-fired at Point Mugu, California, in June 1987.

In February 1988 Kawasaki received a contract for a feasibility study of an air-launched version, to be carried by P-3C Orions.

A new ship-launched antiship missile, SSM-B (presumably SSM-1B), is to replace Harpoon in Japanese service; first trials

were reportedly scheduled for 1988. Procurement was to begin in FY90. SSM-1B or a derivative (sometimes described as SSM-2) is to arm the new Japanese hydrofoil missile boats.

When SSM-1 was originally proposed, unit cost was to have been \$385,000 (FY78 dollars), based on a purchase of 150 missiles. The purchase was increased to 250 missiles, but the current unit-price estimate is \$697,000 (FY87 dollars); the prototypes cost \$728,000 each (FY87).

NORWAY

◆ Penguin (AGM-119)

Dimensions: 28 cm × 2.95 m × 1.42 m span [11 in × 118 in × 55.5 in span]; Mk 2 length 2.96 m [117 in]; Mk 3: 28 cm × 3.20 m × 2.00 m span [11 in × 10 ft 5 in × 3 ft 3 in]

Weight: Mk 1: 330 kg; Mk 2: 340 kg; Mk 3: 350 kg, 400 kg with launcher [Mk 1: 741 lb; Mk 2: 749 lb; Mk 3: 771/882 lb]. Mk 3 weight has also been given officially as 820 lb with a 265-lb warhead.

Warhead: 250-lb SAP [Bullpup Mk 19] **Propulsion:** solid rocket

Speed: Mach 0.7 [Mk 2 and Mk 3: Mach 0.8]

Range: Mk 1: 20 km; Mk 2: 27 km; Mk 3: 40+ km [22/29.5/44 kyd] (Minimum range is 2750 yd in the Mk 1 version.)

Penguin being test fired by a U.S. 65-ft Patrol Boat Mk 3, 1982. (U.S. Navy)

Penguin Mk 2 Mod 7 on board a LAMPS helicopter (Grumman Aerospace)

Penguin was the first IR guided antiship missile (indeed, the first modern NATO antiship missile). It is boosted to an altitude of 80 m, cruising at 66 ft; the IR seeker is activated at a preset range. The designers chose IR homing because the prospective users, the Norwegian and Swedish navies, operate in areas of strong radar clutter dealing, respectively, with fjords and the Stockholm archipelago. IR homing also provides a target with less warning than an active-radar seeker, although requiring the missile to fly at a greater altitude. Prior to launch, the missile is provided with target bearing, target relative speed perpendicular to the line of fire, range to IR-seeker activation, and gyro-platform compensation data. Maximum flight time (Mk 1) is about 85 sec. Total reaction time, from the off condition to

firing, is about 2 min but can be cut to 7 sec if seeker cooling is maintained.

The altimeter is a pulsed laser.

The warhead is a U.S. Bullpup Mk 19 with a U.S. Mk 312-2 contact fuze (delay changed from 8 to 10 msec, to allow some penetration of the target). Total explosive weight is 103 lb.

Mk 1 is carried in the fiberglass shipping container (43.3 × 43.3 × 122 in, 396 lb) from which the missile is launched.

Mk 2 is a longer-range ship-launched version using a new launcher. However, the U.S. Navy plans to adopt Mk 2 Mod 7, a helicopter-launched version, for the LAMPS helicopters (see below).

Mk 3 (AGM-119) is an air-to-surface version that flies a pre-selected search pattern. The missile can be launched at altitudes of 150–30,000 ft and at speeds of up to Mach 1.2. The pilot can launch Mk 3 at up to 50 deg off boresight. There are 4 trajectory options: altitude hold "on" (missile flies either at maximum cruise altitude or at launch altitude, whichever is lower, up to the waypoint); altitude hold "off" (missile descends to preset mid-course altitude); mid-course altitude high (about 300 ft); and mid-course altitude low (sea-skimming). The pilot also selects the search pattern (wide, normal, asymmetrical) before launch.

In Norwegian service the associated fire-control system is MSI-80S, incorporating twin Decca TM 1226 radars, a Marconi-Elliott LLLTV camera/tracker, a laser range-finder, an IR scanner, and ESM. In Swedish service the missile interfaces with the PEAB 9V200 fire-control system; the Greek Navy uses Penguin with the Thomson-CSF Vega 2.

Penguin was developed in 1962–70 by the Norwegian Ministry of Defense and Kongsberg Vapenfabrikk, with some U.S. Navy financing (which is why Penguin uses a Bullpup warhead, and why the U.S. Navy has certain rights to the missile; it has been evaluated several times in the United States). Test flights were completed in 1971, and Penguin entered service in 1972 in the Greek, Norwegian, Swedish, and Turkish navies, on board fast patrol craft and, later, on board Norwegian frigates.

The U.S. Navy evaluated Penguin on board a 65-ft patrol boat (completed April 1982). The missile seemed too heavy for that hull but was chosen for the larger special-warfare craft (SWCM, Sea Viking). Penguin was successfully tested on board the air-cushion landing craft JEFF B in October 1983 in response to a House Armed Services Committee recommendation that alternative missions be sought for the landing craft. For this test the missiles were loaded on a flatbed truck. The U.S. surface-launched Penguin program died with Sea Viking.

By 1983 the fleet had proposed both a helicopter-launched antiship missile (HLASM) and a short-range surface-to-surface missile (SRSSM). A 1983 study rejected SRSSM (for carriers, amphibious ships, and service-force ships) but did show that the combination of LAMPS III and HLASM would be worthwhile. Penguin was the leading HLASM candidate, and in April 1984 the Mk 2 Mod 7 version, with folding wings and with an improved IR sensor, was formally chosen. The program then called for 272 missiles. In 1985 \$14.6 million was provided to evaluate the missile in this role, but rising unit cost led to a reduction from 272 to 192 missiles. In July 1986 the Senate Armed Services Committee objected that Penguin was too expensive, that it would equip only 33 ships (and a total of only 28 helicopters), and that it had a range of only 20 nm.

Production funds were dropped from the FY89 budget, but they were restored in FY90; a contract for 64 Penguin Mk 2 Mod 7s, to be carried by U.S. Navy LAMPS helicopters, was let in October 1989. Another 65 missiles have been requested for FY91. The missile has been proposed to both Korea and Greece, to be carried by adapted SH-2 helicopters. The U.S. designation is AGM-119B (-119A is Penguin Mk 3).

As of 1990, Norwegian Penguins are being upgraded to Mk 2 Mod 5 standard. Penguin Mk 3 was selected by the Royal Norwegian Air Force in 1980 to arm its F-16A/B fighters. Operational evaluation was completed in 1988, and the missile was formally accepted for service on 12 May 1989. Turkey is re-

portedly showing interest in purchasing it, and the U.S. Air Force is testing it as part of the system integration evaluation of the F-16A/B Operational Capability Upgrade program.

NFT is reportedly considering a surface-launched version of Mk 3.

As of 1988, estimated unit cost was \$220,000 for Mk 1 or Mk 2, or \$500,000–\$550,000 for Mk 2 Mod 7 or Mk 3.

◆ Rb 08A

Dimensions: 65 cm × 5.7 m; span 3.6 m [26.1 × 224 × 142 in]

Weight: empty 1720 lb [launched at 2645.5 lb]

Warhead: 250-kg [551-lb] blast-fragmentation

Propulsion: turbomeca Marbore IID jet [882-lb thrust] with solid-fuel booster

Speed: about Mach 0.65 **Range:** 135 nm

This antiship cruise missile was derived from the French (Nord Aviation) CT-20 target drone and developed by Nord and CSF (later part of Thomson-CSF) under the designation M20, specifically for the Swedish Navy. Work began in 1959, and Rb 08A entered production (by Saab) in 1966; 98 were manufactured, and production ended in 1970. The missile was formerly carried by 2 Swedish destroyers and is now used for coast defense.

No speed data on Rb 08 were ever released; the figure above is characteristic of the similar R 20 battlefield-surveillance drone. The CT 20 target, which was lighter than Rb 08 but of about the same size, was credited with a speed of 900 km/hr at 10,000 m [486 kt at 32,800 ft].

◆ Rb 12

Rb 12 is the Swedish designation for the Norwegian Penguin Mk 2 (see above).

◆ RBS 15

Dimensions: 50 cm × 4.35 m; span 85 cm folded/1.4 m spread [19.7 × 171 × 33.5/55.1 in]

Weight: 598 kg (780 with boosters) [1318/1719 lb]

Warhead: estimated 250-kg [551-lb] semi-armor piercing (a modified, heavier warhead is under development)

Propulsion: Microturbo TRI 60-1-077 [370-kg thrust] with rocket boosters

Speed: Mach 0.9 (to Mach 0.7 by 3-sec booster burn)

Range: 70 km [77 kyd]; 150 km for air-launched version

RBS 15 is a fire-and-forget weapon with an active-radar (frequency-agile) seeker. Flight parameters, such as the search pattern, are automatically selectable by the fire-control system. The mid-course inertial system can be updated by data link. PEAB claims that frequency agility in the seeker reduces glint by a factor of 2–4 and increases target-detection range by more than 50%. Frequency agility is also said to eliminate target fading during lock-on, to reduce sea clutter, and to obviate any requirement to allocate different frequencies to the different missiles of a salvo. The seeker is designed to provide home-on-jam as an option, and the missile can also be modified to maneuver evasively (using memory tracking to remain locked-on).

The seeker is designated 9GR400; it is built around the same type of PEAB spin-tuned X- or Ku-band magnetron used in the 9LV200 fire-control system. Typical pulse width is 0.2–1.0 microsec, with a jittered PRF of 1000–4000, a peak power of 65–100 kW, and search limits of 30 deg either side in azimuth and 15 deg up or down in elevation.

Reportedly the RBS 15 airframe is derived from that of the earlier RB04E air-launched missile; the use of components of the earlier weapon drastically cut development time. Reportedly, too, the missile was developed at the urgent recommendation of the Swedish Aircraft Industry Committee to maintain missile design and production capability. The Swedish defense

forces disagreed (presumably on grounds of cost) but were overruled: RBS 15 was chosen instead of the U.S. Harpoon or the French Exocet.

The development contract was let to Saab in June 1979, and the design was frozen in mid-1980. The first live firing was in July 1981. Initial Swedish Navy deliveries were completed in 1985. Finland ordered RBS 15 (15M version) in March 1983, and the missile entered service on 7 June 1984; Finland also uses the missile for coast defense (first delivered in April 1988). This weapon has been ordered by Yugoslavia to replace existing Soviet-supplied SS-C-3 Styx coast-defense missiles and may also be carried by new *Kobra*-class missile boats. Estimated unit cost is \$479,000 (FY87).

There is also an air-launched version, RBS 15F, for use by Swedish Air Force Viggen fighters. A projected submarine-launched version was rejected by the Royal Swedish Navy, on the grounds that long-range wire-guided torpedoes were preferable.

◆ Hellfire (RBS 17)

TAIWAN (ROC)

◆ Hsiung Feng I/II

Hsiung Feng I is an unlicensed copy of the Israeli Gabriel; the name originally meant Male Bee, but was changed to Proud (or Brave) Wind in 1980/81 in line with a general redesignation of new Taiwanese (ROC) systems with "Wind" names. Reportedly, the developers experienced problems with the rocket motor and with the copied guidance system. The warhead is a 70-kg blast-fragmentation type. This missile is used both on board ship and in coastal batteries. Hsiung Feng may not be a true sea-skimmer, since at least some films show it flying well above the sea and then diving steeply into its target.

The associated fire-control radar is SPG-24.

Reportedly, work on the Hsiung Feng I fire-control system began in the 1970s. The missile project was completed in 1977 (it was first reported in January 1977). The initial test firings were conducted on board the former torpedo boat *PT 1*. Israeli-supplied Gabriels had been mounted on board some ROC destroyers as early as 1974. In the absence of any Israeli radar, these missiles may have relied on radio-command guidance, which is a backup control system for Gabriel I.

Hsiung Feng II resembles the U.S. Harpoon but is reportedly powered by a license-produced Turbomeca Arbizon IV turbojet, which has a somewhat greater diameter than the U.S. engine (but develops 10% more thrust). Film footage of the initial trial shows folding wings, and the missile appears to approach its target at very low altitude (5–7 m), using an active-radar seeker. Reports indicate that the missile can accept mid-course guidance data, e.g., from a helicopter. The data link involved is probably similar to that of Hsiung Feng I. Unlike Harpoon, Hsiung Feng II incorporates an IR sensor, officially described as Automatic Target Recognition Image Tracking Module Mk 2. The missile is carried in a fairing above the main (radar) seeker. Presumably, the combination of radar and IR will defeat the relatively simple countermeasures currently employed on board PRC ships.

Film of test launches, shown in February 1988, appears to show a modernized *Fletcher*-class destroyer (Wu-Jin I or Weapons Improvement Mk I) launch platform. Reportedly, the Taiwan Navy will employ Hsiung Feng I and II side by side, as the Israeli Navy employs Gabriel and Harpoon. The land-based version of Hsiung Feng I is deployed in a triple towed trailer. A land-based version of Hsiung Feng II exists, and an air-launched version is planned, for use with the new Ching-Kuo fighter and also possibly with the AT-3 trainer. Reportedly, a submarine-launched version is also under development.

Hsiung Feng being fired by a Taiwanese destroyer. (*Defense Technology*)

A Hsiung Feng I missile on parade in Taiwan. (Fu S. Mei)

Hsiung Feng I being fired from a Taiwanese destroyer. Note the command-guidance director in the foreground. The unmanned director is a U.S.-type Mk 51 controlling the twin 40-mm gun mount visible below the director to the right. (Fu S. Mei)

Hsiung Feng I being fired by a Taiwanese PSMM Mk-5 class (*Lung Chiang*-class) fast attack boat. She carries an OTO-Melara 76-mm gun forward, and the main air-search radar is the stand-alone version of the U.S. SPS-58, which is unique to the Taiwanese (ROC) Navy. The radome presumably covers a Hsiung Feng control radar of unidentified type. (Fu S. Mei)

USSR

Many Soviet naval missiles have alternative nuclear warheads, as noted below. Many may also have chemical warheads; certainly chemical weapons are very common in Soviet land forces. No detailed information on naval chemical weapons has been published, and it is sometimes argued that a fleet subject to a chemical attack could steam out of the chemical cloud, relying on short-term measures such as citadels. Another view is that, since the Soviets themselves class chemical weapons with nuclear weapons as "means of mass destruction," nuclear deterrence would also deter them from using chemicals.

One can imagine an attack in which explosives or bomblets were used to open ships for follow-up chemical attack. Gas attack was taken very seriously before World War II, and no realistic solution was found at that time (in one internal U.S. document, experts suggested that a gassed battleship might as well be scuttled, since it could not be decontaminated). Western consciousness of Soviet chemical-warfare potential has increased enormously over the last few years, and numerous reports of the chemical-security measures that the Soviet Navy has taken

have been adduced to suggest that the Soviets do indeed possess naval chemical weapons. Perhaps the most important antigas devices that Western navies currently use are the gas detectors, most of which use lasers to detect poisonous chemicals in the surrounding atmosphere.

◆ SS-C-2 Salish

See AS-1/SS-C-2 under air-launched weapons.

◆ SS-N-2 Styx (and SS-C-3)

Dimensions: 30 in × 21.3 ft; span 9 ft (SS-N-2C: 31-in diameter)

Weight: 5070 lb (SS-N-2A)

Warhead: 500 kg [1100 lb]; somewhat heavier in SS-N-2C

Propulsion: liquid-fuel rocket (solid booster)

Speed: Mach 0.9 [666 mph]

Range: 25 nm (effective to 16 nm); SS-N-2C: 45 nm

An SS-N-2 being loaded. (Siegfried Breyer)

An SS-N-2 missile being checked before loading. (Sovfoto)

SS-N-2 was the first Soviet sea-based antiship missile to enter large-scale service. Intended to replace the torpedoes of small fast attack craft, SS-N-2 is a radar- or IR-homing fire-and-forget weapon. Styx was the first antiship missile to sink a ship in combat, Egyptian Komar-type missile boats sinking the Israeli destroyer *Eilat* in 1967. Styx was also fired successfully during the Indo-Pakistani War of 1971, by the Chinese (PRC) Navy in the Paracel Islands in 1974, and, reportedly, by the Iraqi Navy during the Iran-Iraq War (1980). In 1988 Iran began to use a land-based version of the Chinese (PRC) equivalent, Silkworm (HY-2 and derivatives), against shipping in the Persian Gulf. Styx was also used, unsuccessfully, during the October War (Israel-Arab) of 1973. At that time the reported reason for the weapon's failure was the excessive time required to run up the missile's gyros before firing: the Arab missile boat crews, under attack, tended to fire before their weapons were ready. In addition, be-

cause the missile had been designed to attack large warships, its seeker could not always distinguish the small Israeli missile boats, parts of whose superstructures had been covered in radar-absorbing material.

SS-N-2 A and B (introduced 1958 and 1964, respectively) are I-band active-radar homers, the B-versions having alternative IR homing. SS-N-2B (Osa-II-class missile boats) also has folding wings and, reportedly, sea-skims on its final approach to the target. These weapons are carried by Osa- and Komar-type missile boats. SS-N-2C (originally designated SS-N-11) has a maximum range of 45 nm. Both radar and IR homing versions are in service. A forward observer is needed to take advantage of the increased range; presumably, larger ships can accommodate the necessary communications and plotting facilities. Therefore, this weapon, introduced in 1967, is carried by Modified Kashin- and Kildin-class destroyers, by Tarantul-class missile corvettes, and by export Nanuchkas (Soviet Nanuchkas fire SS-N-9 missiles). All versions of the missile have been widely exported.

The Soviet designation is P-15 (industrial index number 4K40); SS-N-2C is P-20 and P-21. The coast-defense version, SS-C-3, is P-20/21. The Finnish designation for this missile (SS-N-2B) is MTO-66; it is used both afloat and for coast defense (in the latter role, together with the French SS 11).

Development began in 1954. Although Styx-armed missile boats entered service in 1958 or 1959, final testing (in the Northern Fleet, by two Osa-IIs) was not completed until 1960–61. Reportedly, the liquid-fuel rocket was chosen over a turbojet for quick acceleration, and the weapon was not provided with a nuclear warhead because of its short range (initially 13 nm): the firing platform might have suffered damage. Initial Soviet estimates were that 2 hits were needed to sink a destroyer (as in the case of the *Eilat*), and that 12 missiles (3 boats) had to be fired to achieve them. Boats were, therefore, organized in units of 3, and standard doctrine called for the dispatch of 2 units to ensure that 1 would reach the target area. Missile installation and arming initially took 15 hr, but that period was later reduced to 12 hr, and by 1962 an Osa could be fitted with her 4 missiles in 4–6 hr.

Missiles are loaded with storable liquid propellant, which gradually corrodes the missile body. Weapons, therefore, tend to be expended in large numbers, the usual lifetime being about 2 yr.

The Square Tie targeting radar of an Osa or Komar can detect a destroyer at up to 22 nm under favorable conditions (maximum theoretical radar range is 48 nm), and fast patrol boats can be detected at about 10 nm. The operator sets a range gate around the expected target position, and data for firing the missile can be computed for ranges of 3–15 nm. For longer ranges, at least in the original version, the appropriate firing range must be calculated manually, by plotting board, and that significantly reduces hit probability. The missile-firing platform must turn into the direction of fire. The missile is launched at a 15-deg angle to the horizon, then climbs at 45 deg to an altitude of about 450 ft. The seeker, operating on 1 of 6 preset frequencies, is switched on at about 6 nm from the calculated impact point. At least in early versions, the seeker cannot distinguish fixed from moving targets and chooses the one with the strongest echo. The seeker is, therefore, quite vulnerable to deception by chaff. Altitude is preset at 100, 150, 200, 250, or 300 m [330, 500, 660, 825, or 1000 ft]. Reportedly, the initial design of the missile included provisions for mid-course guidance, the weapon flying at 400 m [1300 ft] until it neared the target.

As of 1973, Styx's minimum range was 4.5 nm, and estimated effective operational range was 12–18 nm (for -2A and -2B versions). Most firings to that date had been at altitudes of 500 ft or less. The terminal radar seeker in SS-N-2A was a conical scan (on receive only) radar, and the use of such a seeker (in Styx as well as in contemporary Soviet air-launched antiship weapons) explains British interest in the masthead reflector countermeasure. In a maximum-range attack, the Styx seeker would be activated at an estimated range to the target of 6 nm, but in a

minimum-range attack it could be activated at an estimated range of 2.5 nm. In each case, the missile approached its target at a glide angle of 1–2 deg. The SS-N-2C terminal radar activates at an estimated range of 15 nm from the target, allowing the launch platform much more freedom of maneuver during launch (but also providing the target with much better warning).

The warhead is a large shaped charge, carried just abaft the fuel tank. In theory, then, the effect of a hit is to blast a hole deep into the target while filling it with burning fuel. Soviet doctrine is to fire 7–8 missiles at a cruiser, or 4 against a destroyer. Because hit probability against a fast patrol boat is limited (because of its small radar cross section), the doctrine in this case is to fire 2–4.

Some major limitations in the original SS-N-2 were the minimum range of 5 nm (the homing and arming mechanisms are not activated until the missile has flown that far) and the inability to seek out the preferred target among a group of ships. Nor can targets be attacked from seaward within 4 nm of the shore, because of radar clutter. At least in its original form, SS-N-2 cannot be fired if the air temperature is below 4 deg F or above 101 deg F.

Although the Soviets considered SS-N-2 strictly an antiship missile, the Indian Navy very successfully used this missile against shore installations, such as refineries (which are strong radar reflectors) during the 1971 Indo-Pakistani War.

The coast-defense version, SS-C-3, was developed in the late 1970s to replace the much larger SS-C-1 (coast-defense version of SS-N-3). Meanwhile the Chinese were using essentially the same Styx missile for coast defense. However, the standard Soviet transporter carries 2 Styxes and a Plank Shave fire-control radar, plus a control cabin, whereas the standard Chinese launcher is a single rail. Thus, each Soviet launcher truck is, in effect, an independent fire unit, even though Soviet doctrine calls for several such units to attack most warships. Effective engagement range is limited by the performance of the truck-mounted Plank Shave, which can probably detect a target at about 35 km [38,000 yd] at maximum elevation.

Exports of this missile began in 1983–84, initially to East Germany and then to Yugoslavia, followed by Soviet clients in the Middle East. As in the case of SS-C-2, the standard organization is a 3-battery battalion, each battery consisting of 6 launchers.

Iraq manufactures the SSC-3 version of Styx under the designations Faw-70, -150, and -200. The numbers probably indicate the maximum range in km, Faw-70 being a locally built SSC-3, and Faw-150 and -200 having enlarged fuel tanks. All were advertised for export at the Baghdad exhibition in 1989.

◆ SS-N-3 Shaddock (and SS-C-1)

Dimensions: 38.3 in × approx 33 ft (SS-N-3C: 39 ft); span is about 16.8 ft **Weight:** 11,900 lb

Warhead: 1000 kg [2200 lb; nuclear version reportedly 350 kT]

Propulsion: liquid-fuel rocket **Speed:** Mach 1.4 [1040 mph]

Range: 250 nm (400 nm for SS-N-3C)

Shaddock was the first Soviet OTH ship-launched anticarrier missile. It seems to have originated as a strategic cruise missile but is listed under antiship weapons because all of the platforms (Echo-I-class submarines and Whiskey-class conversions) de-

SS-N-3 missiles in their launch tubes on board a Juliett-class submarine, being raised for firing. (U.S. Navy)

SS-N-3 launch tubes and the control device, Scoop Pair, on the after side of the mast above. There are 2 independent antennas, so the ship can presumably engage 2 targets using this director. The radomes on the side of the mast are for electronic countermeasures: the big radome is a Top Hat jammer (another pair is on the tower foremast). Above and below the jammer are smaller Bell-series radomes and the squatter, broader-diameter radome of Guard Dog. Presumably, the latter is a wide-open detector, whereas the Bells contain spinning antennas for accurate direction-finding and, therefore, for directing the jammers in the Top Hats. (C. P. Lemieux)

The SS-N-3 missile and the transporter for its coast-defense version, SSC-C-1b. (Steven Zaloga)

SS-N-3 (Shaddock) soon after launch, with the booster still burning.

signed to use the missile solely in the strategic role have been converted to other uses or discarded. However, the nuclear-armed nonhoming strategic version remains in service. This version might also be usable against moving formations, depending upon the details of the targeting technique.

Because the homing version of SS-N-3 flies so far, i.e., spends so long in flight, the missile requires mid-course assistance to ensure that it hits the right ship within the target formation. That help generally involves a Bear-D radar-reconnaissance aircraft, which provides the firing submarine or surface ship with a radar picture of the target formation. This picture is matched against that provided by the missile itself. Hormone-B helicopters also carry an appropriate targeting radar. The firing platform uses a radar tracker/transponder: Front Door/Front Piece in submarines (Juliatt and Echo-II classes), Scoop Pair in a Kynda- or Kresta-I-class missile cruiser. Some missile cruisers also have Plinth Net antennas (probably passive) clearly associated with this missile system; they appear to be receivers for targeting data derived from the missile seeker.

The targeting technique can be upset by the destruction of the radar platform or by an attack on the launching platform before it has locked the missile(s) onto the desired target. The high-altitude radar search by the missile itself can provide a target with useful warning. The Soviets are well aware of these weaknesses, the much faster SS-N-19 providing the ultimate solution. An interim solution would be to accept a much shorter engagement range, hence a much shorter flight time, and then to use the weapon in a fire-and-forget mode. The efficacy of such a tactic would depend upon the quality of prefiring data and upon the speed of the missile (i.e., upon flight time). The better the pretargeting data, the closer to the target the missile could turn on its seeker, hence the shorter the effective warning time.

SS-N-3 typically climbs from its launcher at an angle of 15–20 deg, attaining a maximum (cruise) altitude of about 13,000 ft. The terminal homer is activated at an estimated range from the target of about 70 nm; once it locks on, the missile dives at 20 deg, leveling off for a terminal run-in. In a typical attack at a range of 150 nm, the missile would attain maximum altitude about 100 nm from launch and would begin its dive about 50 nm from the target. Total flight time in such an attack would be 14.2 min. When these figures were compiled, minimum range was estimated as about 12 nm, but it seems unlikely that attack from so short a range was ever practiced or contemplated. The seeker scanned conically (at 60 Hz) on receive only, in I-band. These data were compiled in 1971–73, at which time the missile was credited with a speed of Mach 1.2–1.4, with a maximum range of 220 nm and an operational range of 150–170 nm. A submarine firing SS-N-3s would launch them in pairs. Apparently, because the Front Door/Front Piece could not track 2 salvos simultaneously, the submarine could not fire a second salvo until the first had locked on, so the salvo interval was about 15 min. This limitation may explain the installation of a

A Soviet submarine's missile-guidance antennas, Front Door/Front Piece, folded down inside the sail. The front and side of the sail hinge to expose the antennas. The glassy strip on the front of the sail (at left) covers a sonar; the windshield at right indicates the forward part of the manned portion of the sail.

secondary antenna, Plinth Net, on board some surface ships armed with SS-N-3; the additional antenna might be used to communicate with distant missiles while the main guidance radar (Scoop Pair) handled a second pair of missiles, closer to the ship.

SS-N-3C, the inertially guided version, was probably actually the first developed. It appeared in 1960. SS-N-3A, fired by submarines (Juliatt and Echo-II), entered service in 1962, contemporary with SS-N-3B, for surface ships (Kynda and Kresta-I).

The Soviet designation for the original strategic weapon is P-5, P-5D being an improved version with a doppler altimeter. It appears that P-6 and possibly P-7 were the submarine-launched nuclear-armed anticarrier versions, and that P-35 was the surface-ship version. S-35 is the coast-defense version. All were designed by the Chelomei bureau.

SS-C-1 is the Western designation for the coast-defense cruise-missile version.

This weapon evolved into SS-N-12 and SS-N-19.

◆ SS-N-7 Starbright

Dimensions: approx 21–22 in × 23 ft **Weight:** 7440 lb
Warhead: approx 1100-lb [500-kg] HE
Propulsion: liquid-fuel rocket
Speed: Mach 0.9 **Range:** 35 nm

SS-N-7 is an underwater-launched analog of SS-N-2, i.e., a replacement for previous submarine antiship torpedoes. Starbright is carried by Charlie-class nuclear attack submarines and, like SS-N-2, is a fire-and-forget weapon. SS-N-7 appears to exist only in a conventional version.

Charlie was apparently not a very successful submarine, and there is some question as to whether the Soviets consider the short-range fire-and-forget submarine missile a dead end. If that is true, then the 65-cm torpedo (see the Antisubmarine Warfare section) may be this missile's true successor, in effect functioning as an underwater cruise missile. Alternatively, the new 65-cm tube may provide sufficient volume for a new antiship cruise missile.

In 1971–73 the U.S. Navy credited SS-N-7 with a maximum range of 30 nm and a minimum range of 4–5 nm; probable operational range was 25 nm. The missile could be launched at depths down to 150 ft, and cruised at 100–300 ft. The terminal seeker was activated at an estimated range from the target of 25 nm, after which the missile dove toward its target at an angle of 3 deg or less. The seeker was a J-band conical scanner (on receive only, at 200 Hz) with sector scan switches to limit its FoR. Total flight time from 30 nm was 3.2 min at a speed of Mach 0.95.

From a Western point of view, SS-N-7 was particularly frightening when it appeared in 1968 because, unlike previous longer-range Soviet antiship missiles, it would provide very little warning. It would pop out of the water only about 2 or 3 min before hitting a ship. Even though it would fly high enough to be detected, such detection might not occur early enough for defenses to be activated. SS-N-7 thus inspired a variety of countermeasures, including the British Sea Wolf missile, the U.S. New Threat Upgrade (IADT), and the U.S. decision to provide the *Perry*-class frigate with a highly automated anti-aircraft fire-control system, in principle capable of initiating fire against a pop-up missile. All of these measures were partly inspired by the threat of the Styx missile, which had just demonstrated its efficacy against the Israeli *Eilat*, but it seems more likely that SS-N-7, which could appear anywhere on the world ocean, was the terrifying new threat against which NTU was designed.

The missile itself is essentially a longer-range equivalent of Styx (SS-N-2) and physically may be somewhat similar to some of the Chinese Styx derivatives. SS-N-7 in turn gave way to the dual-purpose (surface- and submarine-launched) SS-N-9. When the Charlie-class submarine first appeared, it was evaluated as firing, not a winged cruise weapon, but rather an antiship equivalent of the U.S. SUBROC ASW missile—which would have been an even more difficult target for anti-aircraft defenses.

There appears to be no antiship version of the SS-N-21 torpedo-tube cruise missile (see the Strategic Strike Systems section) presumably because the Soviets demand a combination of high speed and large warhead, to overcome target defenses and to damage large warships.

◆ SS-N-9 Siren

Dimensions: length 8.84 m [348 in] **Weight:** 6500 lb [2950 kg]
Warhead: 1100-lb HE **Propulsion:** liquid-fuel rocket
Speed: Mach 0.8 **Range:** 58–65 nm

SS-N-9 launch tubes on board a Nanuchka-class missile corvette. The big radome, Band Stand, probably contains a surface-search radar and a data-link receiver that allows the ship to attack targets beyond her horizon. The gun aft is a twin 57-mm controlled by a Muff Cob director, and the back-to-back surface-search radar in front of Band Stand is Peel Pair. Forward of it is the Pop Group director of the SA-N-4 missile launcher that is located forward of the superstructure. (U.S. Navy)

Nanuchkas firing SS-N-9 missiles.

Carried on board Nanuchka-class missile boats and Charlie-II-class nuclear attack submarines, SS-N-9 is a longer-range equivalent of SS-N-2. Siren may have originated in a 1961 project for a 50–70-km patrol-boat missile. Effective targeting at the ranges possible with this missile requires third-party assistance, presumably directly to the firing platform. The missile system is associated with the Band Stand radar (actually, with the radome; it is not certain that the same equipment always occupies it). The radome may contain a radar receiver for down-linked third-party data.

This weapon has not been exported; Nanuchkas produced for Soviet client states are armed instead with SS-N-2C. That circumstance may reflect the security of the down-link or of the inertial guidance required for long-range flight before the active seeker is switched on.

There may be a nuclear version (200 kT), as at extreme range the missile is far enough away not to damage the firing platform.

SS-N-22 is the successor weapon.

◆ SS-N-12 Sandbox

Dimensions: ca. 90 cm × 11.7 m with span 260 cm [35.4 × 461 × 102 in]
Weight: about 11,000 lb **Warhead:** 2200-lb HE or nuclear
Propulsion: liquid-fuel rocket
Speed: Mach 2.5 [1850 mph] **Range:** 300 nm

SS-N-12 missile launchers on board the cruiser *Slava*, 1984. Their tracker/data-link radar, Front Door/Front Piece, is on the forward side of the foremast, below the big air-search radar. Below it is a Kite Screech fire-control radar for the twin 130-mm gun forward. The air-search radar on the foremast is Top Steer; the larger back-to-back radar farther aft is Top Pair. The large fire-control radar aft is Top Dome. The small guns abaft the 130-mm turret are 30-mm Gatlings, controlled by Bass Tilt directors. (HMS *Excellent*)

The Front Door/Front Piece missile transponder tracker (for SS-N-12 control) on board the *Slava*-class missile cruiser *Marshal Ustinov*, which visited Norfolk in 1989. Above the tracker is a Palm Frond surface-search radar, and below is a Kite Screech fire-control radar. (S. Zaloga)

Sandbox is a faster successor to SS-N-3; like the earlier missile, SS-N-12 presumably exists in both nuclear and conventional versions. Like SS-N-3, SS-N-12 requires mid-course correction.

These weapons are carried on board Echo-II-class submarines and on board *Kiev*- and *Slava*-class cruisers.

◆ SS-N-19 Shipwreck

Weight: about 10,000 lb

Propulsion: liquid rocket **Range:** 300 nm

Punch Bowl, the targeting satellite data-link antenna, on board the *Slava*-class cruiser *Marshal Ustinov*, in Norfolk in 1989. (S. Zaloga)

To date, Shipwreck is the ultimate development of the SS-N-3 concept. SS-N-19 is so fast that it needs no mid-course guidance. An Oscar-class missile submarine can, therefore, fire the missile submerged, on the basis of information provided by a radar satellite via the Punch Bowl down-link antenna. This weapon is also carried by *Kirov*-class missile cruisers.

◆ SS-N-22 Sunburn

Dimensions: length about 30 ft **Warhead:** 1000-lb HE

Propulsion: liquid rocket **Speed:** Mach 2.5

Range: 55–68 nm

SS-N-22 is the larger, faster, and lower-flying successor to SS-N-9 and thus the ultimate current expression of the Styx concept. Sunburn is similar in concept but should be more difficult to counter, although, given its sheer size, SS-N-22 probably cannot fly as low as Western sea-skimmers. At present *Sovremenny*-class missile destroyers and *Tarantul*-III-class missile boats are the only platforms, although it is possible that this missile will form the battery of a Charlie successor.

Light Bulb is the antenna of the associated data link system, presumably connecting the firing ship to an OTH sensor, such as an aircraft radar.

SS-N-22 missiles in their launch tubes on board the missile destroyer *Otchayanny*. The Band Stand radome is like that on board a Nanuchka-class corvette. Above the radome is a Kite Screech director, controlling the twin 130-mm gun forward; note the hole in the dish for a television camera. The enclosed radome to one side of the foremast is Front Dome, to control the SA-N-7 anti-aircraft missile (whose single-arm launcher is visible forward of the bridge), and the big air-search radar is Top Steer. The 3 surface-search radars are Palm Fronds. Note the IFF array atop the 3D radar. (U.S. Navy)

Light Bulb (the radome alongside the funnel), the targeting data-link antenna associated with the SS-N-22 missile, on board the *Sovremennyy*-class destroyer *Otlichnyy*, which visited Norfolk in 1989. (S. Zaloga)

◆ SS-NX-25

Late in 1988 a new East German fast attack craft, about 52 m long, tentatively code-named BAL-COM-10, was observed on her sea trials. She carried 8 missile canisters, similar in size to those used for Western Harpoon or Exocet (MM 40) missiles. Presumably each canister holds a new Soviet antiship missile. The new weapon would seem to be a considerable departure from previous Soviet practice, seeming unable to carry anything remotely like the current standard 500- or 1000-kg warhead. On the other hand, a boat carrying 8 such missiles can present a Western antimissile defense system with a degree of saturation that, in the past, would have required either several boats firing together or else a large surface combatant like a *Slava*.

Balcom 10 shows the new SS-NX-25 missile in its canister launcher. (West German Ministry of Defense)

There are several possible explanations for this development. One is that, in the Baltic, the Soviets will generally face relatively small Western warships and, therefore, will not really need the massive warheads adopted in the past to attack carriers and other major warships. Another is that the Soviets realize that they cannot achieve much more in the way of penetrating terminal defenses unless they adopt smaller and more numerous weapons. For example, it is unlikely that a big supersonic missile like SS-N-22 can really sea-skim.

Much depends on the details of the new weapon. If it is a rocket, like Exocet, then it can saturate defenses by sea-skimming and streaming in, but it cannot execute elaborate way-point maneuvers. If the weapon uses a small turbojet, like Harpoon, it can sea-skim and then attack from many directions by using way points.

Soviet willingness to adopt smaller warheads might also point to a decision to buy smaller air-launched antiship weapons (i.e., those that might be carried internally) and perhaps to adopt a 53-cm torpedo tube-launched antiship weapon (the salvo effect could be achieved by firing such weapons from several tubes, in rapid succession).

SS-N-25 was first tested in 1987, on board a Soviet Nanuchka III.

UNITED STATES

◆ Harpoon (AGM-84/RGM-84/UGM-84) and SLAM (AGM-84E)

Dimensions: 13.5 × 182.2 in (151.5 in long for air launch) (SLAM is 177 in long)

Weight: 1145 lb (air launch), 1439 lb (ASROC launcher), 1500 lb (SAM launcher), 1503 lb (capsule/canister launcher), 1385 lb (SLAM version)

Warhead: 488.5-lb HE (blast; semi-armor piercing)

Propulsion: J402-CA-400 Turbojet (cruise) (600-lb thrust) with solid-fuel booster (12,000-lb thrust for 2.9 sec) for ship or submarine launch **Fuel:** 100 lb **Speed:** Mach 0.85

Range: 75–80 nm surface-launched, 120 nm air-launched

Harpoon is probably the most widely deployed of all modern Western antiship missiles; it is used by 19 navies (including 9 NATO navies). Originally developed for air-to-surface use, Harpoon also exists in surface- and submarine-launched versions, the latter employing a buoyant capsule for launch. The object was to develop a weapon that could be carried on board virtually all naval platforms. That requirement in turn limited Harpoon's dimensions to approximately those of the Standard Missile (Surface-to-Air) so that Harpoon could be fired from the usual surface-ship launchers. Even so, most Harpoons on board surface ships are carried in canisters that, incidentally, can only be replaced in harbor.

Harpoon was originally a P-3 weapon. It is also carried by standard U.S. and foreign naval attack aircraft, and the first launch from an F/A-18 was in the summer of 1986. The U.S. Air Force currently carries Harpoon antiship missiles on board B-52G bombers (12 internal, up to 8 external) to support its maritime warfare MoU with the navy; the first operational air force launch was in the Caribbean, 20 April 1986.

McDonnell Douglas, the manufacturer, has proposed Harpoon as a coast-defense weapon, analogous to an existing form of Exocet.

Harpoon first saw combat on 24–25 March 1986, when A-6Es used the missile to sink 2 Libyan ships. Harpoon was also successfully used during the Persian Gulf engagement in April 1988.

Harpoon was conceived in 1965 by the Naval Air Systems Command as a longer-range (25 nm) follow-on to Bullpup, to be carried by ASW aircraft attacking surfaced submarines (i.e., a harpoon to kill whales). That mission was later expanded to include antiship attack (e.g., attacks against Soviet missile-bearing fast patrol boats), and the missile was being considered for ship mounting even before the *Eilat* incident of 1967 publicized the potential of antiship missiles. The project began formally in 1968, an RFP being released in 1970. McDonnell Douglas, whose in-house studies of long-range antiship missiles began about when NAVAIR became interested, was chosen as prime

Harpoon is fired from the ASROC launcher of USS *Knox* (FF-1052). (U.S. Navy)

contractor in June 1971, flying the first missile on 17 October 1972. The requirement for long (over 50 nm) range was imposed after McDonnell Douglas was chosen, a small turbojet being substituted for the rocket envisaged in early studies. Production began in 1975, and Harpoon entered service in 1977. Overall, demonstrated flight reliability has been about 93% in 374 launches (100% since 1982).

All versions home using a Texas Instruments active Ku-band frequency-agile radar (fire-and-forget). A strapdown-inertial system is used to maintain course until the missile reaches a preset position where radar homing is turned on. Alternatively, the missile can be fired as a bearing rider, with the radar on throughout flight, to attack a target whose range is not known. Warning of the approach of the relatively small missile should be primarily by detecting its radar emission; the better the initial target position, the shorter the time the radar seeker need be switched on. Early versions flew directly toward the intended target, but later types (Blocks IB and IC) may incorporate waypoints, the missile flying an indirect course and perhaps switching the radar on intermittently. It is also possible to select either a nearly horizontal approach to the target or a terminal pop-up (steep climb and then dive) that may frustrate many types of terminal defense.

As originally designed, the missile (when launched by a ship or submarine) was boosted ballistically to 1300 ft before diving

Typical mission profiles for Harpoon (left) and TASM (Tomahawk Antiship Missile). (McDonnell Douglas)

Air-launched Harpoon, as carried by a P-3. (McDonnell Douglas)

into its cruise path. That profile would clear nearby ships, but it would also expose the missile to radar detection. In particular, submarine operators feared that the column of smoke and water coming out of the sea would disclose their position, and some versions apparently provide much less of a tell-tale signature.

The warhead is designed to survive penetration of a submarine's pressure hull or of a surface ship's hull. Reportedly, 1 hit should suffice to kill anything the size of a *Nanuchka* or smaller; 2 should disable a frigate (e.g., a *Krivak*), and 4, a missile cruiser; 5 should disable a *Kiev*. That estimation of effectiveness does not take missile reliability and terminal defenses into account. Most warships carry 8 Harpoons in 2 clusters of 4 canisters each.

Block IB incorporated an advanced guidance package, for the Royal Navy, which wanted a sea-skimming terminal phase for submarine-launched Harpoons. Deliveries to the U.S. Navy began in June 1982.

Block IC shows increased range and selectable terminal trajectory. It can also fly several doglegs to the target (way-pointing), concealing the position of the firing ship. A ship equipped with a Harpoon fire-control computer (SWG-1) can use way-pointing to arrange for several Harpoons to arrive simultaneously from different directions. IC is the current (1988) production version. Earlier versions can be upgraded to IC standard at a unit cost of about \$20,000. The Royal Navy is having this work done in the United Kingdom.

McDonnell Douglas expects to produce a Block II for the 1990s, with a range of 100+ nm, with variable mission profiles, and with improved discrimination between targets and nontargets. Range can be improved by about 15% by replacing the current JP-5 fuel with JP-10, and a greater improvement is possible if the fuel tank section of the basic airframe is lengthened. There is also continued interest in better target discrimination; for example, in future it may be possible to set the radar to seek out smaller high-priority targets instead of larger low-priority ones. McDonnell Douglas has reportedly proposed modifying the overall system to feed target-signature data to the weapon before launch.

As of the fall of 1988, Block II was described as a combination of Block IC features with a new Dash-4 seeker.

McDonnell Douglas received a contract to develop a new version, probably to be designated Block ID, in September 1989. It is about 2 ft longer and 150 lb heavier than earlier Harpoons, to achieve about twice the aerodynamic range, and it can re-attack a target not detected on the first pass by flying cloverleaf-shaped search patterns. The missile needs the re-attack capability to exploit its additional fly-out range, as it lacks any means of mid-course update. Reportedly Block ID will incorporate more radar absorbing material in its structure for better stealth. The FY91 U.S. Navy budget request includes 126 of these Improved Harpoons, which should become available about 1991. Reportedly, McDonnell Douglas is also working on a supersonic Harpoon successor with twice the range of the current missile.

The navy requested, but failed to obtain, FY87 funds to start work on an extended-range Harpoon with increased maneuvering capacity. The missile would have been lengthened, the fu-

selage plug adding a fuel tank to double the range; minor increases in skin friction would have been more than made up for by the additional fuel.

An FY90 research project to improve missile lethality by detonating unexpended fuel presumably applies to Harpoon. Design work is to begin under the FY91 program.

The standard stand-alone shipboard launcher is a quartet of Mk 141 canisters, ships typically carrying 2 sets (although the battleships have 4). The canisters cannot be reloaded at sea, and typically they are replaced rather than reloaded in port. There is no current vertically launched version, although some years ago effort in that direction was reported; the new cruisers and destroyers equipped with vertical launching systems carry canisters. As of late 1988, an armored canister was being developed. Harpoon can also be fired from the standard Mk 11/13 and Mk 26 Tartar/Standard launcher and from the standard ASROC "pepperbox," as well as from standard submarine torpedo tubes (60% of the U.S. attack submarine fleet was equipped to fire Harpoon as of the end of 1988). Some export customers use truck-mounted Harpoon as a coast-defense weapon.

Several countries reportedly use Harpoon for coast defense: Egypt (with Otomat), Spain, and at least one Asian country, probably South Korea. From the early 1990s on, Denmark plans to use Harpoons from the discarded *Peder Skram*-class frigates as part of its coast defenses.

The original Harpoon ship terminal was SWG-1. The Block IC missile uses the much more sophisticated SWG-1A, which contains a graphic display unit and is updated. In SWG-1, the operator makes 1 or 2 engagement decisions. SWG-1A is much more versatile. It takes into account NTDS data, including the identities of background ships near the target. The terminal automatically generates missile flight plans with waypoints to optimize angles of approach for the highest probability of acquiring and hitting the target while avoiding being shot down. SWG-1A calculates time on target so that several missiles can be fired together to arrive together, saturating target defenses. It can also calculate from a designated time on target, so that weapons from its ship arrive with those from others.

Early in 1989 it was announced that U.S. Air Force F-16 fighters based at Misawa in Japan would be modified to carry Harpoons. This was the first time that Harpoon was integrated with the F-16 (it is already integrated with the F/A-18).

The air force has requested a longer-range version for B-52s, with a range of over 120 nm. McDonnell Douglas has test-flown a missile with a 13-in plug (extra fuel tankage) that reportedly almost doubled the range.

The ship-launched version was bought for the Australian, British, Danish, Dutch, German, Greek, Iranian, Israeli, Japanese, Korean, Norwegian, Pakistani, Portuguese, Saudi, Singaporean, Spanish, Thai, Turkish, and Venezuelan Navies (a Yugoslav request was turned down in 1984). The submarine-launched version is in service in the Australian, British, Dutch, Israeli, Japanese, and Pakistani Navies. Indonesia, as well as many of the navies listed above, operates the air-launched version. Although Iran ordered 222 air-launched Harpoons, only a very few had been delivered at the time the United States imposed an arms embargo, and 85 of these weapons were bought in FY85 for the Air Force B-52G program, 30 aircraft being modified.

Current (1988) inventory goal is 4023, with production scheduled to continue through 1992. The 4000th missile was delivered on 17 December 1986, at which time 4800 had been ordered. The 5000th missile was delivered on 2 December 1988, by which time more than 5400 had been ordered. As of 1988, 40% of production was for foreign sales. Recent U.S. procurement: FY83, 221; FY84, 315; FY85, 354; FY86, 395; FY87, 96; FY88, 124; FY89, 138. Missiles procured from FY88 onward will have an improved ("Dash-4") seeker and guidance package.

SLAM (AGM-84E) is a modified Harpoon (120-nm range) for long-range precision ground attack, in effect a replacement for the long-dead Condor. SLAM incorporates a Maverick IIR seeker with a Walleye II data link and a GPS satellite-navigation re-

ceiver for mid-course guidance. Condor's problem was that the jam-resistant data link was extremely complex and expensive. Presumably SLAM will fly almost all the way on inertial/GPS instructions, turning on its data link only at the last possible moment, and so avoiding jamming or interception. Although employing off-the-shelf components, SLAM is likely to be quite expensive, and it is being bought only as an interim weapon until the new ASWS (see Air-Launched Missiles above) appears. McDonnell Douglas was awarded a contract for 14 SLAMs on 1 February 1988. As of 1988, procurement of only 290 missiles was planned. The first production SLAM was delivered on 3 November 1988. SLAM was successfully fired from shipboard for the first time on 26 June 1990; a LAMPS III helicopter controlled it near the target. The navy is deciding whether to proceed with development of a shipboard version of the missile.

SLAM land-attack missile. (McDonnell Douglas)

SLAM under the wing of an A-6. Note the nose window for its electro-optical sensor. (McDonnell Douglas)

SLAM was the outgrowth of a long series of IIR Harpoon experiments. In 1981 it was reported that versions of the missile had been flown carrying both the electro-optical seeker originally developed for Condor and 2 types of IIR seeker built by Ford Aerospace. One of the latter used a data link, the operator on the ship designating the target; the other had on-board processing. SLAM could, therefore, be delivered in fire-and-forget fashion by an A-6. In 1 test, the missile successfully identified its target in a harbor, commanded a 360-deg turn, and flew over the ship's funnel. Reportedly, this type of seeker could even distinguish between one ship and others, of a different type, nearby.

SLAM operation requires an advanced data-link pod (AWW-13); operational evaluation of SLAM/AWW-13 began in FY90. It is applicable to both the A-6E and the F/A-18.

SLAM was selected over the air force's AGM-130 in the tri-service Standoff-Weapons Master Plan of 1988. As of early 1990, the FY90/91 requests for SLAM were 48 and 58 missiles, respectively.

Total Harpoon procurement in FY89 was 119 missiles; as of January 1989, the budget called for 190 in FY90 and 215 (rather than the 184 forecast in January 1989) in FY91.

◆ Harpoon II

Reportedly, Martin Marietta has proposed a surface-to-surface version of its Supersonic Low-Altitude Target (SLAT: BQM-127A) as a follow-on to Harpoon, with the unofficial name Har-

poon II. The missile is powered by an integral rocket-ramjet; its design is based on the ASALM (Advanced Strategic Air-Launched Missile) flight-tested in 1979. As currently (1987) conceived, this missile would be dropped by an airplane at an altitude of about 1000 ft, 55 nm from the target. Descending to about 30 ft in the first 10 nm, the missile would cruise at that altitude for 45 nm at Mach 2.5, popping up over the target. The full-scale engineering-development program will also seek a capability for Mach 3 flight at altitudes over 30,000 ft. Flight tests began in the latter half of 1987.

The unique Martin-developed engine combines a solid booster with a liquid-fuel ramjet. The solid booster case becomes the combustion chamber of the ramjet once the solid fuel has been consumed; the booster accelerates the missile to Mach 2.1 in about 6 sec, after which the ramjet accelerates the missile to Mach 2.5.

The SLAT full-scale engineering-development contract was awarded in September 1984; it covered 15 flight-test missiles, with navy options for 330 more. The navy has indicated a requirement for a total of 1000 operational missiles. SLAT presumably simulates the Soviet SS-N-22 missile and, therefore, would seem a natural starting point for a future U.S. supersonic antiship weapon. SLAT dimensions are 21.2 × 218.2 in (launch weight 2445 lb).

SLAT carried by an F-4. (Martin Marietta)

SLAT in action. (Martin Marietta)

◆ Hellfire (RBS 17; AGM-114A)

Dimensions: 7 × 64 in; span 14.25 in
Weight: 108.5 lb (compared to 99.6 lb antitank)
Warhead: approx 20 lb **Propulsion:** solid-fuel rocket
Speed: Mach 1+ **Range:** 3+ nm

This U.S. Army weapon, built by Rockwell, has been adapted for coast defense by the Swedish Navy. The missile is laser-guided (semiactive homing). As of 1988, 25 battalions were scheduled for formation, to replace 32 battalions firing French SS 11 wire-guided missiles (1989–95). The first 700 missiles were ordered in June 1987. The air-launched version, which has 2 shaped-charge warheads in tandem (for follow-through attack against, e.g., reactive armor) is the primary armament of army AH-64 attack helicopters and of Marine Corps AH-1W and AH-1J attack helicopters. The Swedish version has an antiship warhead (Bofors blast-fragmentation, downward-pointing) and a modified autopilot. It is fired from a portable launcher.

The missile is designed as a combination of 4 modules: seeker, warhead, autopilot, and motor. The standard army version uses a semiactive laser seeker, an analog autopilot, a

Hellfire (RBS 17) in its coast-defense version. The missile weighs 48 kg (with its container, 71 kg). (Bofors)

shaped-charge warhead, and a minimum-smoke motor. Rockwell offers some other options: IIR, RF/IR, or mm-wave seekers; a digital autopilot; a multipurpose warhead; and an extended-range (pulsed) motor.

The Swedish designation is RBS 17, and in Swedish service the laser designator is the El-Op PAL (portable advanced laser). Hellfire made 4 hits out of 4 shots at a range of 5 km in initial Swedish tests in September 1989. The laser designator has an effective range of 8 km. Reportedly, the Norwegian Navy is interested in buying Hellfire for coast defense.

The U.S. Navy already buys Hellfire for Marine Corps helicopters and in 1987 tested it as a possible SEAL-boat weapon. In 1989 it was again tested by the U.S. Navy, 4 being fired from an LTV Crossbow launcher on board the SES-200 surface-effect ship, and 3 being fired from a Crossbow ashore. In the shipboard tests, 1 hit a "billboard" target and another a 56-ft target boat, at a range of about 3000 yd. Two others missed a smaller target boat. The missile is being considered for a projected class of coastal patrol boats.

Hellfire entered U.S. Army service in January 1985.

The basic missile is being improved, probably with a tandem warhead (to defeat reactive armor) and a multipulse motor (for longer range). Two new passive (fire-and-forget) seekers are under development, a joint services 3-5 micron focal-plane IIR array (Ford Aerospace/Texas Instruments) and a mm-wave seeker. The latter is being developed by Martin Marietta/Westinghouse under the U.S. Army Airborne Adverse Weather Weapon System program (Longbow). Marconi is developing an active mm-wave seeker (in a Hellfire version called Brimstone) to meet an RAF Staff Requirement (SR(Air) 1238) for a fire-and-forget weapon to attack second-echelon tanks. Flight tests of rounds with digital autopilots began in early 1988. Missiles so fitted can use more maneuvering power, can dive more steeply, and can be launched from high-speed fixed-wing aircraft.

The army contract for the conceptual design of the optimized missile was let in June 1989. Goals were reduced weight, length, and unit cost, as well as hardening of the laser seeker against countermeasures. This program includes work on the future seekers described above.

◆ Crossbow

LTV's Crossbow is a stabilized pedestal-mounted stand-alone weapons platform suitable for fast attack craft. Crossbow is included in this section because its most likely application is to carry small antiship missiles on board craft in the same class

as the current 65-ft Patrol Boat Mk 3 and 4. The platform has also been demonstrated on board trucks and on board wheeled and tracked personnel carriers. Crossbow carries a television camera and can accommodate a FLIR and a laser designator or range-finder. The system is designed for automatic target acquisition and tracking while the off-mount operator identifies the target, selects the weapons, and (according to LTV) optimizes the firing. The latter phrasing suggests some form of computer threat evaluation and even weapon assignment. The system automatically leads the target.

Elevation limits are $+75/-10$ deg, and total weight, including up to 1500 lb of weapons and sensors, is less than 3000 lb. LTV lists a wide variety of missiles and guns suitable for the Crossbow pedestal, including Hellfire, the British Starstreak, TOW, the French Mistral, the U.S. Stinger, the Swedish RBS 70, a variety of unguided rockets, 0.30- and 0.50-caliber machine guns, the Oerlikon KAA 20-mm cannon, the Mauser 25-mm cannon, and the Bushmaster (Mk 38) cannon. There is an associated fire-control console incorporating a gripstick.

Acquisition and tracking tests were conducted on board the surface-effect landing craft LACV-30 at Patuxent River, as part of a PMS 300 Foreign Weapons Evaluation effort (the weapon in question was the Bofors-modified version of the Rockwell Hellfire, its foreign feature providing the occasion for evaluation). The tests are a collaborative NAVAIR/NAVSEA effort, and NAVSEA is paying for further evaluation for a near-term application to Special Warfare (i.e., to craft like the 65-footer). The Crossbow on LACV-30 managed to track surface and air targets, such as Cobra helicopters and Septar fast surface targets, in a simulated firing mode. The laser could not be demonstrated in the LACV-30 tests because of range safety limitations. The next test stage was a series of 3 unguided missile firings at Huntsville, Alabama, to test the ability of the launcher to overcome transient firing motions, so that its laser designator can be held on the target. Early in April 1989 Crossbow was to be tested at Yuma, firing guided weapons from a Hummer truck. A seagoing mount was tested on board the SES-200 surface-effect craft late in September 1989.

At the U.S. Navy League show in March 1989, LTV displayed a model of Crossbow carrying a pair of Hellfires on one side, a 2.75-in rocket pod on the other, and a 0.50-caliber machine gun.

Crossbow launches a Hellfire missile during a shipboard test, 1989. During other at-sea tests, Crossbow has successfully launched RBS 70 missiles and 2.75-in rockets and has fired a 0.50-cal machine gun and the 25-mm automatic cannon. The window (with wiper) visible above the launcher carries the system sensor, a military-rated television camera. (LTV)

◆ Sea Ray

Dimensions: 8 × 118 in **Weight:** 400 lb
Warhead: 150-lb fragmentation
Propulsion: Mk 78 solid-fuel rocket motor
Speed: subsonic **Range:** ca 7 km [7700 yd]

Texas Instruments announced in 1985 that it was developing this missile for an unnamed foreign customer, most likely South Korea. The missile can be fired from shipboard, from a helicopter, or from an airplane. Sea Ray uses many existing components: the Paveway III laser and guidance unit and the Shrike Mk 78 motor. The missile flies a ballistic path until the laser designator is switched on, about 10 sec before expected impact. Texas Instruments stated that during sea trials on board the customer's ships, a round hit the target at 7-km range within 9 in of the nominal aim point.

Development began in 1981, and Sea Ray may have entered service in 1987. Sea Ray is also the name of a fiber-optic guided-naval-missile program under development at the Naval Ocean Systems Center in Hawaii (see below).

◆ Fiber-Optic Weapons/Sea Ray

There are several ongoing programs for fiber-optically guided missiles. Such weapons exploit the high-data capacity of an optical fiber, sending back to the operator an image of the scene they observe. The link is unjammable and, in theory, undetectable. It should also be quite inexpensive, as the only sensor aboard the missile is a simple television camera. Such missiles should also be stealthy since they do not use emitting sensors. Fiber-optics might be seen as a way to achieve the advantages of an imaging sensor without the great cost of automatic interpretation inside the missile. The first project of this type was the army FOG-M, now defunct; Boeing is now trying to sell the army a fiber-optically guided mortar round (FOMP).

As of early 1989, a ship-launched antiship weapon, Sea Ray, was under development at the Naval Ocean Systems Center, Hawaii. No details were available. Meanwhile, China Lake was testing a fiber-optic link for Walleye. Skipper is being developed in fiber-optic form (at the specific behest of Congress, using FOG-M technology; it is called FOG-S and is a technology-demonstration program). The FOG-S project began in FY88, and the FY89 program included completion of the demonstration of the fiber-optic data link as paid out from a single pylon, using a FOG-M missile. That year's program also included initial work on longer-range payouts from an alternative air vehicle (e.g., Recoverable Test Vehicle) and/or steps toward exploring issues in powered Paveway vehicles (interaction between the missile exhaust and the fiber) and advanced seekers.

The FY88 Advanced Technology Transition program (which develops technology for near-term application to specific systems) included work on an ultra-low-loss, coated fluoride fiber, work on Sea Ray, and also work on an all-optical towed array. The FY89 program included a 10-km test of advanced fiber-optics technology and a demonstration of Sea Ray. At that time Sea Ray was scheduled to transition to development during FY90.

There is also a Fiber-Optic Technology program. Hughes has developed a range of fiber-optic missile links. Up to 100 km of fiber has been wound on a spool 0.3 m in diameter × 0.6 m long, and Hughes hopes ultimately for ranges up to 400 km.

UNGUIDED BOMBS AND AIR-LAUNCHED ROCKETS

FRANCE

◆ Bombs

An Étendard attack fighter displays the standard French guided and unguided weapons, including the standard rocket pods and AS 30 missiles and DEFA 552A guns. (ECP Armées)

Super Étendards carry 250- or 400-kg [551- or 882-lb] free-fall or retarded bombs. Typical dimensions are 273 × 2253 mm [10.75 × 88.7 in] or 324 × 2121 mm [12.75 × 83.5 in] for 250 kg, and 403 × 2195 mm [15.9 × 86.4 in] for 400 kg.

The standard French laser-guided bomb is the BLG 400 or BLG 1000 (400 kg and 1000 kg, respectively). It uses a Thomson-CSF seeker. Development began in 1978, and trials (BLG 400) began in 1984, with deliveries (including export orders for Iraq and at least 1 other customer) beginning in 1985. Standoff range is 2–8 km. BLG 400 is specifically described as having an antiship capability. BLG 1000 has a dual-charge warhead to penetrate heavy structures; it entered service in 1988. A BLG 250 is now being developed.

◆ Dispenser

The Super Étendard can carry an Alkan 530 bomblet dispenser carrying 2 blocks, each with twenty 74-mm [2.9-in] Thomson-Brandt grenades or cartridges in tubes facing sideways. Each cartridge is 74 × 214 mm [2.9 × 8.4 in] and weighs 2 kg [4.4 lb]; each grenade is 70 × 190 mm [2.76 × 7.5 in] and weighs 1.6 kg [3.5 lb]. Cartridges carry chaff and IR flares. Grenades are parachute-retarded antiarmor bomblets, which can penetrate 200 mm of armor.

◆ Durandal/CBU-15

This French (Matra) antirunway bomb is in service with 10 nations. It was nearly adopted by the United States but was rejected in favor of the U.S. Air Force's developmental hard-structures munition. In the absence of such a bomb, it takes an enormous, perhaps prohibitive, number of sorties to achieve any reasonable chance of putting a concrete runway out of action. Given the immature state of hard-structures munition development, Durandal may yet become attractive to the U.S. Navy. The U.S. designation is CBU-15.

The bomb can be dropped at altitudes down to 200 ft and at speeds of 400–625 mph. It is braked by a double parachute, and an internal rocket fires when it reaches a 20–30-deg down-angle. At a terminal velocity of about 850 ft/sec, its forged steel nose penetrates up to 16 in of concrete. A 1-sec delay fuze bursts it under the runway to form a crater about 6.5 ft deep and 16 ft in diameter, with a lip pushed up out to a radius of about 23 ft, and concrete fractured farther out.

The standard tactic is to drop Durandal from triple ejector racks; 6, 9, or 10 such bombs (which can be delivered by 2 aircraft) being considered sufficient to disable a typical runway. Dimensions: 223 mm × 2700 mm [8.8 × 106.3 in]; fin span

430 mm [16.9 in]; weight 219 kg [483 lb]. The warhead weighs 100 kg [202 lb]. Durandal entered service in 1977.

◆ Nuclear Weapons

The standard bomb carried by the Super Étendard is the AN.52; it is now being retired in favor of the ASMP standoff missile. Reportedly, there are 2 versions of the bomb, with yields of 25 kT (elsewhere reported as 15 kT) and 6–8 kT. The bomb weighs about 1300 lb.

◆ Rockets

Super Étendards carry Matra 155 pods (eighteen 68-mm [2.68-in] rockets). This pod can also be carried by British Sea Harriers. There are 2 types: first-generation rockets with unitary warheads (shaped-charge, blast-fragmentation, or chaff); and second generation multidart warheads (antiarmor or illumination). Typical dimensions are 68 × 910 mm [2.68 × 35.8 in], 5 or 6.2 kg [11 or 13.7 lb] for first generation; 68 × 1380 mm [2.68 × 54.3 in], 8.3 kg [18.3 lb] for second generation. Range is 1000–4000 m [1095–4375 yd].

USSR

◆ Bombs

Soviet naval aircraft carry gravity bombs as well as missiles. For example, naval Badgers dropped bombs in Afghanistan. The Yak-38 Forger VTOL fighter can carry 250- and 500-kg [551- and 1102-lb] free-fall bombs of various types. Reportedly, there are over a thousand different Warsaw Pact bombs, but that number may include numerous obsolete types.

Published designations consist of a prefix indicating the bomb type and then the weight in kilograms. Standard types include:

General-purpose Bombs (FAB Series): Both high-drag (World War II) and low-drag (equivalent to U.S. Mk 80 series) configurations. One published photograph shows a low-drag bomb being retarded by the Soviet equivalent of the U.S. ballute. The high-drag series are: FAB-8, -10, -15, -20, -25, -50, -110, -500, and -1000. Low-drag: FAB-100, -250, -500, -750, -1000.

Low-drag Blast-fragmentation: OFAB-250, -500.

Demolition (Thin-case): 100, 250, 750, 1100 kg.

Concrete Penetrators (Retarded): BETAB-250 and -500. There is also an M62 penetration bomb (500 kg; also exists in a 250-kg version).

Napalm (low drag): PLAB-250, -500. PLAB-150L is a reported designation for a 150-liter napalm bomb.

Incendiary (low drag): ZAB-100, -250, -500, -750, -1000; there is also a ZAP-200 incendiary container weapon.

Cluster Bombs: RBK-180 and -250; there is also an RAB-120 carrying fragmentation bomblets. RRAB (no weight given) contains incendiary bomblets. An RBK-250 carries 60 antipersonnel or 30 antitank bomblets. The former are AO-2.5-2, and each is about as effective as a single 81-mm mortar round. The shaped charge bomblets (number indicates weight of bomblet) are PTAB-1.5, -2, -5, and -5/1. There are also fragmentation bomblets (RAP-2.5, -3.5, -16). AK-2 is a dispenser for 240 1-kg chemical bomblets (mustard and Lewisite). DPT-150 is a reported cluster-bomb designation (54 PTAB-1.5, 44 RAP-2.5, or 34 RAP-3.5).

Dispensers: PKPE-1 contains twenty-nine 70-mm tubes, each containing 2 or 3 submunitions, launched laterally by a small charge; the submunitions are either blast-fragmentation grenades or shaped-charges (similar to the RPG-7 warhead). A helicopter or ground-attack airplane typically carries 2, firing to each side.

Chemical weapons: The Soviets have displayed high-drag bombs of World War II vintage and presumably have developed modern low-drag equivalents. VAP-200 is a container bomb;

VAP-1000 (BATT) is a dispenser (700 liters of hydrogen cyanide for low-altitude spraying); and KhAB-500 is filled with 180 kg of phosgene. VAP is probably a general dispenser designation, and newer weapons include an NOV-AB series of bombs containing nonpersistent toxic agents and an SOV-AB series containing persistent toxic agents.

It is not clear to what extent the designations quoted are of Western, rather than Soviet, origin.

◆ Nuclear Weapons

Reportedly, there are at least 14 types of tactical nuclear weapons. The current standard weapon is reportedly a 1000-kg bomb with a 350-kT yield, and a 700-kg bomb with a 250-kT yield is being introduced. Presumably, the Soviet nuclear depth bomb has a much smaller yield, on the order of tens of kT.

◆ Rockets

The Yak-38 Forger VTOL fighter can carry pods: UB 16-57 and UB 32-57 with, respectively, sixteen and thirty-two 55-mm S-5 series folding-fin rockets. The "57" refers to tube diameter. There are 9 warheads, including HEAT, high explosive, fragmentation, and chaff. Typical burnout speed is 620 m/sec [2034 ft/sec].

UNITED KINGDOM

◆ Bombs

The standard Sea Harrier load is 3 British Mk 13/18 or U.S. Mk 83 1000-lb bombs. During the Falklands War, Sea Harriers also delivered U.S.-supplied Paveway laser-guided bombs, reportedly using hand-held laser target-designators. Mk 13/18 is considerably fatter than the U.S. low-drag bombs but has a fairing for streamlining. Mk 13/18 can be fitted with a parachute retarder.

◆ Carrier Bomb Light Stores

Sea Harriers carry BL 755 bomblet dispensers (419 × 2451 mm [16.5 × 96.5 in], 277 kg [611 lb] loaded), which carry 21 shaped-charge/fragmentation bomblets in each of 7 compartments.

◆ Rockets

The standard Royal Navy rocket pod carries nineteen 2-in rockets; Sea Harriers also carry the French Matra 155 pod and the U.S. LAU-69/A (2.75-in FFAR).

◆ Nuclear Weapons

Sea Harriers aboard the 3 light carriers are equipped to deliver tactical nuclear weapons. These probably are 200–400-kT WE-177A/B bombs of the type also carried by RAF aircraft, including the shore-based Buccaneers and Tornados assigned to maritime missions. The Royal Navy also uses a reduced-yield WE-177C nuclear depth bomb, the airframe of which may be related to that of the U.S. B57 (which British aircraft, such as the Nimrod, can carry). Shipboard Sea King and Lynx helicopters and shore-based Nimrods carry the depth bombs. An unofficial estimate credits Britain with a total of 180–200 WE-177s, of which 155–175 are A/B versions. All 3 versions use the same "physics package." Presumably, the versions correspond to the different yields of the U.S. "dial-a-yield" bombs, except that in the British case the yields are preset.

UNITED STATES

◆ Bigeye

Bigeye is a new binary chemical bomb, developed about 1985 but not yet deployed. The binary weapon is safer to handle than unitary munitions since its components are not lethal until they mix in the air. They mix only after release, to produce VX nerve gas, which the bomb sprays from its nose. Critics of this program have suggested that the mixing process is so lengthy that the bomb must be released either at high altitude or in a toss maneuver; both releases increase the vulnerability of the launching aircraft. In 1986 Congress repealed a 16-yr morato-

An F/A-18 can carry all the standard U.S. unguided weapons, which are shown here. LDGPs are low-drag (i.e., streamlined or "slick") general-purpose bombs; FAE is fuel-air explosive. (McDonnell Douglas)

rium on U.S. production of chemical weapons, but only for army 155-mm shells and not for Bigeye.

In 1986 the Grumman A-6 was validated for Bigeye delivery.

◆ Fuel-Air Explosives

Fuel-air explosives (FAE) are not currently in service, but several types have been developed, and presumably, they can easily be deployed. The only type used in battle in significant quantities was the BLU-73/B, containing 72 lb of ethylene oxide, 3 of which were carried by the CBU-55/B cluster bomb. CBU-55/B was tested in 1969-70 and standardized in 1971 for mine-field or landing-strip clearance. Each bomblet forms a fuel-air cloud about 15 m [about 50 ft] in diameter and about 2.5 m [about 8.5 ft] thick; in Vietnam such a cloud could clear a jungle area 30 m [about 100 ft] in diameter. The bombs also proved very effective against area targets since the blast wave was not stopped by buildings or small land features, such as hillocks.

CBU-72 was an improved version intended for delivery from fast aircraft.

Work on a second generation naval FAE, concentrated on an FAE glide bomb, began in 1973; the McNulty test was intended to simulate a near miss by such a weapon. Reportedly, there was also interest in underwater detonation of FAE as an ASW weapon, FAE warheads being exploded at simulated depths of 1500-2300 ft. Presumably, in these cases the warhead carries a compressed oxidant that is released together with the fuel; the

objective is a strong underwater shock wave. None of these weapons appears to have been adopted.

There was also a parallel U.S. Air Force program, begun in 1967, to develop a 2500-lb retarded FAE bomb (Pave Pat). An FAE cluster bomb, BLU-76, was designed specifically for delivery by the F-4 Phantom. Reportedly, the major difference between air force and navy FAE weapons was the fuze delay, more than 4 sec for the air force and 125 msec for the navy.

The most recent weapons are BLU-95 (XCL-1)/B and BLU-96 (XCL-1)/B, originally known as FAE-I and -II (500 and 2000 lb). Other types developed but not deployed included FAESHED, MADFAE, SLUFAE, HFS-I, and HFS-II. The CATFAE mine-clearance device is now under development. Work was already underway at China Lake as early as 1960.

FAEs are interesting as an attempt to get more explosive effect out of a given weight and volume, since weight and volume are strictly limited for any airborne weapon. The fuel carried by the bomb is mixed with the surrounding air to form an explosive mixture, then detonated when it reaches an appropriate density. The bomb, then, need not carry its own oxidant, whereas much of the weight of any conventional explosive is oxygen. For example, 100 kg of TNT contains 42 kg of oxygen in its molecules. On the other hand, 100 kg of propylene oxide takes 69 kg of oxygen from the air when it burns. For Decane, the ratio is 100:34; for aluminum powder, 100:89. In some cases, a conventional explosive, dispersed as a powder, reacts with air like an FAE; FAE and such powders are grouped with other high-impulse explosives under the name EBM (enhanced-blast munitions). Weight for weight, propylene oxide and aluminum release 7.9 and 7.4 times as much energy as TNT. Decane releases

The effect of a fuel-air explosion, shown in a sequence of 1972 photographs of a simulated near miss on the former destroyer escort *McNulty*. Note the dispersion of the cloud before the detonators are fired into it. The second and third photos show how the cloud envelops the ship and then goes off (note the shock wave in the water). (U.S. Navy)

10.3 times as much energy as TNT. These figures are not quite so encouraging for volume, but they are still impressive.

There are 2 problems. First, FAE is a pure-blast explosive. Most weapons combine blast and fragmentation, and the latter effect is often the most devastating. The burst of an FAE is quite dramatic, but often the structure being attacked is only lightly damaged. The ship illustrated here did eventually sink, but quite slowly. FAE is most effective against soft targets such as aircraft, communications antennas, missiles, unarmored vehicles, and troops. For a soft target, the FAE's lethal radius is generally far greater than that for TNT. Impulse (integrated pressure) can be as much as 100 times that for TNT, although peak pressure is less, and by no means comparable with nuclear effects.

Second, it is not easy to ensure that the FAE will detonate

properly. The fuel must be distributed just right, and the detonators must be distributed within the fuel cloud (and fired) just right. Wind, temperature, even humidity can ruin the effect.

◆ Low-Drag Bombs/Snakeye/Ballute

The Mk 80 series are the primary U.S. Navy bombs, developed in the late 1940s at the suggestion of Douglas Aircraft. All have the same aerodynamic shape (aspect ratio 8.5), the Mark number indicating the weight: Mk 81, 250 lb (9 × 76.1 in); Mk 82, 500 lb (10.8 × 90.9 in); Mk 83, 1000 lb (14 × 110.9 in); and Mk 84, 2000 lb (18 × 154 in). Ninety percent of navy bombs dropped in Vietnam were Mk 82s, with Mk 83s accounting for most of the rest.

The 2 main developments have been retarders and anticook-off casings. Retarders make low-level delivery practical (so the bombs will not explode directly under the airplane). The major current retarder is a set of 4 pop-out fins (Snakeye); but they are not always reliable, and accidents have occurred. Goodyear developed an alternative, the inflatable Ballute. Snakeyes may be designated with an R suffix, as in Mk 82R.

Anticook-off bomb casings reduce the risk inherent in flight-deck fires. A conventional Mk 82 in a fuel fire will cook off in about 4 min. A coated Mk 82 will last 9 min and will then burn rather than explode, so that it can be tossed off the flight deck.

After Vietnam an advanced general-purpose bomb (AGPB) program was begun, to produce improved 500-, 1000-, and 2000-lb weapons. The 500-pounder was a blast-fragmentation type for close air support, fuzed for either instantaneous or delayed explosion or for air burst. The medium bomb was designed for moderate penetration (e.g., against buried ammunition). The heavy bomb was a demolition weapon for attacking bridges, roads, and deep tunnels. AGPB never received very much funding, partly because the Mk 80 series had been manufactured in such great numbers during Vietnam, and partly because of a general belief that guided bombs had made unguided weapons obsolete.

◆ ABF

The new Advanced Bomb Family is to be compatible with the stealthy A-12 attack bomber; presumably, these are low-observable weapons that can be carried externally without compromising the stealth of the airplane. The bomb's stealth is more likely to be achieved by material than by shape.

Lockheed exhibited its version of the ABF at the U.S. Navy League show in April 1990. The 500- and 1000-lb bombs are both cylindrical, differing only in length. Each is an all-up round, ready for flight in its shipping container. Fuze and retarder (parachute or ballute) are already in place. The fins fold to wrap around the bomb body, so they do not require preflight assembly. Fuzing option is selected in flight. The 500-lb version, replacing Mk 83, is a blast-fragmentation bomb; the 1000-lb version, replacing Mk 84, is a hard-target warhead capable of penetrating at least 1 ft of concrete. The all-up round configuration is attractive because it can drastically reduce turn-around time between sorties. The common fuze, to be developed as part of the program, will have settings for delivery mode (high/low drag), safe aircraft separation time, and bomb-burst time delay following impact. It will also incorporate an extended time (random delay) antitamper feature and an air-burst proximity sensor. The fuze will be able to accept signals from a future underwater mine adapter, so the bomb will be adaptable as a future Quickstrike bottom mine.

Some (25–40%) of the 1000-lb bombs produced will have inertial guidance systems with movable tail fins.

The Lockheed designs are only tentative since the RFP has not yet been issued (as of April 1990 it was expected in February 1991). The ABF Tentative Operational Requirement (TOR) was issued in 1983, and the OR in 1989. A formal Industry Briefing was scheduled for May 1990, with contract award in the first quarter of 1992 and production go-ahead late in 1995. Unit cost targets are \$3900 for the 500-lb version and \$5900 for the 1000-lb version.

Two Lockheed ABF bombs, the 500-pounder at left and the 1000-pounder, with fins unfolded, at right. The cutaway section shows the fuze and the retarding mechanism. (Lockheed)

An AV-8B Harrier II drops Snakeye (Mk 82) retarded bombs; note the fins opening. (McDonnell Douglas)

◆ Napalm

The current standard weapon is BLU-27 (750 lb, filled with 100 gal of Napalm-B).

◆ Nuclear Bombs

The current standard strike bomb is B61. However, there is also a version of the B57 nuclear depth bomb rated as a lay-down weapon. B57 is now quite old, and it is to be replaced by a dual-purpose nuclear depth bomb/nuclear strike bomb (NDB/NSB), B90, for which 1 candidate is a modified B61. The advantage of the dual-purpose weapon is that it limits the carrier magazine space that must be devoted to nuclear weapons. The B61 "dial-a-yield" bomb is the current standard air force/navy weapon. Development began in 1963, and B61 was fielded in 1967. The current Mod 5 entered service in 1977; the other current naval versions are Mods 0, 1, and 2. A new Mod 6, with improved safety and command features (presumably, a better permissive-action link), should enter service in 1991. The yields of these bombs can be adjusted ("dialed") without any modification of the internal physics package. The reported maximum yields vary with the version, 1 unofficial claim being 10–100 kT for Mod 0/2, 345 kT for Mods 3/5, and 900 kT for Mod 1. The minimum yield may be as low as 1 kT. Dimensions are typically 13.4 in × 10 ft 11 in. There is also an earlier high-yield nuclear bomb, B43 (18 in × 13 ft 8.5 in, 2060 lb). In 1990 the U.S. stockpile included 350 B43s, 1600 B57s, and 3025 B61s of various versions. An unofficial estimate credits the navy with 250 B43s, 475 B57s, and 625 B61s.

◆ Rockets

The 2 primary U.S. air-launched rockets are the 2.75-in folding-fin aircraft rocket (FFAR) and the 5-in folding-fin Zuni. Both are normally carried in pods.

FFAR ("Mighty Mouse") was conceived as an air-to-air weapon. It is 47.85 in long and weighs about 18 lb. The original 2.75-in rocket developed through motors Mk 1 through 4; the final version, Mk 4, developed 750 lb of thrust for 1.2–1.4 sec, accelerating the rocket to 2300 ft/sec [1570 mph]. Improvements over earlier versions increased warhead weight from 6 lb to 10 lb by the mid-1960s, and by that time range was 550–6500 yd (3750 yd effective). Mk 40 was a new motor for a helicopter-borne version. Because the helicopter is a slow platform, the nozzle is arranged to impart greater stabilizing spin.

The most common warheads of these versions of FFAR are M151 (10-lb HE, white phosphorus, or fragmentation), M156 (10-lb chemical), M229 (17-lb HE, white phosphorus, or fragmentation), and WDU-4A (flechettes). M151 is considered equivalent to an 81-mm mortar round, M229 to a 4.2-in mortar round. The flechette antipersonnel round developed from a program for improved artillery ammunition. There are also shaped-charge antitank warheads.

These rockets are typically carried in expendable 7-rocket (Aero 6, then LAU-32) or 19-rocket (Aero 7, LAU-3 and LAU-69) launchers. FFAR is sometimes carried by marine attack helicopters, and it was used against Iranian attack boats in the Persian Gulf.

Zuni replaces the earlier fixed-fin high-velocity aircraft rocket (HVAR), which may survive in some navies. It is 110 in long, weighs 107 lb, and reaches 2370 ft/sec, about 1400 kt. It is typically carried in a 4-rocket LAU-10 pod and has either a general-purpose or a shaped-charge warhead. During the Vietnam War ship-launched Zunis were used to disperse chaff (see the Antiaircraft Warfare section).

Under the FY88 program, work continued on an ongoing program to develop 2.75-in rocket submunitions (M261/267). Under the Foreign Weapons Evaluation program, the navy tested a Canadian Bristol Aerospace high-impulse 2.75-in rocket motor (CRV 7), and it conducted a NATO Cooperative Test (NCT) of a Raufoss HEISAP (high explosive, incendiary semi-armor-piercing, analogous to the company's 0.50-caliber bullet) anti-ship warhead and a Thomson-Brandt antimateriel warhead. De-

velopment of a chaff warhead began in FY89, with smoke screening, smoke marking, multimode, and antiarmor flechette warheads and an Advanced Rocket System improved launcher following in FY90. Presumably, the latter warheads are the army types described below under Hydra 70.

◆ Advanced Rocket System

Early in 1989 the U.S. Navy announced a program to develop an Advanced Rocket System to replace the existing 2.75-in weapon, to enter service in FY95. The new rocket motor is to provide a velocity (with a 10-lb warhead) of at least 1000 m/sec [3280 ft/sec] at zero aircraft speed; it is to have a low smoke signature (for stealthy operation), and it is to be insensitive (i.e., relatively safe aboard a burning carrier). Minimum effective range is to be 10,000 m (15,000 m in loft mode). The new weapon will reportedly use multipurpose warheads. Initial work is funded under the 2.75-in-rocket account, but a new ARS project is to begin formally in FY92. An RFP was scheduled for FY90. Apparently the new rocket, like the current 2.75, would be carried in a 19-weapon pod.

Reported mission requirements are: dry marking (to use a family of different colored markers other than the current toxic white phosphorus); antipersonnel (1 pod to cover 15,000 m²); antimateriel (to penetrate a minimum of 1.5 in of armor); antiarmor (to penetrate a minimum of 3 in of armor); antihelicopter (4 rockets to cover an area of 2500 m²); anti-coastal shipping (to penetrate 1 in of steel at a range of 4 km, with a delayed-action fuze and incendiary effect); chaff (for self-protection and deception); flare (1 million candlepower for 1.5 min); night marking (2-min marker, observable by FLIR and other night-vision devices); smoke screening (pattern 50 × 400 m, duration 5 min in less than 5–10 kt wind, effective in visual, IR, and ER spectra); and training. The requirements stated above are for ranges of up to 10 km (up to 4 km for the antishipping mission) and are to be met from a hovering helicopter.

Some slippage in the advanced rocket schedule is likely to leave the marines short of the current Hydra rocket. In June 1990 it was reported that the marines were 200,000 rockets (24%) below their wartime inventory requirement and, hence, had to reduce the level of firings in training. At this time the advanced rocket was in preliminary full-scale development, to be completed in FY95. The rocket, which replaces both Hydra and Zuni, is to enter service in FY97. It will use either the current Mk 66 motor or a new high-performance motor now under development.

◆ Hydra 70

Hydra 70 is the current U.S. Army and Marine Corps 2.75-in rocket, superseding the earlier FFAR; it is manufactured by BEI, the only current U.S. 2.75-in-rocket maker. A variety of warheads can be combined with the standard Mk 66 motor: M151 HE (10 lb nominal, actually 8.7 lb, of which 2.3 lb is Composition B-4), M247 (shaped-charge antitank), M274 TP (10 lb [training]), WTU-1 inert, M261 (MPSM), M267 (MPSM, training), M255 (flechette), M262 (illumination flare), and M264 RP (smoke). Chaff, smoke marker, and shot rocket warheads have not yet been standardized.

BEI is currently developing 2 alternative navy smoke markers for this rocket: an orange smoke marker and a multimode smoke marker consisting of smoke, chaff, and a pulsating flare. The latter is intended as a target marker rather than as a countermeasure.

The Mk 66 motor supersedes the earlier Mk 4 and Mk 40; it has better performance and produces less smoke. Mod 1 is the standard army and air force version, Mod 2 the standard navy and marine version (it differs from Mod 1 in having a filter to protect the rocket from stray shipboard electromagnetic radiation). It achieves 1400 lb of thrust in 38 msec, providing a burn-out velocity of about 3300 ft/sec. The fluted nozzle spins the rocket to 600 rpm in the launcher and then to 2100 rpm in flight, for much better accuracy than previous U.S. 2.75-in weapons.

M261 is a multipurpose submunition warhead, carrying 9 M73 HE grenades and an expulsion charge that can be set by analog (to 6000 m) or digital (to 12,000 m) fuze. Each grenade has a shaped-charge to attack armor and is also scored internally for fragmentation. M267 is the corresponding training round. M264 ejects 72 red phosphorous wedges, to form a persistent smoke screen. The flechette warhead, M255, is currently being tested by the U.S. Army. It carries either 585 × 120-grain or 1200 × 60-grain flechettes, for air-to-air, air-to-surface, and surface-to-surface attack. The flechettes fly outward in a 6.5-deg cone when the rocket bursts, stabilizing about 150 yd from the point of burst to form a cylinder about 115 ft in diameter and 1 flechette deep, and moving at about Mach 2 (2400 ft/sec). The flechettes were originally developed to attack personnel; BEI proposes them as an antihelicopter weapon, effective out to 3500 m.

The shot rocket contains 2 clusters, each of seven 450-grain subrockets (kinetic penetrators), each with its own 21-mm rocket motor, to accelerate it by 1500 ft/sec, so that on impact each is traveling at about 4000 ft/sec. Applications include antiship attack, as well as attacks on armor and on aircraft such as helicopters.

◆ Rockeye/Sadeye/Gladeye/Gator

Rockeye is an unguided bomblet-dispenser. Unlike most such dispensers, Rockeye is dropped by the airplane carrying it, so the airplane need not fly directly over its target. This weapon was originally developed by China Lake and was widely used during and after Vietnam. The current Rockeye II carries 247 armor-piercing bomblets in a 13.2 × 92-in (94.5 in, including fuze cover) casing (490 lb total). Four fins pop out of the rear end of the casing (span 17.2 in closed, 34 in open). Minimum release altitude in level flight is 250 ft, or 100 ft in pitch-up (toss delivery). The typical bomblet pattern from 500 ft forms a 30,000-ft² oval. Each bomblet has a short standoff fuze and a shaped-charge warhead.

Rockeye (Cluster Bomb Mk 20 Mod 1). (U.S. Navy)

A Gladeye strongback with its submunitions containers. (U.S. Navy)

The basic Rockeye concept is well known, and many similar weapons are used by other forces. Chile produces its own version (Cardoen Industries).

The other major U.S. cluster bombs developed in parallel with Rockeye were Mk 15 (Sadeye) and Mk 17 (Gladeye); Rockeye is Mk 12, and Rockeye II is Mk 20. Sadeye is fin-retarded and carries 2100 bomblets. Gladeye uses 2 separate time-delay cartridges in a canister, which is itself carried on a standard strongback slung from a bomb rack. The strongback carries 7 Gladeyes, each filled with 330 M40 antipersonnel bombs.

The principal current naval cluster bombs are CBU-30, -52, -58, -59, and -71. The list below is more inclusive, as earlier weapons may still be available, and also as air force weapons may be available for naval use. It seems unlikely that the gas and BW bomblets listed below were ever deployed, and any examples produced have probably been destroyed.

Cluster bombs:

CBU-1 SUU-7 dispenser filled with 509 BLU-4 bomblets. SUU-7 was the first U.S. underwing (fixed) dispenser, launching bomblets to the rear by compressed air.

CBU-2 SUU-7 dispenser filled with 360 BLU-3 bomblets. *CBU-2B* is filled with 409 BLU-3 bomblets.

CBU-3 SUU-10 dispenser filled with 352 BLU-7 bomblets; total weight is 660 lb. *CBU-3B* is 371 BLU-7s in an SUU-10B dispenser.

CBU-7 SUU-31 dispenser filled with 1200 BLU-18s.

CBU-11 Smoke bomb: 261 BLU-16s in an SUU-7 dispenser.

CBU-12 Smoke bomb: 261 BLU-17s in an SUU-7 dispenser (640 lb).

CBU-13 Smoke bomb: mixture of 261 BLU-16s and -17s in an SUU-11 dispenser.

CBU-14 SUU-14 dispenser filled with BLU-3 bomblets.

CBU-15 Gas bomb: SUU-13 dispenser filled with BLU-19 bomblets.

CBU-16 Gas bomb: SUU-13 dispenser filled with CDU-9 clusters of gas bomblets.

CBU-17 SUU-13 dispenser filled with practice bomblets.

CBU-18 SUU-13 dispenser filled with BLU-25 bomblets.

CBU-19 Twin strongback for 16 modules, each carrying 33 BLU-39 gas bomblets.

CBU-22 Smoke bomb: 72 BLU-17s in an SUU-14 dispenser.

CBU-23 SUU-31 dispenser filled with BLU-26 bomblets.

CBU-24 SUU-30 dispenser filled with 665 BLU-26 or -36 bomblets. SUU-30 dimensions: 16.12 × 87.89 in (including nose cap).

CBU-25 SUU-14 dispenser filled with BLU-24 bomblets.

CBU-26 SUU-10 dispenser filled with dummy bomblets.

CBU-28 SUU-13 dispenser carrying 40 CDU-12 cluster units, each made of 120 BLU-43 bomblets.

CBU-29 SUU-30 dispenser filled with 670 BLU-36 bomblets (840 lb).

CBU-30 SUU-13 dispenser carrying 40 CDU-12 clusters, each made of 30 BLU-39 gas bomblets.

CBU-33 SUU-36 dispenser carrying 30 BLU-45 bomblets.

CBU-34 SUU-38 dispenser carrying 10 CDU-18 or -19 clusters, each of 54 BLU-42.

CBU-37 SUU-13 dispenser carrying 40 CDU-3 clusters, each of 120 BLU-44 bomblets.

CBU-38 SUU-13 dispenser carrying 40 BLU-49 bomblets.

CBU-41 SUU-51 dispenser carrying 18 BLU-53 bomblets (485 lb).

CBU-42 SUU-38 dispenser carrying 10 CDU-20 or -21 clusters, each containing 54 BLU-54 bomblets.

CBU-43 SUU-37 dispenser carrying BLU-48 bomblets (840 lb).

CBU-44 Antipersonnel fragmentation bomblets.

CBU-45 Cluster bomb carrying APAM bomblets (1000 lb).

CBU-46 SUU-7C dispenser carrying 640 BLU-24 or -66 bomblets (880 lb).

CBU-47 SUU-13 dispenser carrying BLU-55 bomblets.

CBU-49 SUU-30 dispenser carrying 670 BLU-59 bomblets (840 lb).

CBU-50 SUU-13 dispenser carrying 40 BLU-60 bomblets.

CBU-51 SUU-13 dispenser carrying 40 BLU-67 bomblets.

CBU-52 SUU-30 dispenser carrying 254 BLU-61 bomblets (770 lb).

CBU-53 SUU-30 carrying 670 BLU-70 bomblets (815 lb).

CBU-54 SUU-30B dispenser carrying 670 BLU-68 bomblets (815 lb).

CBU-55 FAE weapon: 3 BLU-73s, each 13.75 × 21 in (total bomb dimensions are 13.75 × 78.75 in). Each bomblet weighs 100 lb, including 72 lb of ethylene oxide; *CBU-55* weighs 460 lb (500 lb nominal) and has a retarding drogue chute.

CBU-57 SUU-14 dispenser carrying 132 BLU-69 bomblets.

CBU-58 SUU-30 dispenser carrying 650 BLU-63 bomblets.

CBU-59 Rockeye II, carrying 717 BLU-77 bomblets.

CBU-60 SUU-60 dispenser filled with 264 BLU-24 bomblets.

CBU-61 Gas bomb (using bomblets).

CBU-61 SUU-30 dispenser carrying M38 fragmentation grenades (840 lb).

CBU-63 SUU-30 dispenser carrying M40A1 fragmentation grenades (each 23 lb; total 840 lb).

CBU-66 SUU-51 dispenser carrying CDU-24 canisters carrying BLU-81 bomblets; canceled.

CBU-68 SUU-30 dispenser filled with BLU-48 bomblets.

CBU-70 SUU-30 dispenser bomb.

CBU-71 (*Gator*) SUU-30 dispenser carrying 670 BLU-86A/B fragmentation bomblets, or *Gator* antitank or antipersonnel mines.

CBU-72 FAE bomb, carrying 3 BLU-73s (see *CBU-55*, above). In this case the bomblets burst at an altitude of 30 ft, each creating a cloud 60 ft in diameter and 8 ft thick, producing 300 psi overpressure when it explodes.

CBU-75 SUU-54 dispenser carrying 1800 BLU-63 bomblets.

CBU-76 SUU-51B dispenser carrying 290 BLU-61 bomblets.

CBU-77 SUU-51B dispenser carrying 790 BLU-63 bomblets.

CBU-78 SUU-58 dispenser carrying 45 BLU-91 and 15 BLU-92 bomblets. Dimensions: 13 × 85 in (490 lb). This is the U.S. Navy version of the *Gator* air-delivered land mine system. The dispenser is a modified Rockeye.

CBU-83 SUU-58 dispenser carrying BLU-92 bomblets.

CBU-84 SUU-54 dispenser carrying BLU-91 or -92 bomblets.

CBU-86 SUU-4 dispenser carrying BLU-92 bomblets.

CBU-87 Combined Effects Munition using the SUU-65 dispenser and 202 BLU-97 bomblets. It is intended to replace the Rockeye series and *CBU-58* in air force use. Bomblets can be

delivered at any altitude over 200 ft and at any speed up to 700 kt, the dispenser spinning at a selectable rate of 0-2500 rpm.

CBU-89 Gator dispenser, consisting of SUU-65 carrying 72 BLU-91s and 22 BLU-92s (total 710 lb); it can be dropped from 200-40,000 ft. Dimensions: 16 × 92 in, including protruding nose fuze. This is the U.S. Air Force version of the Gator air-delivered land mine system.

CBU-92 Extended-range antiarmor munition, now under development by the air force for deployment in 1993; it is an SUU-65 dispenser carrying 9 antitank and 3 area-denial submunitions. The antitank submunitions carry Skeet submunitions of their own, plus fuzes capable of classifying objects within a range of 500 ft and then firing 2 Skeets at them. See BL-108, below. Total weight is 950 lb.

CBU-97 Sensor-fuzed weapon (SFW), the air force weapon now under development for direct attack against armored formations. Dimensions: 15.6 × 92 in, using an SUU-64 dispenser carrying 10 BLU-108 bomblets, each carrying 4 Skeets. In this application the Skeets are released in flight, and each uses its own IR sensor to decide when to burst.

Bomblets:

BLU-3 1.75 lb "Pineapple" bomblet for use against unarmored vehicles, carrying a 0.35-lb Cyclotrol filling and 250 steel pellets.

BLU-4 1.2-lb antimateriel bomblet, firing a spherical fragmentation device to explode 10 ft above ground. This is the filling of the CBU-1 bomb.

BLU-7 1.4-lb antitank (shaped-charge) bomblet using a stabilizing parachute.

BLU-16 1.6-lb cylindrical smoke bomblet.

BLU-17 1.1-lb cylindrical smoke bomblet (white phosphorus).

BLU-18 0.4-lb triangular antipersonnel fragmentation bomblet with delay fuze.

BLU-19 Gas bomblet.

BLU-20 Gas bomblet.

BLU-21 BW bomblet.

BLU-22 BW bomblet.

BLU-24 1.2-lb "Orange," a spherical antipersonnel fragmentation bomblet using plastic fins and a spin-delay fuze; its case contains 300 embedded steel fragments.

BLU-25 Cylindrical antipersonnel bomblet.

BLU-26 1.2-lb "Guava" spherical antipersonnel and antimateriel bomblet, 2.36 in in diameter, filled with 0.7 lb of Cyclotrol or TNT; forming 600 steel fragments (lethal to a 40-ft radius) on detonation. It has an air burst, impact, or delay fuze. The air burst is set at a height of 30 ft, and the delay can be 1 min or more.

BLU-36 0.95-lb antipersonnel and antimateriel (APAM) bomblet with a random-delay fuze.

BLU-39 0.18-lb gas bomblet.

BLU-40 1.7-lb fragmentation bomblet with random-delay fuze.

BLU-41 Spherical fragmentation bomblet with spin-arming and a spin-delay fuze.

BLU-42 Spherical antipersonnel minelet, 0.25 lb of Composition B explosive.

BLU-43 "Short Dragontooth," a triangular antipersonnel blast minelet.

BLU-44 "Long Dragontooth," a triangular antipersonnel blast minelet.

BLU-45 Shaped-charge antitank minelet.

BLU-46 Antipersonnel bomblet.

BLU-47 General-purpose bomblet.

BLU-48 Spherical fragmentation bomblet.

BLU-49 13.4-lb ring-tailed fragmentation bomblet.

BLU-53 Canister fire bomblet (Napalm-B).

BLU-54 Antipersonnel minelet (BLU-42 with long-life self-destruct).

BLU-55 Antipersonnel minelet.

BLU-59 0.95-lb fragmentation bomblet identical to BLU-26 but with shorter-life fuze.

BLU-60 13-lb fragmentation bomblet.

BLU-61 2.2-lb spherical antipersonnel/antimateriel, incendiary/fragmentation bomblet (filled with zirconium and Composition B).

BLU-62 0.95-lb antipersonnel and antimateriel fragmentation bomblet; bounces into the air upon impact.

BLU-63 0.95-lb spherical antipersonnel and antimateriel bomblet with spin and impact fuzes; prefragmented casing.

BLU-66 1.1-lb "Pineapple" spherical antipersonnel bomblet with plastic fins and 260 steel fragments embedded in its casing; impact fuzed.

BLU-67 11-lb cratering bomblet.

BLU-68 0.93-lb spherical incendiary antipersonnel and antimateriel bomblet (APAMB) with zirconium sponge filling.

BLU-69 1.6-lb spherical incendiary antipersonnel and antimateriel bomblet (APAMB).

BLU-70 0.88-lb spherical incendiary antipersonnel and antimateriel bomblet (APAMB).

BLU-73 100-lb FAE bomb, see CBU-55 above.

BLU-77 1.02-lb antitank fragmentation bomblet, intended to discriminate between hard and soft targets, and also with a secondary antipersonnel function (in which case the shaped-charge warhead bounces the bomblet up into the air to burst).

BLU-81 Antivehicle minelet, canceled.

BLU-86 1-lb fragmentation bomblet.

BLU-87 Dummy fragmentation bomblet.

BLU-91 "Gator" antitank minelet, 5.75 × 5.0 × 2.6 in (4.3 lb). Microelectronics in the minelet detect a vehicle and discriminate against unarmored vehicles. An upward-pointing shaped charge (Misznay-Schardin explosive) destroys the vehicle's belly armor.

BLU-92 "Gator" antipersonnel minelet. Dimensions match those of BLU-91, but weight is 3.7 lb. This minelet is intended to discourage attempts to clear BLU-91 mine fields.

BLU-97 3.4-lb submunition of the CBU-87 Combined Effects Munition; dimensions are 2.5 × 6.6 in (10.2-in length with tail extended). The bomblet contains a shaped charge at one end, a fragmenting shell (which disperses when the charge explodes), and an incendiary element.

BLU-106 43-lb (4 × 53.5 in) boosted kinetic-energy penetrator (BKEP) to be carried by Tomahawk cruise missiles (28 bomblets in 2 bays), by the SUU-54 dispenser (AGM-130 missile), and by the SUU-64 dispenser in the Direct Airfield Attack Combined Munition. The warhead is 6.5 lb of HE, and the rocket driving the bomblet into its target is fired when its nose dips below 65 deg below the horizon.

BLU-108 Skeet: each submunition carries 4 Skeet self-forging fragment antitank bomblets, each with its own IR sensor. The

explosive fuze inside the bomblet accelerates the fragment to 9000 ft/sec.

It was reported in 1988 that 40,000 of the 120,000 Rockeye II in U.S. service are to be modernized. Their filling will be replaced by insensitive explosives, and the bomblet casings will be prefragmented. This program is being conducted by the Tactical Systems Division of ISC Technologies (now Ferranti International Signal).

◆ Weteye

Weteye is the unitary chemical bomb analogous to the Mk 80 series. Weteye is currently considered unacceptable for ship-board use because of the danger of leakage; hence the need for Bigeye (see above). As of early 1985, 888 Weteyes were held in U.S. Navy inventory, for use from shore bases. The U.S. Navy also had Cluster Bomb Mk 23, Padeye, which carried 15 gas bomblets, but it is not certain whether this weapon was ever produced in numbers.

AIRCRAFT GUNS

FRANCE

◆ DEFA 552A

Caliber: 30-mm/47 **Muzzle Velocity:** 815 m/sec [2674 ft/sec]
Rate of Fire: 1250 rnds/min **Ammunition Supply:** 125 rnds/gun
Weight: 81 kg [179 lb]

This gun arms the Super Étendard strike fighter (2 carried). Rated barrel lifetime is 5000 rnds. DEFA 552A is a revolver cannon descended from the World War II Mauser MG213C (as is the British Aden). The ammunition is the same as that of the Aden 30-mm cannon.

The revolver has 5 cartridge chambers. Two positions are for loading, one is the firing position, one is for ejection, and one is empty for safety. The gun is gas operated.

DEFA 552 is the production version of DEFA 551, development of which was completed in 1954. Work on a successor, DEFA 553, began in 1968, with first deliveries following in 1971. The rate of fire is increased to 1300 rnds/min, and the new barrel has a 5000-rnd lifetime. The major change is that ammunition can be fed from either side without modification, for easier installation. DEFA 552A, the version in the Super Étendard, incorporates the longer-life barrel and cylinder introduced in DEFA 553.

GERMANY (WEST)

◆ Mauser BK 27

Caliber: 27-mm/62.96
Muzzle Velocity: 1025 m/sec [3363 ft/sec]
Rate of Fire: 1700 or 1000 rnds/sec (other rates selectable)
Ammunition Supply: 180 rnds/gun (Tornado)
Weight: 100 kg [202.5 lb]

This gun arms German Tornado strike fighters. The status of a project to develop a 4-barrel CIWS version is uncertain. BK (Bordkanone) 27 is a gas-operated revolver cannon. Projectile types are AP, APHE, APHE-SD, HE-SD, TP, and TP-FP. Ammunition can be fed from either side. The high rate of fire is intended for air-to-air use, the lower rate for air-to-ground firing. The weapon is unusual in that, although the Tornado program was multinational, it did not use an existing standardized NATO round. It seems likely that the caliber was chosen specifically to achieve a very high muzzle velocity within the weight available.

BK 27 is also carried by German Alpha Jet close-air-support aircraft, by the Swedish Gripen fighter, and by other Tornados.

BK 27 is the latest derivative of the German Mauser MK 213 of World War II, an attempt to achieve higher rates of fire than were previously possible. A conventional gun suffers in 2 ways. First, it must wait through a cycle of recoil, cartridge ejection, reloading, and chambering between firings. Second, that cycle is prolonged because it involves a considerable mass moving back and forth, accelerating and stopping. These problems

worsen if the gun has to fire at high velocity, since the moving breechblock has to be quite massive. Thus, conventional, World War II—aircraft machine guns divided into 2 types: weapons firing relatively light projectiles at high cyclic rates, and others firing much more energetic projectiles at lower cyclic rates. MK 213 tried to combine the virtues of both, which the Germans considered necessary when firing at fast airplanes. The revolver attacks both problems. Each time the gun fires, the chamber in which firing occurs moves away and a loaded and prepared chamber comes into line with the barrel. Second, the cylinder revolves, so there is no start-and-stop motion. Moreover, since the cylinder ejection position is not in line with the breech, cartridges can be punched directly out the back of the gun, making for a simpler design that can be fed from either side.

MK 213 was conceived in 1942, and a prototype was completed that year, but it did not enter service as scheduled in January 1944; at the end of the war there were only 5 firing prototypes and 10 assembled guns. France captured the Mauser factory and developed the MK 213 into its DEFA 552 series. The British equivalent was the Aden gun, and the U.S. version was the M39 (used only by the air force).

A Gatling gun might be considered an extension of the revolver cannon in which each chamber of the revolver is furnished with its own barrel. The advantage is simplicity. Since no gas seal need be made between chamber and barrel, more of the total gas energy can be used for firing. However, the greater inertia of the Gatling limits the rate at which it can be run up to full firing rate, and the motion of the barrels introduces some inaccuracy (the barrel moves sideways while the bullet travels down it).

USSR

◆ GSh-23L

Caliber: 23-mm (0.44-lb projectile)
Muzzle Velocity: 890 m/sec [2920 ft/sec]
Rate of Fire: up to 3000 rnds/min
Ammunition Supply: 200 rnds **Weight:** approx 72 kg [160 lb]

The podded cannon of the Forger VTOL carrier fighter is a twin-barrel gun based on the Gast principle (first tried by the Germans during World War I): the 2 barrels, which are connected by a rocker arm, fire alternately.

The carrier-based Su-27 and MiG-29 are armed with GSh-30-1, which is presumably a new single-barrel 30-mm gun. Because of the need to achieve a high rate of fire, it is presumably a revolver weapon.

◆ NR-23/AM-23

Caliber: 23 mm (0.44-lb projectile)
Muzzle Velocity: 690 m/sec [2260 ft/sec]
Rate of Fire: 850 rnds/min
Weight: 39 kg [86.0 lb]

The twin-turreted NR-23s and AM-23s arm Soviet land-based naval bombers. Some aircraft also carry fixed forward-firing weapons with longer barrels; the data above apply to the short-barreled version. This gun was introduced in 1949. Many bombers (such as later Badgers) are armed with the improved AM-23, which weighs 43 kg [94.8 lb] and is capable of firing 1300 rnds/min. The Badger is typically armed with 7 cannons: a long weapon in the nose (PU-88 mount, with 100 rnds), a twin remote-controlled dorsal turret (DT-V7, 500 rnds, elevation limits +90°–3 deg), a twin remote-controlled ventral turret (DT-N7S, 700 rnds, 95-deg traverse either way, elevation limits +2°–90 deg), and a twin tail turret (DK-7, 1000 rnds, 70-deg traverse either way, elevation limits +60°–40 deg). The overall FCS, which is based on the old U.S. system developed for the B-29, is designated PVB-53C. The tail turret employs a PRS-1 (Argon) radar.

UNITED KINGDOM

◆ Aden Mk 5 Cannon

Caliber: 30-mm/47.8 (projectile approx 1.1 lb)

Muzzle Velocity: 790 m/sec [2590 ft/sec]
Rate of Fire: 1200–1400 rnds/min
Ammunition Supply: 150 rnds/gun **Weight:** 87 kg [192 lb]

A Sea Harrier shows its 30-mm Aden gun pods, as well as 2 Sidewinder air-to-air missiles. (British Aerospace)

Carried by Sea Harrier and AV-8A/8C fighters in a detachable 2-gun pallet, the Aden (Armament Design Establishment, manufactured at Enfield) is a gas-operated revolver cannon based on the World War II German Mauser MK 213 and is broadly comparable to the French DEFA 552. MK 213 existed in both 20- and 30-mm calibers, the French choosing the former and the British the latter. Work on the Aden gun began in September 1945. A formal Air Staff requirement was issued in March 1947, based on the MK 213/30 and its low-velocity (530 m/sec [1740 ft/sec]) ammunition (the 20-mm version used a much higher velocity round, 1050 m/sec [about 3400 ft/sec]). The German barrel was 43.3 calibers long, and its rate of fire was 1150 rnds/min (the 20-mm version was 80 calibers long, and it fired at 1200 rnds/min). After initially adopting the 30-mm caliber, the British then derived a 20-mm version from it (ADEN 30/20), but by July 1950, 30/20 development had been suspended in favor of the original 30-mm version. The gun was first flight tested in a Beaufighter in August 1951, and the low-velocity (LV) ammunition was approved for service in 1953. By that time, however, work was already proceeding on a high-velocity (HV) alternative, which was approved for service use (superseding the LV) in 1955. The LV attained a muzzle velocity of 603 m/sec, compared to 713 m/sec for HV [respectively, 1980 and 2340 ft/sec], both of which could be compared to 1215 m/sec [3985 ft/sec] for the 30/20.

Mk 4 was the main production version. Mk 5, which arms the Sea Harrier, is a modernized Mk 4 with an increased rate of fire (1500–1700 rnds/sec). Mk 3 armed the English Electric Lightning. Earlier Mk 3 and 4 guns are being modified to Mk 5 standard.

RAF Harrier GR.5s are armed with a 25-mm version first tested in the air in October 1985; as of 1986, the Royal Navy reportedly favored Aden 25 for the rebuilt Sea Harrier FRS.2. The argument in favor of Aden 25 was that the existing Aden 30 had reached a limit in rate of fire and muzzle velocity; Aden 25 is credited with 1650–1850 rnds/min and with 1050 m/sec. The new cartridge is longer and has a greater diameter, imposing greater stresses on the breech cylinder, which is made of stronger material to keep down overall dimensions and weight (the increase is about 5 kg). Given its higher rate of fire, a twin Aden 25 matches the rate of fire of the U.S. GAU-12/A Gatling gun. Total weight, including 200 rnds, is 430 kg.

UNITED STATES

◆ Mk 12

Caliber: 20-mm **Muzzle Velocity:** 3320 ft/sec
Rate of Fire: 1000–1200 rnds/min
Ammunition Supply: 144 rnds/gun

This Hispano-type weapon arms the U.S.-built F-8E(FN) Crusader interceptor of the French Navy. Unlike more recent U.S. guns, Mk 12 is gas operated. Performance in combat, in Vietnam, was somewhat disappointing, the gun showing wider dispersion (12 vs. 3 mils) than its predecessors and sometimes jamming during dogfights. Some writers claim that the Pontiac M39, the U.S. version of the wartime German revolver gun (see DEFA 552A and the Aden), arms the F-8E(FN). However, M39 was limited to air force fighters, and it seems unlikely that the F-8E(FN) could have been modified so radically as to take it in place of the navy Mk 12.

◆ M61A1

Caliber: 20-mm/62 **Muzzle Velocity:** 3400 ft/sec
Rate of Fire: 4000 or 6000 rnds/min
Ammunition Supply: 570 rnds
Weight: total 841 lb (gun 252 lb, feed system 270 lb, ammunition 319 lb)

M61A Vulcan as installed in an F-14 fighter. (*Principles of Naval Weapons Systems*, vol. 3, Annapolis: Weapons Systems Engineering Dept., U.S. Naval Academy, 1979)

Data apply to the gun as mounted in the F/A-18.

General Electric's 20-mm Gatling gun is mounted in the A-7E bomber and the F-14 and F/A-18 fighters. This gun is also the basis of the Phalanx close-in defensive weapon (see the Anti-aircraft Warfare section). This gun was originally developed for the air force F-105 fighter, replacing a similar but much less reliable T-171 gun used in the B-58 and F-104. The key improvement was a powered linkless feed. The rounds are stored, nose inward, inside a cylinder on what amounts to a large worm gear. As the gear rotates, they are fed into the feed chute. Current rated barrel life is 20,000 rnds.

In 1986 General Electric announced an improved version of the basic gun, its barrels 48.3 cm (24 calibers) longer, firing improved ammunition with a more compact propellant and a better bullet shape. The muzzle velocity would increase from 1030 to 1200 m/sec. Ammunition would be wrapped in aluminum, and the barrels would be wrapped in composites to reduce total system weight from the current 360 kg to 275 kg.

In 1988 General Electric introduced a reduced-weight version of the M61. Gun weight is reduced from 252 to 205 lb. The company also showed an improved (higher velocity, for shorter time of flight) ammunition (PGU-28/B SAPHEI). Its aluminum cartridge case saves 87 lb per 500 rnds loaded, and the gun has a linear linkless feed that reduces overall system weight. Muz-

zle velocity is 3440–3600 ft/sec, and rate of fire is up to 7200 rnds/min. Dispersion is 8 mils (2.2 mils normal radial dispersion).

The 30-mm GAU-8/A, used in both the A-10 ground-attack airplane and the Goalkeeper (and related) close-in shipboard weapons, is an enlarged version.

With the demise of the F-4 Phantom in U.S. Navy service, all U.S. carrier fighters incorporate built-in cannon. The only major airplane lacking such a gun, the Grumman A-6 Intruder, is apparently not well suited to carrying an external gun pod and, therefore, does not carry it. These pods are, therefore, no longer in U.S. Navy service and are not described here.

◆ GAU-12/U Equalizer

Caliber: 25-mm

Muzzle Velocity: 3500 ft/sec (HEI, TP; 3400 ft/sec AP)

Rate of Fire: 3600 rnds/min **Ammunition Supply:** 300 rnds

Weight: total 900 lb empty, 1230 lb loaded (280-lb gun)

The GAU-12 gun of an AV-8B Harrier II. (General Electric)

General Electric's 25-mm 5-barrel Gatling gun was developed specially for the AV-8B Harrier II attack fighter. This gun incorporates GAU-8/A (30-mm) technology. The gun is in the left-hand pod, and the ammunition on the right. The rounds are moved along a fixed track by a continuous-loop driving chain. The gun takes 0.4 sec to reach its firing rate. Rated barrel life is 15,000 rnds (20,000 rnds MTBF), and dispersion is 1.4 mil.

◆ M197

Caliber: 20-mm **Muzzle Velocity:** 3400 ft/sec

Rate of Fire: 750 or 1500 rnds/min (selectable)

Ammunition Supply: 750 rnds **Weight:** 145 lb

The armament of the Marine Corps AH-1T attack helicopter, M197 is a 3-barreled version of the M61. M197 is mounted in a turret, which has also been suggested as a patrol-boat weapon, and the Japanese Maritime Self-Defense Force uses this weapon as a pedestal-mounted gun.

◆ GECAL-50

Caliber: 0.50-caliber (12.7-mm) **Muzzle Velocity:** 2900 ft/sec

Rate of Fire: up to 4000 rnds/min (3 barrels); up to 8000 rnds/min (6 barrels). In the V-22, the gun is to fire at the rate of 2000 rnds/min. **Ammunition Supply:** 1200 rnds

Weight: 3 barrels 66 lb, 6 barrels 96 lb

GECAL-50 is General Electric's 0.50-caliber Gatling gun. Work began in 1982, and it was pushed harder after the loss of 9 helicopters in Grenada in 1983 showed that the existing 7.62-mm Minigun was not powerful enough. For a time this weapon was projected for the VS-22 tilt-rotor. Late in 1984 it was eliminated from the basic design, although it was later reinstated as an option. Special forces showed a limited interest in the project. GE has now found a partner, Astra Defence Systems of the United Kingdom. Astra is to pursue the naval market,

GE the helicopter market. A pedestal-mounted naval version was displayed at the RNEE show in the fall of 1989. It had a 750-rnd box magazine and was rated at 1000–2000 rnds/min continuous rate of fire for 3 barrels (4000 for 6).

COAST-DEFENSE GUNS

FRANCE

◆ GPFM-3 (155-mm)

Sixteen of these guns have constituted the Chilean coast defenses since well before World War II. GPF means *grande puissance Fillioux* (Fillioux high powered); the gun used a special wide-traverse carriage. Presumably, M-3 indicated a naval (*marine*) mount; this was not an official French army designation. The first GPFs were delivered in August 1917, and this weapon was adopted by the U.S. Army in 1918. In 1940 a derivative was the sole modern French heavy artillery piece. The U.S. "long Tom" 155-mm gun was developed from this weapon. The GPF gun was 38 calibers long and fired a 95-lb shell at 735 m/sec [2411 ft/sec] to a range of 18,600 m [20,300 yd].

FINLAND

◆ 130-mm

This weapon is a locally produced (Tampella) gun, in a turret emplacement, that replaces older 152-mm guns. Range is +25 km; it can fire 6 rnds/min and is remotely aimed (with manual backup). Training rate is 200 mrad/sec (approx. 0.11 deg/sec). Ammunition is of the separate type (12-kg shell, 33-kg cartridge, the latter power-loaded). The normal crew is 9, but the gun can be handled by 3 in an emergency. The standard light coastal weapon is a 100-mm gun derived from that of the Soviet T-55 tank, and there are also towed Soviet-supplied K54 130-mm guns. Finland also still uses some 152-mm guns in splinter shields, as well as 254-mm (presumably Bofors) weapons.

There are 6 readiness forts, 9 manned training forts, about 30 guarded forts, and 11 training units, all organized in 5 military districts. These numbers may be somewhat deceptive, in that many of the forts are probably quite small. The annual intake, in 1989, was 2300 conscripts, with about 3000 reservists being given refresher training that year. The organization consists of a mobile battalion in Vasa and 2 fixed battalions. Coastal artillery is administered by the army.

The fire-control system is RAVAL, a Finnish acronym meaning coastal-artillery automatic-surveillance fire-computing system; it is probably a BEAB system (see the entry for Sweden). Each computer serves up to 16 guns, taking into account local conditions as well as the position of that gun. The system can control fixed and mobile guns as well as missiles. There are 2 sets of software, 1 for surveillance and 1 for fire control. Each center contains 3 consoles and, thus, can engage 3 targets simultaneously. The system as a whole uses radar, laser range-finders, and optical range-finders.

GERMANY (WEST)

◆ 150-mm

Denmark, Norway, and Portugal use 150-mm guns, presumably of German manufacture. During World War II the Germans used a 150-mm/40 for coast defense, firing a 40-kg (88-lb) shell at 800 m/sec [2625 ft/sec] to a maximum range of 14,300 m [15,640 yd]. This weapon presumably survived postwar.

The Danish weapons are 15-cm SKC/28 guns from the battleship *Gneisenau*, in 2 twin turrets, plus 6 single SKL/45s manufactured specifically for coast defense. Both types fire 45.3-kg (99.8-lb) shells to a range of 23,500 m [25,700 yd]. Denmark also has a few ex-U.S. 3-in/50 naval guns in coastal mountings.

◆ 127-mm

Norway uses a 127-mm coast-defense gun, presumably an ex-German destroyer weapon. The German gun was a 127-mm/45,

firing a 28-kg [61.7-lb] shell at 830 m/sec [2723 ft/sec], to a maximum range of 17,400 m [19,030 yd].

◆ 105-mm

Now in Norwegian service, this gun is presumably the standard German 105-mm/65 antiaircraft gun, firing a 15-kg [33.3-lb] shell at 900 m/sec [2953 ft/sec] to a maximum range of 17,700 m [19,360 yd]. The Germans also used a variety of older lower-velocity 105-mm guns during World War II.

◆ 88-mm

Possibly Albania and Yugoslavia still use the old German 88-mm/56 gun in coast defenses, in fixed emplacements. It fires a 44-kg [97-lb] HE shell at a muzzle velocity of 820 m/sec [2690 ft/sec], to a maximum range of 14,860 m [16,250 yd].

SWEDEN

BEAB (formerly PEAB) supplies the electronic elements of Swedish coast defense, some of which have been supplied abroad:

Kondor (9KR 400) is the coastal-surveillance radar, based on the 9GR 600 X-band fast-tuned magnetron and the 9GA 205 antenna. It uses 2 of the same operator displays as STINA (see the Surveillance and Control section) and can be fixed or mobile. This is an ADT radar. This radar can be supplemented by a helicopter-borne 9HCI 200 standoff surveillance radar.

Kaskad is the local (battalion level) command center, using a 23-in color PPI and communicating with Kastell, Kardinal, or Karat battery-level control systems.

Kastell (9KA400)/Kardinal (9KA500) is the coastal TWS fire-control radar, capable of engaging 3 targets simultaneously. It operates in X- or in Ku-band. 9KA500 is the mobile version. See the 9GR series in the radar part of the Antiaircraft Warfare section for electronic details. Kastell/Kardinal can include optronic sensors.

Karat (9KM 400) is an integrated missile-launch and combat-control system, carried on a truck and including an X-band radar and optional optronic sensors. A typical battery might consist of 2 launch vehicles carrying Penguin Mk 2 missiles.

Kolibri (9KA 50)/Kobra (9KA 100) are optronic gun fire-control sensors using paired binoculars and a laser. An image intensifier (starlight scope) and a FLIR are optional. Azimuth and laser range are fed directly into a fire-control computer. Kolibri is a lightweight version for amphibious assault units. Kobra has a higher-powered laser range-finder and a computer-controlled azimuth servo for extra accuracy (presumably in rate-aided target tracking).

Klara (9KM 100) is a missile-firing analysis and launch-control system, displaying a tactical situation as seen at higher-echelon levels so that long-range missiles can be fired without relying on local sensors. It can also be used to integrate data from coastal-surveillance radars, naval vessels, and helicopters. In its brochure for these systems, PEAB mentions RBS 15 as a specific case of a long-range defensive missile that need not be based near the coast, i.e., near both its search sensors and enemy threats.

BEAB manufactures a combined automatic gun sight and ballistic computer, MARIA, for its mobile coastal guns (listed below). MARIA automatically compensates as the gun digs into the ground after each round.

◆ Bofors 254-mm Gun

This prewar weapon may survive in Finnish service; the gun was originally built for 2 Finnish coast-defense ships. This 10-in/45 fires a 225-kg [496-lb] shell at 850 m/sec [2790 ft/sec] to a maximum range of 30,300 m [33,140 yd].

◆ Bofors 155-mm L39 (CD77)

This mobile gun, developed specially for export, uses many

Karin (see below) components. Total weight is 12 tons, and elevation limits are $+70/-3$ deg. Rate of fire is 10 rnds/min. Muzzle velocity (range): 827 m/sec (HEER round: 41.65 kg, 30,000 m or HE round: 42.6 kg, 24,000 m) or 700 m/sec (HCER round: 53 kg, 30,000 m). The HCER is probably the gun bought by Finland.

Sweden still uses 152-mm and 210-mm coast-defense guns, presumably prewar Bofors naval weapons.

◆ Bofors ERSTA 120-mm/62

This fixed coast-defense gun, developed about 1970, had by 1987 replaced about half the Swedish heavy coast-defense weapons, the remainder dating from the 1950s. Maximum elevation is 50 deg (limits $+50/-3$ deg), to achieve maximum range. Rate of fire is 25 rnds/min (200 rnds in 20 min). The gun barrel is water-cooled. Total weight: 70.5 tons plus 103.5 tons of concrete. Muzzle velocity (projectile weight, range): 880 m/sec (HE: 24.6 kg, 24,000 m; HCER: 26 kg, 34,000 m). The shells are similar to those fired by the Karin gun (see below), but the cartridges are larger.

This weapon is used by the Swedish Navy and in 1980 was ordered by Norway (delivered 1987). Norway is installing these guns in 3 new fortifications, at Andfjord (in service 1989), Vestfjord (1990), and Trondheimfjord (1991).

A modern coast-defense weapon: The ERSTA 120-mm gun as emplaced in Norway. (*Ships of the World*)

◆ Bofors Karin 120-mm L55 (CD80)

This mobile gun was first delivered in 1978 and has many elements in common with ERSTA. Karin has the same carriage as the FH77 155-mm field gun.

Typically, there are 4 guns/battery, and they can be towed by road at 70 km/hr. When the guns are emplaced, their arc of fire is 60 deg. Each gun has its own computer. Elevation limits: $+50/-3$ deg. Rate of fire: 15 rnds/min. Muzzle velocity (range): 790 m/sec (HE: 24.6 kg, 21,000 m) or 830 m/sec (HCER: 26 kg, 30,000 m).

◆ Bofors 75-mm L60

This weapon is a turreted gun, actually a 76/62, developed about 1960 for the Swedish Navy and exported to Norway and, prob-

ably, other customers. Elevation has been limited to 20 deg (limits are +20/-5 deg) to minimize the opening in the turret (range is limited to 11,400-16,000 m). Rate of fire is 25 rnds/min. Muzzle velocity is 870 m/sec (range 12,000 m) for the 5.52-kg HE round, and 890 m/sec for the HCER round (6.4 kg, 16,000 m). Total weight is 17.5 tons.

Sweden also uses a mobile form of this gun, on a 4-wheel towed carriage. It has a total of 12 mobile and 53 fixed coast-defense batteries (including missile units).

USSR

◆ 305-mm

The Soviets used both their new 305-mm/56 and their old (dreadnought-type) 305-mm/52 for coast defenses during World War II and planned to emplace 12 batteries of the new guns and 8 batteries of the older ones (four 4-gun in the Baltic, two 4-gun in the Black Sea, and two 5-gun in the Far East). Many of these weapons must have been destroyed, but some reportedly survive in active service, perhaps in the Northern Fleet. The 305-mm/56, which was designed for the abortive battle cruisers, fired a 480-kg [1058-lb] shell to 43,900 m [48,000 yd], probably at about 850 m/sec [2789 ft/sec]. The older 305-mm/52 fired a 470.9-kg [1038-lb] AP shell at 762 m/sec [2500 ft/sec] to a maximum range of 24,620 m [26,925 yd]. In at least one case, the 305/52s were emplaced in a triple turret taken from a battleship.

◆ 152-mm

These guns are in Soviet, Bulgarian, East German, Romanian, and possibly Finnish service. These guns are mounted in the *Sverdlov* class, and some were mounted in Soviet coast-defense batteries during World War II. In coastal service the 152-mm fired a 55-kg [121-lb] AP shell to 29,000 m [31,700 yd], probably at a muzzle velocity of about 885 m/sec [2900 ft/sec].

◆ 130-mm SM-4-1

This gun has been very widely adopted; reported export users are Angola, Bulgaria, Egypt, North Korea, Poland, Romania, South Yemen, Syria, and Yugoslavia. The Israelis captured some when they took Sharm el Sheikh in 1967. In addition, Soviet-type 130-mm guns (presumably of earlier type) arm Chinese (PRC), Cuban, and Finnish coast defenses. Performance approximates that of the 130-mm/58 naval gun, probably with a maximum range of about 29,500 m. Maximum elevation is 45 deg. The APHE shell weighs 33.6 kg and is fired at a velocity of 1050 m/sec. Rate of fire is 5 rnds/min. The gun is mounted on a 4-wheel carriage (with removable axles) with a nearly vertical shield. This weapon does not fire the ammunition of the 130-mm M-46 field gun or the 130-mm KS-30 antiaircraft gun. The associated radar is ZALP-B (Long Bow).

Soviet client states first adopted 130-mm coastal guns in the early 1960s, at a time when the U.S. Navy was eliminating its heavy shipboard guns. The remaining 5-in guns were outranged by the new 130s, and the abortive lightweight 8-in gun program was begun as a counter to this new Soviet-bloc capability.

◆ Other Soviet Guns

122-mm guns are in Cuban, Finnish, North Korean, and possibly Yugoslav service. Finland uses T-55 (100-mm) turrets embedded in concrete and controlled from a blockhouse. Maximum range is about 15 km. Older 100-mm guns are in Bulgarian and Chinese (PRC) service. Finally, the 85-mm gun is in Yugoslav service, and also (presumably copied) in Chinese (PRC).

UNITED KINGDOM

◆ 15-in/45

Vickers Model 1926 is still in service in Spain. The AP shell weighs 859.65 kg [1895 lb], and the HE shell 801.84 kg [1767 lb]; muzzle velocity is 2500 ft/sec (AP shell), and range is 35,100 m [38,400 yd]. Guns are mounted singly, in armored gun houses. There are 12 or 16 mounts in Groupos of 4 (2 batteries

per Grupo). (Probably 7 are operational.) The associated fire-control system is the Swedish 9KA 410 built in Spain.

Spain will keep the 15-in gun in service until it is replaced by a coastal missile in the late 1990s.

◆ 12-in/50

Spain retains 14 Vickers 12-in/50 guns, some of them originally built for its dreadnoughts, some specially built. The gun fires an 850-lb AP shell at 3010 ft/sec.

◆ 9.2-in

This gun is in Portuguese and Turkish service. When Britain and Canada gave up their coast defenses in 1956, they transferred their weapons to the NATO Southern Tier nations, primarily Portugal and Turkey. The standard 9.2-in/47 fired a 380-lb HE shell at 2700 ft/sec, to a maximum range of 36,700 yd.

◆ 8-in

Spain retains 24 British-supplied 8-in coast-defense guns. It is alone in using this caliber. These weapons are probably Vickers 8-in/50 cruiser guns similar to those in the former Spanish heavy cruisers; the guns fire a 256-lb AP shell at 2725 ft/sec to a maximum range of 29,200 yd.

◆ 6-in/50

Vickers 6-in/50 guns, installed in 1915-25, remain in Spanish service, in both single and twin mounts; up to 113 may be operational. Maximum range is 21,600 m. There have been proposals to replace the gun tube with that of the Spanish 155-mm/39 howitzer, which fires standard NATO rounds. The 155-mm coast-defense gun would have a range of 22,500-24,000 m (30,000 m with enhanced-range ammunition) and fire 2 rnds/min (4 rnds/min in a burst).

Brazil and Paraguay use a 6-in Vickers Mk V. Portugal also uses 6-in guns, presumably also of Vickers type.

◆ 3.7-in AA

This gun, the British equivalent of the German World War II 88-mm, is used by Portugal in a coastal role. The original specification was drawn up in 1928, and the gun was placed in production in 1937 (first delivery was January 1938). A longer (65-caliber) 3.7-in gun in a 4.5-in jacket was introduced in 1943 as Mk 6, for use in static mountings; this may be the Portuguese weapon. The original 3.7-in/50 fired a 25-lb shell at 2600 ft/sec to a maximum range of 20,600 yd; maximum ceiling was 41,000 ft (effective ceiling, with contemporary fire control, was 32,000 ft). Mk 6 had a muzzle velocity of 3425 ft/sec, a maximum range of 25,600 yd, and a ceiling of 59,300 ft (effective ceiling, with contemporary fire control, was 45,000 ft).

◆ 6-Pounder

This World War II twin anti-motor-torpedo-boat weapon is used by Portugal in a coastal role. The original specification, for a twin automatic weapon (40 rnds/min/barrel), was drawn in 1925; the first 2 guns were tested in 1928, and the first mounting was delivered in 1934. The gun remained in British service until 1956. The guns were 57-mm/47s, firing 60 rnds/gun/min (6.25-lb HE shell, 2360 ft/sec). Maximum range was 5150 yd.

UNITED STATES

◆ 12-in/45

At least four 12-in Mk V Mod 9 guns were transferred to Brazil about 1945-46. These were originally U.S. Navy guns transferred to the army after the Washington Treaty scrapplings in 1923-24. Others were obtained in 1941-42. These were among the most modern army coastal guns at the time, and work on a new gun carriage began early in World War II, at Watertown Arsenal. The prototype (T 1) was completed only in 1945, and the pilot Brazilian gun shipped in 1945. This was the culmination of negotiations with Brazil begun about 1938. The gun was in an open mount, and elevation/depression limits were

+47/-8 deg. It fired an 870-lb shell with 310 lb of powder, and muzzle velocity was 2700 ft/sec, for a maximum range of 30,000 yd.

These guns may still be in service.

When the U.S. coast defenses were disbanded in 1948-49, some 6-in guns were retained for possible transfer to Norway, Portugal, and Turkey, but they were never shipped abroad. The only other heavy U.S. guns transferred abroad were about eight 10-in and eight 8-in to Canada in 1940-41, and 7-in guns to the Netherlands East Indies at about the same time. None of these weapons survive.

BOMBARDMENT ROCKETS

CHINA

◆ 122-mm Rocket Launcher

At the Paris Air Show in 1989 NORINCO announced a navalized 122-mm rocket launcher, designed for remote operation, and manually loaded with 40 rockets (10 × 4), each weighing 66.6 kg with an 18.4-kg warhead [146.8/40.6 lb], range 40 km [21.9 nm]. The launcher elevates to 60 deg and trains over a 240-deg arc. It can be fired in 17.5-21.5 sec. There was no indication of the state of its development.

ITALY

◆ Breda 81-mm Multiple Launcher

This multiple rocket system carries 36 rnds; elevation limits are +55/-2 deg, and training/elevating speeds are 60/30 deg/sec. Weights: empty, 1270 kg [2799 lb]; loaded, about 1980 kg [4364 lb], depending on rocket type. Trunnion height is 2.15 m, and working circle radius is 1.49 m [84.6 and 58.7 in].

The Oerlikon 81-mm SNORA folding-fin rocket fired by the Breda launcher weighs 19.7 kg and has a maximum range of

about 10 km; maximum speed is 520 m/sec [43.4 lb, 11,000 yd, 1706 ft/sec].

USSR

◆ BM 14/17 and BM 14/18

BM 14/17 is a 17-barrel 140-mm (5.5-in) army-type rocket that entered service in 1954. The 70-lb rocket has a maximum range of 4.8 nm. The designation has been applied by NATO.

BM 14/18 is a 140-mm rocket launcher specially designed for naval service, on board all *Polnocny*-class amphibious ships. This launcher fires the same rocket as BM 14/17.

Maximum elevation of the manually reloaded BM 14/18 is about 50 deg. Reloading takes about 4-5 min. Rockets are ripple fired at 1-sec intervals. Speed is about 400 m/sec [1310 ft/sec], and maximum range is about 10,000 yd.

The 17-rocket launcher is a lighter-weight version for river patrol boats such as the "Shmel" class; extra rockets are stowed in 2 crates abaft the launcher.

◆ BM 21

This 40-barrel 122-mm rocket launcher (101 lb, range 8 nm) is found on board some amphibious ships. It is automatically reloaded: the launcher carries 2 clusters of 20 tubes, empty sets being discarded and replaced from below. The rockets carry a 19.2-kg fragmentation warhead.

A 40-rocket BM 21 has been the standard Soviet army rocket launcher since the mid-1960s. The naval system is 2 half-launchers carried on a specially designed mounting. The rockets are 2.8 m long and weigh about 140 lb each; range is about 23,000 yd.

Shmel-class monitors can carry an 8-barreled 122-mm launcher. The *Pomornik* class LCAC carries 2 × 22-tube 122-mm rocket launchers. They retract into its side walls and reload below decks.

BM 14/18 rocket launchers forward on board a *Polnocny*-class landing ship. The radar is Drum Tilt, controlling a twin 30-mm gun at the after end of the superstructure. (U.S. Navy)

Soviet 122-mm barrage rocket launcher, showing its two 20-rocket clusters.

UNITED STATES

◆ ABRS/ATACMS

The army's bombardment systems were proposed to support the current Marine Corps OTH assault concept, which requires fire support from 50–60 nm. In October 1990 the Senate approved an amendment to the FY91 defense bill, calling for the navy to evaluate the LTV ABRS (assault ballistic rocket system), an unguided-rocket system already in NATO service. LTV has been trying to sell it to the navy for some years, and for several years there have been congressional calls for studies of dedicated landing fire-support ships or systems. These proposals generally die because the problem in really long range fire support is forward observation; finding and designating the targets cost far too much per target. Moreover, none of the proposed missile systems can provide the required volume of fire at a reasonable cost in terms of money or ship's volume and weight. The idea is not new: in the mid-1960s the navy considered a variety of landing fire-support weapons, including an adapted Lance missile, which could have been fired from the Terrier launchers of first-generation missile cruisers, then becoming obsolete.

In army service, ABRS weapons are fired from multiple launchers (MLRS). Each rocket carries 644 antipersonnel/anti-vehicle submunitions. ATACMS is a new longer-range (130-km) weapon (formerly Assault Breaker), offered as an alternative.

AIRBORNE ECM

Airborne EW systems divide into reconnaissance (ELINT and, to a lesser degree, ESM), targeting (ESM), standoff or escort jamming, and self-protection (also called defensive ECM, or DECM). Radar-warning receivers (RWR) are the major form of defensive ESM, the receivers being used to initiate chaff launching.

The distinction between RWRs and more elaborate forms of ESM is gradually fading; future systems are likely to provide a pilot (or, more importantly, an aircraft CDS) with detailed threat information. At present, the distinction is mainly in the degree of information provided. An RWR generally uses 4 antennas and does little in the way of comparison between their outputs. It provides little more than the quadrant in which the threat is detected. Similarly, it generally uses a crystal video receiver, so it obtains little threat-signal detail.

An early Vietnam-era RWR used 4 cavity-backed spirals; its output was distinguished by band. Video was passed to a processor measuring pulse train parameters and frequency ranges to determine the radar type. Directional signals, typically on a 3-in CRT, showed signal power vs. bearing. These RWRs could detect only the main lobe of a radar and, thus, could have no electronic intelligence capability. Wartime development effort was concentrated on the detection and identification of new types of radars (and new operating modes), and on improved displays. Digital RWRs developed (but not deployed) by 1975 had a single display showing both radar identification and relative location (using alphanumeric characters on a CRT). They could be reprogrammed for new threat types and could handle more signals simultaneously. However, location and frequency data were still crude.

The next step is better signal characterization, as in the U.S. ALR-67ASR. It is easier to achieve than better target location since it does not require installation of new (and, inevitably, larger) antennas. The new capability is bought by replacing older solid-state technology.

Beyond that is the integration of the RWR and targeting ESM. The A-12 may be the first such case, as stealthy operation makes fully passive target detection very attractive. In theory, because an airplane is a moving platform, a very accurate ESM device combined with very accurate inertial navigation should suffice for fully passive targeting of nonemitting weapons.

CHILE

◆ ITATA

This air electronic intelligence system is manufactured for the Chilean Air Force by ENAER (Empresa Nacional de Aeronautica) and is also probably used by the Chilean Navy. ITATA was first displayed at the FIDA show in 1984. Production began in 1986, and the system was installed in a Learjet 35-A in 1987. It has also been installed in Beech 99, Gardian Falcon 20, and EMB-111N aircraft; as of 1989 about 10 had been manufactured.

Frequency coverage is 3 MHz–18 GHz in 6 bands; it can scan either the entire range or any selected band or bands within it. Antennas cover 360 deg. ITATA is a microprocessor-controlled, superheterodyne system with a pulse analyzer, using a servoed dish antenna (under the fuselage) for accurate direction finding. Targets are located by triangulation as the airplane moves. Output: angle of arrival, bearing to emitter, threat type and classification. ITATA can measure PRFs of 0.092–12.83 kHz and pulse widths of 0.05–24 microsec (resolution 0.05 microsec). It analyzes PRF and pulse-width jitter. The dish beam is 8 deg wide in S-band, 1.8 deg wide in Ku-band (beamwidth resolution is within 0.2 deg). Signal amplitude is displayed in dB steps, and the system can blank out signals below a predetermined threshold. ITATA also examines the emitter antenna's rotation rate. Data are displayed on a CRT (selected signals can be strobed), and detailed parameters are shown on digital (LED) displays. Outputs can be recorded in digital form. There are 2 operators. Selected received signals can be heard as an audio tone by the DF operator. The DF module can use either crystal or superheterodyne demodulation for either broad sweep or high sensitivity, as required. Operation is manual or semiautomatic, the system locking onto a signal of interest and then analyzing it. Compared to contemporary U.S. and European ELINT equipment, ITATA is relatively bulky, but it is an indigenous development suggesting the sort of equipment that Third World manufacturers can currently produce.

FRANCE

◆ ARAR-10B/ARAX-10B

Thomson-CSF's ESM system for Atlantic 1 and Nimrod patrol aircraft covers 2.3–11.1 GHz. The antennas are on top of the tail fin. This system gives data on pulse width, PRF, beam width, and scan rate. ARAX-10B is the associated frequency-measurement device.

◆ ARAR-13A

This ESM system for the Atlantique Mk 2 maritime-patrol aircraft is similar to the Thomson-CSF Dalia 500 and to the shipboard ARBR 17. The antennas are in wingtip pods and in the tip of the vertical tail, for high DF accuracy and reduced interference with (and from) other aircraft systems. Bandwidth is greater than that of the Atlantic Mk 1 system.

ARAR 13 was designed specifically for antiship, as opposed to ASW, operation. Detection is automatic, and the system incorporates an IFM. Signals are analyzed, classified, and tracked; ARAR 13A incorporates a 2000-mode threat library. Radar signals are detected on 1 scan, and the system provides automatic threat warning. Signals are displayed on a panoramic 3-color screen (bearing vs. frequency) and on alfa display (analysis, ID data). Signal data are also automatically recorded for later analysis. Computer-integrated ECM is available as an option.

The first preproduction units were delivered in November 1986.

◆ BF

This Thomson-CSF RWR is for Super Étendard and other tactical aircraft, including helicopters. It employs 4 broad-band antennas (2 spirals flush with the aircraft sides, and 2 cones for fore and aft reception) and a video unit. It can detect and recognize pulse (600–12,000 pps), CW, and ICW signals and provides an audio and visual alarm. Signal direction is indicated by 4 lamps. Total weight is 9.2 kg.

◆ Caiman

This Thomson-CSF noise/deception support jammer is used on French Mirage F1 air force fighters and has been exported for users of French fighter-attack aircraft such as the Mirage 2000 and the Jaguar. Thus it may well be used in support of antiship attacks. The pod carries 2 jammers, each with its own receiver, and receiver antennas at each end. Each transmitter provides 250 W at 10 GHz and 1 kW at 1 GHz. The jamming bandwidth must be preprogrammed before flight. There are 3 operating modes: manual (the pilot selects 1 of 3 preset frequencies), semi-automatic (a signal indicates which transmission is being received), and automatic (the jammer is activated by a transmission). The jammer is driven by ram air.

Caiman was developed from the earlier Alligator.

◆ DR-2000/3000A/4000

These ESM systems are also used on board ships. Dalia (DR-2000) is a manual frequency-measuring system operating in the D- through J-bands. Applications include the Embraer EMB-111 (with 6 D/F and 1 omnidirectional frequency-measuring antenna) and German Navy Sea Kings.

The commercial designation for DR-2000 (when combined with an ARIAL 15 analyzer) is TMV 026. ARIAL is an acronym for *analyze radar pour identification et alerte*; the number indicates the size of its library, 15 emitters. Alternatively, it can be combined with Dalia 500 or 1000. A new DR-2000 Mk II is reported in production for EMB-III's and Sea Kings.

DR 3000 is a heavier (50 kg), fully automatic system for maritime-reconnaissance aircraft. It covers the D- through K-bands and has a direction-finding accuracy of about 6 deg.

DR 4000, which is also carried by frigates, is intended for large maritime-patrol aircraft. It uses 12 direction-finding antennas (DR 2000 uses 6). The commercial designation is TMV 202.

◆ Remora/Barem

Remora is a Thomson-CSF jammer pod, carried by Super Étendard and Mirage aircraft. There are 2 types, DB-3141 for low-band and DB-3163 for high-band threats. DB-3141 is 0.25 × 3.5 m (175 kg) and covers the H- through I-bands. Its pod carries a single receiver and fore and aft transmitters (TWTs). A look-through receiver cuts off jamming when the target radar ceases to transmit. The high-band pod (0.254 × 3.52 m, 175 kg) deals with both pulse and CW (illumination guidance) radars; it has

The Barem self-protection ECM pod. (Thomson-CSF)

a superheterodyne receiver with antennas at both ends. The pilot chooses among 6 preprogrammed frequencies, and the pod can jam 3 threats simultaneously by electronic switching (time-sharing). Threat data are stored digitally.

Barem (TMV 015) is a developed version, a reprogrammable pod with modular software and a superheterodyne receiver. It can be repackaged for internal installation. Threats are identified by comparison with a stored library and jammed using signals matched to the intercepted signals, all within 1 sec of reception. The pod can jam 2 threats at the same time (front or rear), and it records jammed parameters. Dimensions are 16 cm × 3.45 m (85 kg).

◆ Serval/Sherloc

These are Thomson-CSF RWRs for tactical aircraft, covering, respectively, the 2.5–11 and 2–18 GHz ranges. Sherloc can be extended to cover 1–40 GHz and can be integrated with a Thomson-CSF laser warner. Both systems employ sets of 4 antennas (wingtips and vertical fin). They display the direction of a received signal and estimate its threat level by identifying it in a look-up table. Sherloc employs crystal video receivers and a high-speed hybrid processor; its library contains 100 radar modes. It can display 8 threats simultaneously. Threats generate both an aural warning and (in Sherloc only) a synthetic voice message.

Thomson-CSF offers a combination system, MSDS (Barem and Sherloc), for combined crystal video and superheterodyne reception for more accurate signal identification. There is also a shipboard version of Sherloc, Shiploc.

◆ Spectra

The integrated EW suite for the new Rafale fighter is being developed by a consortium led by Thomson-CSF (with Dassault Electronique and Matra). Spectra's antennas are electronically steered, and it incorporates digital RF memories, VHSIC, and artificial intelligence for threat recognition and response. The device's technology is MMIC on GaAs substrate. The overall system's weight is less than 180 kg. Spectra is intended for direct integration with other combat-system elements, i.e., as part of the new generation in which RWR evolves toward ESM.

◆ SPIRALE

Matra's *Système de Protection Infrarouge et Radar avec Alerte et Leurage* is for the Mirage 2000 and other fighters. Presumably, it is also planned for the Super Étendard since Matra lists the associated Corail decoy dispenser as a Super Étendard system. SPIRALE detects both missile launches and missiles in flight using DDMs (*Detecteurs de Départ Missile*, i.e., launch detectors) and IR warning receivers in the backs of the Magic (AAM) launchers. The DDM, which is made by SAT, is an IR signal processor. The system is tied together by a pair of processors, 1 analog and 1 digital, and it includes 2 chaff-dispensing tubes in each wing root and 2 IR cartridge dispensers in the fuselage near the bottom of the tail pipe. Deliveries began in

1987 for several air forces (presumably including the only foreign operators of the Super Étendard, Argentina and Iraq).

◆ Syrel

Thomson-CSF's pod-mounted electronic reconnaissance pod is used on board French Air Force Mirage FIs and Mirage 2000s; it is presumably also applicable to French Navy Super Étendards. Dimensions are 0.42 × 3.57 m (265 kg). The pod carries antennas forward and aft.

◆ Expendables

The current standard Phimat chaff dispenser pod is 108 mm × 3.6 m (105 kg); it is also used by the French Air Force and by the RAF. Three expendable airborne jammers are under development, 2 by Thomson-CSF and 1 by ESD (CAMEL, *Cartridge Active Miniature Électromagnétique Expendable*). Of the 2 Thomson-CSF decoys, 1 is a self-protection device, fitting in a flare container, covering the C- through Ku-bands (ERP about 10 W); it has a delta wing and relatively long endurance to provide a realistic target for doppler radars. The other is an offensive (penetration) device, operating over the L- through S-bands, with about 20-min endurance.

Super Étendards carry Alkan Type 5020 chaff dispensers containing 7 modules, on a special hard point. There are 2 cartridge lengths, 150 mm (40-mm-diameter chaff cartridge, 60-mm-diameter IR cartridge, or 59 × 17-mm cartridge) and 8 in (1 × 1 in square or 1 × 2 in rectangular). The standard modular magazine carries eighteen 40-mm chaff cartridges or eight 60-mm IR cartridges or twenty-four 1-in²-section cartridges, or twelve 1 × 2-in rectangular-section cartridges. Each type of module carries an identifying chip that communicates with the decoy system. Firing sequences are chosen either automatically (by the threat-detection system) or manually (among 9 alternatives).

A Phimat chaff-dispenser pod carried by a French Navy Super Étendard. (Matra)

◆ Camel

Dassault Electronique's active expendable decoy works against pulse-doppler and monopulse radars as well as active/semi-active seekers. It is intended to fit current dispensers.

◆ CORAIL

CORAIL (*Contre-mesures Optronique et Radar Intégré par Leurage*) is a Matra pod or conformal gondola carrying 56 or 112 decoy cartridges (IR, radar, or electro-optical), for the Super Étendard and other fighters, complementing their internal SPIRALE systems. Matra also proposes it for heavy aircraft, such as the Atlantique 2. CORAIL operates in manual, automatic, semiautomatic, emergency, and navigation (presumably target marker) modes.

GERMANY

◆ Cerberus/TSPJ

The Telefunken Cerberus II (1980) and III (1985) are the standard countermeasures pods of German Tornado strike aircraft, carried on outer wing stations. Cerberus has reportedly encountered technical problems; Israeli RF subsystems are being fitted. Cerberus itself was derived from the Israeli EL/L-8202. In 1990 it was suggested that the latter had been derived from Loral's Rapport (ALQ-178) system, reportedly supplied to Israel on board F-16 fighters. Rapport is unusual because of its distributed architecture, which combines warning, jamming, and decoy launch in a single internal system. Signals are processed (and the system is controlled) by a central programmable computer; separate microprocessors are responsible for RWR, display, and jamming. Typically, separate fore and aft jammers are used.

TSPJ is the latest version of Cerberus for Tornados. It has a high output, with power management, and can operate in high pulse densities. Fully programmable, it works either autonomously or under ERWE control.

◆ ERWE II

This digital, hybrid, threat-warning system (C/D- and E-J-bands) was codeveloped by Litton and TST for the Tornado. ERWE II controls Cerberus/TSPJ.

◆ FL1800H

See FL1800S in the Antiaircraft Warfare section.

◆ ISRAEL

Apart from the recent Australian contract, known sales are limited to the Elta EL/L-8300 system. However, published information is too uncertain to determine that the other advertised maritime-patrol-aircraft systems have not been sold or used by Israel.

◆ CR-2800

This Elisra (Tadiran subsidiary) ESM/ELINT system is apparently a competitor to the Elta EL/L-8300. Maximum effective range is 330 km, and coverage is 0.5–18 GHz; the system can track up to 64 emitters simultaneously. Antennas: one omni (for IFM), four 10-in cavity-backed spirals, and eight 3-in cavity-backed spirals, for 2 frequency bands. All antennas are flush-mounted in pods or blisters. The directional antennas are grouped in 4 sets, each with adjacent amplifiers. For more precise signal data, for targeting, the system can be supplemented by a superheterodyne receiver and a rotating directional antenna. Total weight, in the basic version, is 300 kg. Reportedly, this system is operational with the Israeli Air Force, alongside the more elaborate EL/L-8300.

◆ EL/L-8300

Elta's electronic reconnaissance system is used for both ground and naval operations. Argentina bought 5 after the Falklands, 2 of them for installation in its Lockheed Electra maritime-reconnaissance aircraft. This system has probably also been installed on board 1 or more of the Indonesian Boeing 737 surveillance aircraft (which are also equipped with SLAMMR side-looking radars). It has been sold to South Africa and probably also to Thailand (for installation on board a converted DC-8F). The system first appeared on board a converted Israeli Boeing 707 in 1981. The Indonesian sale followed in 1983, and the Argentine sale in 1985. A total of at least 18 (plus 3 prototypes) had been manufactured by 1989.

The full system consists of:

EL/L-8312A, which monitors the C-J-bands (0.5–18 GHz). Key modules include EL/L-8312R, a superheterodyne microwave receiver; EL/L-8320, a pulse digitizer; the EL/L-8610 computer; and the EL/L-8570 display unit. The pulse digitizer operates on signals reduced to intermediate frequency, with 3 alternative bandwidths: 50–70 MHz, 140–180 MHz, and 300–500 MHz.

The system processes pulse descriptions in the form of four 16-bit words (giving pulse width, pulse amplitude, fine frequency, time of arrival, and status). Direction is measured by differences in time of arrival between nose, tail, and wingtip antennas. There is also an omnidirectional antenna in a radome beneath the forward fuselage. The manufacturer claims that an emitter can be triangulated within 20 sec of receipt of the first signal.

EL/K-7032, a narrow-band system with a frequency resolution of 1 kHz for the 20–500 MHz band, scanning over a 10-, 20-, 50-, or 100-kHz band around a preselected frequency. This section conducts signal analysis, monitoring, and intelligence gathering in the HF, VHF, and UHF bands. It uses microprocessor-controlled fast switching to cover a wide frequency range and can be entirely computer controlled. This system employs a series of blade antennas distributed over the belly of the airplane, some of them in pairs. The manufacturer claims that it can handle 300 signals simultaneously, 3 of them in the same frequency band. All are subject to automatic direction finding.

EL/L-8350, the Command and Analysis Station that controls the system.

The supervisor station contains an *EL/S-8570A* computer controller, 2 *EL/K-1150* VHF/UHF receivers, a display, and a tape recorder. In addition, there are up to 4 *EL/K-1150* or *-1250* receivers in a traffic-collection unit.

From nose to tail, an airplane equipped with *EL/L-8300* contains a 1- or 2-operator *ELINT* section (*EL/L-8312A*), a 2-operator supervisor/control section, a 4-operator *COMINT* unit (*EL/K-7032*), an operations section (*EL/L-8350*), and a command-and-analysis suite. This airplane carries a threat library for fast analysis of intercepted signals. Maximum detection range is 400–450 km from an airplane flying at 12,000 m.

An *EL/L-8300* is supported by an *EL/L-8352* postmission analysis station and an *EL/L-8353* ground station.

System capabilities are suggested by the range of signals that can be simulated by the associated *EL/L-8351* ground trainer: up to 270 distinct emitters, ranging over 100 MHz–40 GHz, 1 of 3 different antenna patterns, 1 of 4 scan patterns (circular, conical, bidirectional, or fixed), different scan rates (1–6 rpm circular, 20–50 Hz conical), variable effective power (over 2 orders of magnitude), and variable on-off time (20 sec up).

◆ Elta P-3C System

In the fall of 1989 Elta won a contract for new ESM systems for the 10 newest Australian P-3Cs, beating out Elisra. Best and final contract offers were submitted in March 1989. The 2 Israeli firms were the leading contenders, the other being BAe Australia/Thomson-CSF. As of late 1989, there was also an RAAF requirement for a new radar to replace the existing APS-115 of the P-3C.

Elbit had already won an Australian contract for a new omnidirectional ESM antenna; in the spring of 1989 it delivered the first of 4 under a November 1987 contract. The new antenna is a miniaturized version of the EA 2818 2–50-GHz antenna, a stack of 3 vertically polarized, biconical antennas covered by a slant 45-deg polarizer, sealed in a radome. Two short active stubs adjacent to the bicones extend the bandwidth to cover 100 kHz–2 GHz.

◆ Owl

Owl is a lightweight (136 kg total) Tadiran system for maritime-patrol aircraft and other surveillance. It employs 2 RF front ends (in pods, wingtips, or in the aircraft fuselage), to cover the 0.5–18 GHz band (extendable to 40 GHz). Signals are automatically detected and identified (using a library); the system uses a wide-band data bus to accommodate exotic signals. Direction of arrival accuracy is 0.5 deg, and instantaneous bandwidth is 5, 15, or 40 MHz in narrow-band mode, or 4 GHz in wide-band mode. Frequency accuracy is 1.25 MHz, and resolution is typically 0.2 MHz. Signals from up to 16 emitters can be deinterleaved. Response time is 0.5 sec.

A recent Tadiran pamphlet describes an Owl-MT version specifically for maritime reconnaissance using light aircraft (it shows a Dornier 228), with 5 antennas in each wingtip. Total weight is given as 90 lb, and direction-of-arrival accuracy as 2.5 deg.

Israel uses Arava light transports for communications and electronic intelligence, and this type of equipment would seem to be appropriately sized for such applications. Similar considerations probably apply to the naval Sea Scan (converted Westwind executive transport) aircraft.

◆ RAS-2A

Tadiran's wingtip-mounted interferometer ESM system covers 0.7–18 GHz (extendable to 0.5–40 GHz) and is described as intended for small- and medium-sized transports. The single operator console can show the detected enemy order of battle, and it can also be used to target antiradiation or antiship missiles. Direction-of-arrival accuracy is 0.8 deg (left/right; 5 deg fore and aft); elevation coverage is ± 10 deg. Frequency accuracy is 0.2 MHz; resolution is typically 0.4 MHz.

As of 1989, RAS-2A was described as in development. An earlier system, RAS-1A, was described as in service. It was designed to cope with 2 emitters/sec, and it requires 2 operators. Frequency coverage matches that of RAS-2A, but accuracy is not as good (1.3 deg over 0.7–2 GHz, 0.7 deg over 2–18 GHz); frequency accuracy (resolution) is 2.5 (1.25) MHz; and PRI accuracy (resolution) is 200 (100) nanosec.

ITALY

◆ Colibri (ELT/161)

Elettronica's ESM system is for naval helicopters such as the AB-212. The basic installation is ELT/161, consisting of a receiver, processor, and warning display. The typical antenna array consists of 2 conical omni antennas, 2 half-cylindrical half-omni antennas, and 8 hemispherical DF antennas. In a typical light helicopter (AB-212) installation, the 2 half-omnis are under the nose, facing port and starboard. One of the omni cones is mounted above the windshield, forward, and the other is in the extreme tail. The DF antennas are spread around the helicopter, 4 of them in the nose, 2 amidships (just below the engine exhaust), and 2 of them facing aft, on either side of the after cone. Two separate sets of omnidirectional antennas are needed to feed IFMs working at S- and X-bands; the IFMs in turn feed the warning processor. There is also a dual-band DF display.

Claimed performance (range at which an emitter can be detected):

<i>Flight Altitude</i>	<i>S-band</i>	<i>X-band</i>
300 ft	34 nm	26 nm
1000 ft	50 nm	41 nm
2000 ft	63 nm	47 nm

The basic warning device can be supplemented by an ELT/261 analysis module, for monopulse direction finding, automatic analysis, and library look-up of received signals. Selected emitters can be tracked. Other possible additions are the ELT/562 self-defense deception jammer (see below) and the ELT/361 noise jammer (used for standoff jamming of hostile search radars). ELT/361 requires its own directional antenna. The other 2 systems use Colibri antennas.

Colibri is in service with the Italian Navy and up to 10 export customers.

NICE (see below) is intended as a next-generation replacement for this system.

◆ ELT/156

Elettronica's tactical RWR uses 4 antennas and 2 radio-frequency heads. The display is the usual polar plot of bearing against frequency, and several threats can be displayed simultaneously. The device provides audio warning. Total weight is 10.3 kg.

Colibri DF antennas on an Italian AB-212 helicopter. The radome below the 2 forward antennas carries an omnidirectional (IFM) antenna, and the radome over the cockpit carries a directional antenna, typically a radar antenna that can be used for precision direction finding, in analogy to some versions of ALR-66. The tail carries a pair of DF antennas and another omni. (Elettronica)

◆ ELT/263

Elettronica's lightweight maritime-patrol-aircraft ESM system uses the same type of directional antenna as Colibri. ELT/263 is intended to detect and locate E- through J-band radars. ELT/263 employs 4-6 directional antennas plus an omnidirectional antenna for IFM. System memory is sufficient for the aircraft to locate an emitter by triangulation as it flies past, and the system can blank off reception of the airplane's own radar to avoid confusion. The system is arranged to transmit emitter location to a surface station.

Typical detection ranges, based on altitude, match those listed above for Colibri.

ELT/263 was originally designed for the Beech 200T light maritime-patrol aircraft but has been adapted for others, including the P68T, Casa C212, Bandeirante, F27, Gardian, GAI Searchmaster, Learjet 36A, Maritime Defender, and the Piaggio P-166. At least 60 are in service, in Algeria, Finland, Indonesia, Italy, South Africa, Spain, Thailand, and the United Arab Emirates.

◆ ELT/562 and ELT/566

These Elettronica jammers can function with an ESM system such as Colibri. They cover the 6-20-GHz band. ELT/562 counters pulse radars; /566 counters CW radars.

◆ IHS-6

This is Selenia's alternative to Colibri. It has less impact on the helicopter or airplane airframe but pays with some restriction on overall capability. Development began in 1975; IHS-6 is a combination of RQH-5 and TQN-2. The system can carry 50 target tracks, and it covers the 1-18-GHz frequency range. It was developed primarily for naval use, e.g., for task force EW and for standoff and stand-in jamming in support of strikes. Of several users, the only publicly announced one is Egypt (on board Westland Commando helicopters, delivered 1980). It has been selected for the Italian maritime-patrol-aircraft update (as SL/ALR-730) and for the Italian Navy version of the EH-101 helicopter (as SL/ALR-735). An RWR version for supersonic aircraft is SL/ALR-743.

Commercial variants: Series 730 for maritime-patrol aircraft; Series 740 for fighters; Series 780 for ESM/ELINT/EW aircraft.

◆ NICE

Elettronica's New Integrated Computerized ESM system is intended to replace the existing Colibri and ELT/263. It was displayed at the Paris Air Show in 1989. Compared to Colibri, NICE dispenses with the semicylindrical half-omni antennas

but retains the 2 conical omnis and the 8 DF antennas (which are air-backed spirals). NICE offers the full range of analysis, identification, and surveillance functions in a single set of lightweight boxes and with a single CRT display, this improvement over Colibri being possible thanks to adoption of surface-mounting semiconductor technology and a fast computer. The internal equipment consists of a processor, a correlation unit, a keyboard, and the single display. NICE uses both wide-open and superheterodyne receivers. It can detect coding within a pulse (i.e., pulse-compression coding), and should be capable of precise frequency measurement and accurate direction finding. As in Colibri, there is an emitter library.

◆ RQH-5(V)

Selenia's helicopter ESM set is a component of IHS-6. It can provide direction of arrival and target parameters to other systems. Frequency coverage: 0.65–18 GHz (optional extension to 40 GHz). Parameters: frequency, pulse width, intrapulse structure (e.g., to identify pulse-compression radars), fine structure (fingerprinting, for electronic intelligence, and fine frequency measurement), jitter, stagger, PRI agility, antenna pattern, amplitude changes (which can be displayed as a histogram). The system employs up to 2 omni antennas (for IFM) and 4 or (more usually) 8 directional antennas. It is designed for very dense environments, accepting up to 20 new emitters every 20 msec. The library normally contains 3000 radar modes but can be expanded to 20,000. Options include more accurate direction finding with a multibeam antenna (sectoral monopulse direction finding) and several alternative multibeam flat arrays for different instantaneous fields of view and increased accuracy. The system can also be fitted with a steerable K-band antenna and with a fine-analysis ELINT receiver.

SWEDEN

◆ BOH 300/BOL 300/BOP 300/BOZ 100

BEAB (formerly PEAB) chaff/flare dispensers. BOH is for helicopters; BOP is for combat airplanes. BOL is intended for installation inside a missile launcher rail. All are controlled from a dedicated data bus. There is also a BOZ series, for Swedish high-speed combat aircraft (BOZ 100 is a chaff pod). BOP 300 and BOH 300 fire standardized chaff cartridges.

BOH 300 is installed on board Swedish Navy Vertol 107 helicopters, the standard box carrying 2 triple rows of dispensers firing outboard, and 1 row of 4 dispensers firing aft.

The U.S. Navy is currently evaluating the BOL chaff dispenser, which can be controlled by an ALE-47 and which is being considered for installation on the F-14. BOL employs a unique chaff-dispensing approach: chaff is released like individually wrapped slices of bread. BOL has been tested on the F-14 and will be installed inside the LAU-7 missile rails, to take advantage of unused space there.

The British MoD has also ordered BOL for evaluation.

BOP 300 is the chaff dispenser planned for the Fokker Maritime Enforcer Mk 2 maritime-patrol aircraft. BOP 300 can include up to 8 units, each of them carrying 2 rows of 3 tubes each. The control system computer memory can hold 16 separate dispenser programs and is easily reprogrammable. In the automatic mode the associated RWR senses the threat, and the ECM system automatically selects program and ejects. There is also a semiautomatic mode, in which the computer selects the mode but the pilot initiates action, and a fully manual mode. Using the latter, in the event of malfunction, a pilot can still deliver decoys via a program permanently stored in the dispensers; all would launch simultaneously. To create the largest chaff cloud, within the threat radar range gate, solid-state squib drivers can generate firing pulses at intervals of less than 100 msec in 1 dispenser; they may generate firing pulses at shorter intervals using several dispensers. The system memory holds 16 separate dispensing programs, and it can be reprogrammed to deal with a specific threat.

The current versions, for fast combat aircraft, use 2 or 4 dis-

pensers, weighing, respectively, 17 and 31 kg empty (27–35 and 51–66 kg loaded, depending on ammunition type). Dispensers can be loaded with standard square-section ammunition (chaff and flares) and with BOP circular-section ammunition (which have greater chaff and flare capacity). A BOP magazine contains 6 rnds each loaded with IR flares (1, 2, or 3 bodies/cartridge) and chaff (broad-band or peaked dipole); chaff and flares can be ejected in subrounds.

BOZ 100 chaff/flare pods are carried by some Tornado aircraft, as well as by French Jaguars and by Swedish Viggens (designated BOX 9 in the latter case). It operates either manually or automatically and has a reprogrammable dispenser-program library. The pod is suspended from a 14- or 30-in bomb rack; dimensions are 380 × 4000 mm (maximum loaded weight is 325 kg).

USSR

◆ Naval Support ECM

Soviet naval air-strike tactics include the use of both jammers and chaff-corridor layers. Badger-H (Tu-16PP, for *postanev-schchik pomiekh*) carries up to 9000 kg [19,840 lb] of chaff, sufficient for a 60-nm-long corridor, in its bomb bay. As in U.S. bulk-chaff systems, the chaff is cut as it is dispensed; the bomber monitors the radars it is to jam to determine their wavelengths. Badger-H has a pair of radomes like those of Badger-E (see below), plus a smaller radome just forward of the bomb bay. This combination might equate to having a pair of high-gain antennas to determine an emitter's location and having an IFM in the small radome. The chaff itself is dispensed from a hatch abaft the former bomb bay. Badger-J (also Tu-16PP) is the complementary jammer (for A–I-bands), first identified publicly in 1987. The jamming antennas are carried in a canoe under the former bomb bay, and there are also flat-plate and podded antennas at the wingtips (presumably, to determine an emitter's location and to monitor the effects of jamming). There is a small blister immediately forward of the canoe. Reportedly, a typical antiship regiment of the early 1980s consisted of 2 strike squadrons (each consisting of 9–12 missile attack bombers), supported by a third squadron consisting of 2–4 Badger-Hs, 1 or 2 Badger-Js, and 3–6 Badger tankers.

No equipment code names have been released. As the Badgers are discarded, corresponding versions of the current Backfire will presumably appear.

Other Soviet naval electronic reconnaissance (signals intelligence) aircraft are:

An-12 Cub-B and -D Cub-D (first seen 1982) has very large teardrop fairings on the sides of its forward fuselage. Aircraft are, reportedly, assigned to the Baltic and Black Sea Fleets, although they have appeared over the Indian Ocean.

Il-20 Coot-A (Also surveillance) Radomes include a large canoe (10.3 × 1.2 m) under the forward fuselage, cheek radomes (about 4.4 × 0.9 m) on the forward fuselage, and a twin array atop the fuselage just abaft the cockpit. Reportedly, the canoe houses a

A Soviet IL-20 Coot-A ESM airplane, photographed from an F/A-18 of VFA-151 off the USS *Midway*, March 1988. (U.S. Navy)

J-band side-looking radar, the cheeks house optical or infrared sensors, and the dorsal array is for satellite communications. Aircraft are assigned to the Northern and Baltic Fleets.

Badger-D (Signals intelligence/maritime surveillance) Aircraft are, reportedly, assigned to the Northern and Pacific Fleets. The *Badger-D*, a converted *Badger-C* (missile bomber), was first observed in 1962. The missile pylons were deleted, but the big nose radome of the *Down Beat* radar was retained. The teardrop-shaped chin radome (for *Puff Ball*) under the nose was slightly enlarged. Three new radomes were added, 2 small ones (not quite identical) at either end of the former bomb bay, and a larger one (somewhat larger than the chin radome) just forward of the center of the former bomb bay.

Badger-E (*Tu-16R*) is a modified *Badger-A* (bomber, with glassed-in nose) with cameras in a bomb-bay pallet and a pair of radomes, fore and aft of the bomb bay. The radomes are about the same size; presumably, they are used to triangulate an intercepted signal. This and other later electronic-reconnaissance or jamming versions have the chin radome of the original *Badger* bomber, and the chin radome houses an RPB-4 (Rubin 1) ground-mapping radar. *Badger-E* entered service in the early 1960s.

Badger-F is another version of *Tu-16R*, first seen in January 1963. It has a pair of large under-wing radomes. Some *Badger-F*s also have the under-fuselage radomes of the *Badger-E*; others have 2 large blade antennas mounted on the lower fuselage just abaft the bomb bay, with a small radome forward of the bomb bay. The bomb bay itself may carry a camera pallet. Some *Badger-F*s have an internal noise jammer for strike support. At least one *Badger-F* had a large tail cone replacing its tail gun turret. Others have been observed with extra antennas over the cockpit or alongside the nose. *Badger-F* often operates with *Badger-D* and was probably a related program.

Badger-K is the most recent electronic-reconnaissance version (1981); it differs externally from *Badger-E* in that the -K's forward ESM radome is noticeably smaller than the after one. Some *Badger-K*s have enlarged chin radomes. A photograph of a modified naval *Badger-K* (unofficially designated *Badger-L*) appeared in August 1986. This aircraft has a thimble radome protruding from its glassed-in nose, and it carries a pair of under-wing pods, probably to dispense self-protection chaff or flares. There are also new blisters under the nose and around the air intakes (the latter have also been seen on *Badger-K*s). This aircraft has the new, larger, flatter nose radome, which presumably houses a new ground-mapping radar.

Tu-22 Blinder-C (Signals intelligence/photo-reconnaissance) This aircraft carries 6 cameras in its bomb bay, plus antennas under dielectric panels on its forward fuselage sides. Aircraft are assigned to the Baltic Fleet.

◆ Sirena

Sirena is a generic Soviet designation for RWRs, installed in aircraft ranging from fighters through large bombers. Soviet pilots claim that the *Sirena* 3 version in a *MiG-29* is accurate within 12 deg of bearing and that the system displays the type of threat and the direction of the most dangerous threat. A photograph of the *MiG-29*'s cockpit shows a small rectangular CRT or liquid-crystal display above a series of lamps around the outline of a generic airplane: 4 to either side of dead ahead, and 1 to either side of the tail; there are also 6 slits (probably lamps) below this display. Presumably, they give some indication of threat type. The lamp display recalls Western RWRs of the early-Vietnam period; one account suggests that *Sirena* 2/3 are equivalent to the old U.S. APR-25.

UNITED KINGDOM

◆ ARI 18228

Marconi's Sea Harrier FRS.1 RWR operates over 2–18 GHz and uses a CRT display to show the direction of the threat; several threats can be shown simultaneously. There is also an audio alarm. ARI 18228 was developed from the ARI 18223 carried by RAF Jaguars and Harriers; the earlier system used a lamp to

indicate threat quadrant. ARI 18228 was originally developed for 2-seat aircraft such as the *Buccaneer* and *Phantom*.

The antennas are on the vertical fin, in the squared-off protrusion.

◆ ARI 18240 (Yellow Gate)

Nimrod MR.2 ESM system. See Loral EW-1017 in the U.S. section below. This system is being installed on board British AWACS (E-3D).

◆ Hermes

Hermes is the Marconi Defense Systems's ESM system supplied for Indian Navy Sea King helicopters. It is derived from the ARI 18241/1 radar-homing-and-warning receiver fitted to RAF Tornado F.2 and F.3 fighters.

◆ Kestrel (Orange Reaper)

Racal's ESM system is made for the EH-101 helicopter and for small maritime-patrol aircraft. Orange Reaper uses the same 6-port antenna as Orange Crop (MIR-2) but is described as an airborne equivalent of Cutlass. The processor and display match those of Sabre (see under shipboard radars and fire-control systems in the Antiaircraft Warfare section). The design emphasizes accurate frequency data (for radar identification) over high bearing accuracy, and there is a 2000-emitter threat library. Total weight is 47 kg. Frequency coverage is 0.6–40 GHz, bearing accuracy is better than 3.5 deg, using pattern-correction techniques, and processing time is less than 1 sec.

Orange Reaper is the Royal Navy version for the EH-101 helicopter. In this application it shares the helicopter's main display. Kestrel has been ordered for Royal Danish Navy Lynx helicopters to replace MIR-2. In these helicopters the ESM display is a 20 × 7.5-cm color CRT.

◆ MIR-2 (Orange Crop)

Racal's ESM system for helicopters covers the C- through J-bands. Orange Crop was designed for the Lynx helicopter but was extended to Sea Kings during the Falklands War. The system uses 6 antennas, each covering a 60-deg arc. The display shows frequency band (the 0.6–18-GHz range is divided into 4), bearing (the scale is divided into 10-deg steps), and amplitude. Strobes are used to select signals by band and bearing for pulse analysis and accurate bearing measurement. For pulse analysis, the PRF is displayed digitally; bearing is displayed on a 30-deg display calibrated in 2-deg steps. Bearing accuracy is 4.5 deg. Signal limits: pulse width 0.1–10 microsec, PRF 50–10,000 pps. Total weight without antennas is 30.7 kg. This system was originally designed to intercept and locate submarine burst transmissions.

Two Orange Crop antennas (broadside and facing aft) on a Sea King helicopter, off HMS *Ark Royal*, 1990. There are 2 more such antennas on the nose of the helicopter, and each antenna consists of 2 cavity-backed spirals, to cover 2 frequency bands. (Author)

A current upgrade to Mk 3 configuration, involving 2 line-replaceable units (LRUs), provides a PRF library for pulse analysis and a capacity to recognize important CW (missile-guidance) radars. Mk 1 was the original system with an RWR and a search-radar receiver in the same modular unit. Mk 2 added an optional radar-altimeter input, as well as track-data input and output. It was installed on board all RN Lynx and Sea King helicopters, with some pods (Orange Blossom) for RAF C-130s, for radar surveillance and self-defense warning.

MIR-2 was first displayed in July 1978, and the first contract for installation in Lynx helicopters followed in October 1981. Unit cost is about \$350,000.

Although originally developed for helicopters, MIR-2 was later extended to surface craft. The ship-based version is described in the Antiaircraft Warfare section. Racal has discussed license production in France.

◆ Sky Guardian 200

Marconi's RWR for the Sea Harrier FRS.2 incorporates an EEPROM threat library (over 400 emitters, over 2500 emitter modes) and is capable of triggering defensive measures (presumably limited at present to chaff). It divides signals in the E-through J-bands into 3 bands; C-D-band and K-band coverage can be added as options. Four broad-band spiral antennas (52 mm in diameter) provide better than 10-deg DF accuracy. The basic system uses broad-band crystal video receivers and 3 computers: 1 for measuring signal parameters, 1 for sorting and initial analysis, and 1 for arranging signals into individual emitter tracks and comparing them with the threat library. Total multiprocessor memory is 336k (RAM, PROM, and EEPROM), with 100% growth capacity. It can be reprogrammed in about 60 sec on the flight line. The processor operates at 5 MOPS. Response time is less than 1 sec from detection to identified display.

The main display is a high-brightness 3-in CRT compatible with NVGs, showing up to 15 emitters with identity, status, and bearing (pseudo-PPI). There is also an alternative tabular format showing parameters such as frequency band and PRF. The CRT display is persistent, to show fleeting intercepts. The system's digital output can also be passed to a HUD, as in the Sea Harrier FRS.2. Aside from the CRT, the pilot is provided with continuous true audio (presumably at PRF frequency, giving an idea of the nature of the threat) and with synthetic alarm tones.

Antennas can be added for more precise direction finding; the basic system uses the amplitude comparison typical of RWRs. An IFM can also be added (normally Sky Guardian uses crystal video receivers). The threat library can be updated in flight, and emitter data can be recorded for later playback and analysis.

MTBF is over 700 hr.

Sky Guardian was developed from ARI 18223/18228 (see above). Series 100 is intended for helicopters and light aircraft, Series 200 for combat aircraft, and the projected Series 300 for large maritime-patrol and ASW aircraft. Series 300 adds an IFM and horn antennas for accurate DF. Series 200 is carried by RN and Indian Sea Harriers and Spanish EAV-8As. Sky Guardian is also on board Sea King and Puma helicopters.

The British MoD rejected a suggestion that the Sea Harrier be fitted with the Plessey Avionics Missile Approach Warner (MAW), a rearward-looking pulse-doppler radar analogous to the U.S. ALQ-156. MAW has been bought for RAF Harrier GR.5s.

◆ Yellow Veil

The Whittaker Electronics (U.S.) jammer for Lynx helicopters operating in the Persian Gulf is designed to protect British warships against Iranian antiship missiles. Based on the U.S. Navy ALQ-167(V), Yellow Veil can be carried either internally or as a pod, in the latter case replacing 2 Sea Skua missiles. Yellow Veil is also based in part on Falklands experience. The system protects a Lynx attacking with Sea Skua from hostile antiaircraft sensors; the helicopter is limited in maneuverability because it must keep the surface target illuminated. Yellow Veil is also carried by some Sea King HAS.5 helicopters.

The long pod of Yellow Veil is carried by this Royal Navy Lynx helicopter. (Whittaker Electronic Systems)

The U.S. Navy and NATO use the ALQ-167 dual-mode noise/deception pod (0.4–11 GHz) for training, to simulate enemy jammers. The pod in turn is a modified version of DLQ-3, a blip-enhancer that could be carried by a drone (operating as an antiaircraft target), to make it appear larger to an opposing radar.

◆ Prophet

Prophet is a Racal RWR designed for export, particularly on board Hawk trainer/attack aircraft. However, Royal Navy Sea King helicopters operating in the Persian Gulf have been fitted with this system, an installation completed in 2 weeks. Prophet reduces its false-alarm rate by measuring the frequency of an intercepted signal, an unusual feature in so simple a system (most measure only PRF within a broad band and may, therefore, easily confuse signals). Total weight, including a 4-port antenna and an LED display, is 9 kg. Coverage is either 2–18 GHz or 6–18 GHz, and the threat library can store signatures of more than 100 emitters. Designed response time is less than 1 sec.

EXPENDABLES

◆ ADS-10

The Widney-Aish helicopter missile decoy system was announced in 1989. Standard square-section (25 × 25 mm) chaff, IR, or smoke screen cartridges are loaded in four 4 × 4 magazines ("intelligent dispensers"), which swing out for reloading. Alternatively, the magazine can be loaded with 2 × 4 MJU-7/B type flares. The user can program the system to fire up to 64 rnds/salvo, at random or staggered intervals of 0.1–60 sec (the standard system fires up to 9 rnds/salvo, with intervals of 0.1–9 sec). Electrical contacts at the rear of the magazine detect the presence of ammunition and relay that information to the microcomputer that controls the system. Similarly, the contacts report back when cartridges are fired.

Total weight, loaded, is 24 kg.

UNITED STATES

◆ AAR-37

Hughes's IR warning system is made for P-3 aircraft.

◆ AAR-47

Honeywell's electro-optical warning sensor is designed to detect close-in incoming missiles that may not register on RWRs, e.g., IR- and laser-guided weapons. The system detects the IR signature of the missile plume and eliminates nonthreats by spectral analysis and also by temporal algorithms, i.e., by measuring

The ADS-10 helicopter-countermeasures dispenser, on display at the RNEE show in 1989. It is opened for loading, with a typical magazine at left. The contacts on the inner panel identify the magazine to the system and allow the system to launch cartridges. (Author)

the dynamics of the approaching object. The system automatically launches flares (e.g., from an ALE-39) and provides an audio and visual alarm for the pilot. Four sensors hard-mounted on the aircraft skin provide all-around coverage. AAR-47 was approved for production in 1987 after opeval and techeval, and in February 1988 the U.S. Naval Air Systems Command ordered 111 for the CH-53, CH-46, AH-1, UH-1, OV-10, SH-2 (LAMPS I), V-22, and MH-53J (air force special operations). Another 373 have been ordered, applications including army helicopters and air force reserve C-130s. Projected naval applications are the P-3C, the AV-8B, and the CH-46 helicopter.

AAR-47 was installed on board SH-60B LAMPS III helicopters of the Middle East Force during the Gulf War.

◆ AAS-43

This is GE's passive-IR detection system for the A-12.

◆ ALD-8

ALD-8 is the E-Systems direction finder for EP-3E aircraft.

◆ ALD-11

This is Litton's radar direction finder for the A-12.

◆ ALE-39

The Goodyear/Tracor chaff-cartridge dispenser is standard on U.S. Navy aircraft. It is a square container typically attached to the side of an underwing hard-point pylon. Normal capacity is

60 cartridges, but it can be expanded to 300. This pod can launch three types of decoy (flare, chaff, and expendable active) in multiples of 10; options include multiple flare ejection.

◆ ALE-40

Chaff pod, normally used by the U.S. Air Force; the (V)6 version is carried by British Nimrod maritime-patrol aircraft. In contrast to U.S. naval chaff launchers, air force launchers use square-cross section chaff cartridges. The (V)4, 5, and 6 versions are internal chaff dispensers intended originally for the F-16 fighter; each carries 30 RR-170 chaff cartridges or 15 MJU-7/B flares. (V)1, 2, and 3 are pylon-mounted for the F-4 series. (V)7, 8, and 9 are intended for semi-internal mounting on F-5s, (V)10 is for the A-10, and (V)11 is for the air force version of the A-7.

◆ ALE-41

This chaff pod, which can be carried underwing, is used to sow an 80-nm chaff corridor. It succeeds the earlier ALE-2 and ALE-32 and is based on the air force ALE-38. Bulk chaff is carried in the shell of the old ALE-2. Capacity: 280–360 lb of aluminum or metallized glass chaff. The chaff is carried in six 50-lb cartridges containing dipoles between Mylar films, spread by the wind as the tape unravels. Dimensions: 19 × 131 in (500 lb loaded). The pod is programmed on the ground, controlled either by a cockpit switch or by the aircraft's radar detector. It was approved for service use in 1977. ALE-41 is currently carried by EW training aircraft.

◆ ALE-43

The Lundy chaff dispenser cuts chaff from 8 spools of aluminumized glass fiber. The resulting chaff can counter radars from VHF up to millimeter-wave. In pod form (640 lb), ALE-43 carries 320 lb of chaff. This dispenser can also be housed internally, as in the EA-6B (total weight 420 lb). Chaff is carried in up to 9 packages, each feeding a roller and cutter.

This type of bulk pod is generally used to lay a chaff corridor.

◆ ALE-47

Tracor chaff dispenser, intended to replace both ALE-39 and the air force ALE-40; it is to be interchangeable with ALE-40. There will also be new programming formats, to take advantage of the range of new expendables now available. ALE-47 will be the second fully automatic dispenser system in U.S. service; the first was the ALE-45 on board the air force's F-15C/Ds. Tactics are programmable, and ALE-47 continuously receives data from both the aircraft platform's avionics (giving, for example, its air speed and altitude) and from the threat warner. ALE-47 can operate in fully automatic mode (the system selects its tactics), semiautomatic mode (the system selects tactics but the crew initiates), or fully manual mode. In each case, ALE-47 can program smart (active) expendables such as GEN-X. ALE-47's predecessors could operate in preprogrammed sequences but could not change from sequence to sequence, as ALE-47 can. Nor could they be triggered automatically by the aircraft's threat warner. Tracor received a 4-yr full-scale-development contract in August 1989; ALE-47 is to be integrated with the new ALQ-165 (ASPI) jammer. As of fall 1990, development was running about 12–18 months late because of the 1986 decision to make ALE-47 a biservice program (it began in 1983 as an air force program). The only difference between the 2 versions will be the magazines (cylindrical for the navy, square-section for the air force).

◆ ALE-50

Raytheon's advanced airborne expendable decoy (AAED, a towed decoy to confuse monopulse radars) is part of the IDAP program. ALE-50's 2.75-in-diameter shell contains a mini-TWT to generate a sufficiently large target to compete with the radar return of the airplane itself. Hughes is the follower producer. The current (1990) cost goal is \$10,000–\$15,000 per expendable decoy.

◆ ALQ-39

CHAFFBUOY is a delayed-deployment chaff cartridge intended to countersurveillance systems. Aircraft are used to deploy ALQ-39 so as to bring it far enough from the fleet. The distances involved permit delays of an hour or more in deployment, and the countersurveillance decoys need not be as large as those used to decoy missiles away from large ships. See also ALQ-190.

◆ ALQ-41

The Sanders track-breaker is part of the EA-6B suite. It is also carried by the EA-3.

◆ ALQ-76

Raytheon's jammer (2–8 GHz) for EP-3 aircraft.

◆ ALQ-78

Magnavox's ESM system for P-3 aircraft is to be replaced by ALR-66 in U.S. service. ALQ-78 uses a swept superheterodyne receiver fed by a high-speed rotating antenna in a pylon under 1 wing of the airplane. It intercepts and DFs submarine radar signals. Production began in the mid-1970s. A reprogrammable processor was added in the late 1970s to support Harpoon targeting. The U.S. FY82 program included modifications and upgrades to support operations in a multisignal environment, including modifications to system logic and the use of fine frequency information to improve sorting among pulses. A pulse-train separation circuit was added. ALQ-78 is manufactured under license by Mitsubishi, for Japanese P-3Cs. This device is also carried by the EP-3E signals-intelligence airplane. Foreign users are Australia, Canada, Japan, the Netherlands, and Norway. Estimated unit cost is \$160,000.

This Japanese P-3C shows an ALQ-78 radome under its port wing root (to the right in this picture). (W. Donko, 1989)

◆ ALQ-81

Sanders's jamming pod for A-7B and -7E light bombers was produced 1971–74.

◆ ALQ-86

The Bunker-Ramo ESM system was used originally in EA-6A (with the Loral ALQ-53 electronic reconnaissance system) and then in EA-6B ADVCAP.

◆ ALQ-91

Magnavox's communications jammer (to defeat the command links of surface-to-air missiles) for A-4Ms and F-14s was first ordered 1971.

◆ ALQ-99

ALQ-99 is the tactical support jamming system of the EA-6B Prowler, the standard U.S. Navy ECM airplane. The EA-6B de-

rives its flexibility from the use of pod-mounted jammers, analogous to the underwing stores of the A-6 attack bomber, that are controlled by an inboard computer and sensors (just as the A-6's attack is controlled by a computer and the APQ-148/156 radar). The pods were conceived in connection with a 1960 Grumman proposal for an EA-6 to be built around the new ALQ-53 (Giraffe) and to carry noise jammers (ALT-13, -15, and -16), track-breakers (ALQ-41 and -51), and a VHF jammer (QRC-1022 AL). The standard A-6 APQ-92 radar was simplified (as APQ-103) and moved slightly forward to create a bay for the ALQ-53. A radome was built on the vertical fin aft to accommodate most of the sensor antennas. The advantage of the radome's position was its 360-deg field of view. Other antennas were located in the canopy.

The logic of the podded jammer was a combination of flexibility (pods could be changed to match the threat) and the need for sheer jammer power: an internal jammer probably could not match what could be carried underwing, powered by a ram-air turbine. The proposed pod, designated ALQ-31, had a trainable, elevatable antenna so that the jamming airplane could track an enemy radar while maneuvering in an almost unrestricted manner. Moreover, because the jamming airplane probably would not face the full spectrum of enemy radars during any one mission, the aircraft could carry only the jammers it needed, using the remaining hard points for additional fuel or (now) for anti-radar weapons. ALQ-31 carried 2 complete jamming systems (noise, communications/navigation, or multitarget repeaters). The first pod to become operational, ALQ-76, carried 4, so that an airplane with 5 hard points could, at least in theory, jam up to 20 individual radars. The airplane itself was designed with the potential to add 4 more hard points, for a total of 9. Alternatively, each hard point could carry a 300- or 450-gal drop tank.

The first ECM version of the A-6, the EA-6A (which is still flown by reserve squadrons), carried an ALQ-86 receiver and display/control system instead of the ALQ-53 initially planned, and ALQ-76 pods. There was provision for the ALQ-54 noise-jammer pod and for chaff-dispenser pods (ALE-32, -41, and -42), so that the EA-6A could lay chaff corridors. EA-6As carried ALQ-55 communications jammers, to disrupt ground-controlled interception. The EA-6A also carried defensive systems to protect itself: an onboard chaff dispenser and a self-protection jammer (ALQ-100).

This system was limited because its different elements had been conceived and developed separately and could be integrated only through the skills of the single ECM operator. This operator in turn could easily be overcome by the sheer complexity of a dense electromagnetic environment. The operator had substantial electronic firepower but lacked the means to acquire and identify targets rapidly, particularly because the computer intended for ALQ-53 was not available in time. The operator, therefore, had to watch the system scan mechanically

An EA-6B of VAQ-140, 1988, displays the leading features of the ALQ-99 system: the tail radome (for all-around view) and the underwing pods. The 2 strakes on the vertical tail are ALQ-99 receivers for Bands 1 and 2. The short stub protruding aft from the tail radome (the "beer can") is for ALQ-126, added during the ICAP-1 program. (U.S. Navy)

through its frequency range every 2 sec, listening for the tone of an enemy radar. Worse, at this time the Soviets were introducing tunable radars, to overcome spot jamming. To be effective against such radars, a jammer must periodically shut down ("look through") to check whether its target is still emitting on the same frequency: the target has to be tracked both in position and in frequency (and, for that matter, in operating pattern).

Navy work on an integrated ECM airplane began in 1963, and Grumman conducted its own in-house study of an EA-6A at about the same time. The EA-6B, which is almost synonymous with the ALQ-99 system, was the result. The new idea was to develop the ECM system as an integrated whole instead of as a federated set of separate systems. The development contract was awarded in August 1966.

The key requirement was automatic radar identification and tracking in a very dense environment. Without accurate identification, jamming power could be wasted on low-priority radars such as IFF systems and airport landing systems. Very quick reaction was essential in the face of modern missile-control systems. Moreover, an operator would be presented with radars in very fast succession. Grumman estimated that in one case an airplane flying at 20,000 ft at 400 kt would encounter about 10 distinct emitters/sec, a rate that would double at 40,000 ft (because of the longer lines of sight). The solution was a combination of computer identification and of correlation of target bearing with emitter characteristics (radar function on land is generally associated with particular geographic positions). That solution, in turn, would require a computer memory.

The new system, ALQ-99, consisted of a series of antennas and signal processors feeding a central computer and integrated displays and jammer controls, which in turn fed self-contained pods with their own automatic frequency-and-direction tracking. The airplane itself had a doppler radar feeding a dead-reckoning navigator, which assisted in signal processing and jammer pointing, and defensive ECM for protection against counterattack. Even though ALQ-99 was much more automated than earlier ECM systems, it required 3 operators (ECM officers, or ECMOs). The standard A-6, then, had to be stretched to accommodate 2 more side-by-side seats.

Pods were designed for specific frequency bands, and aircraft were launched with a prebriefed set. Each consisted of an exciter flanked by 2 transmitters, with trainable antennas underneath. The typical load was 3 pods (centerline and outer store stations) and 2 drop tanks.

Thus the EA-6B began as a strike-support weapon, to jam acquisition and targeting radars. In the face of SAMs, for example, neutralizing the acquisition radar prevents hand-off to the missile-control system. Neutralizing the tracking radar of the missile system in turn prevents successful missile firing. Both tactics were often used in Vietnam. Early Prowler tactics called for the airplane to fly near a strike target, but outside the strike pattern proper. For example, an EA-6B on the strike axis could jam the radar net toward which the strike aircraft were flying. The next step was to jam defensive communications. The Soviets tend to rely very heavily on ground-controlled interceptors, and even if the directing radars work, the airplanes are helpless without their communications. It was natural, then, for the Prowler to be upgraded to deal with voice communications. The next step for the Soviets is to use a digital data link, which is more difficult to jam; and the next step for the Prowler is to neutralize that link as well.

A second mission, fleet defense, was added during the late 1960s. Prowlers could jam airborne targeting radars (which, in many cases, were needed to fire the surface-launched as well as the air-launched weapons) and, to a lesser extent, the missiles themselves. The EA-6Bs could also use their receivers for surface surveillance, providing passive early warning of the approach of enemy forces without disclosing the presence of the carrier group.

About 1985 the requirement to be able to physically destroy enemy radars, by firing HARM missiles, was added. By this time

HARM was valued not only as a means of neutralizing ground defenses but also as a means of rendering enemy warships vulnerable to salvos of antiship weapons. The rationales are quite different. A HARM may put a land-based radar out of action for a few hours or for a few days, when a particular target (among many) is hit. At sea, even temporary dislocation due to a HARM should open a ship to fatal damage.

These upgrades have been applied to virtually all EA-6Bs, which are periodically returned to Grumman for remanufacture (as of 1987, some had been rebuilt as many as 3 times). The major series are XCAP, ICAP-1, ICAP-2, "Block '86," and, in the near future, ADVCAP (Block '91). The flexibility inherent in the podded concept is very important here.

ALQ-99 coverage is defined in terms of bands, which are distinct from the usual ECM series. Bands are: 1, VHF; 2, A-band; 3, B-band; 4, C-band; 5/6, 1–2.5 GHz; 7, 2.5–4 GHz; 8, 4–7.8 GHz (most of G- and H-bands); 9, 7.8–11 GHz (upper H-, I-, and lower J-bands); and 10, 11–20 GHz. In traditional radar terms, Bands 6 and 7 are S-band, Band 8 is most of C-band, Band 9 straddles X-band, and Band 10 (for which there is as yet no ALQ-99 jammer) is Ku-band. Of current Soviet shipboard radars, only Top Dome (approximately 10.5–13 GHz) is outside ALQ-99 coverage.

The original EA-6B, which entered service in 1972, was limited to 4 countermeasures bands, together accounting for 96–98% of the electronic threat in Vietnam: Band 1, 64–150 MHz (VHF communications); Band 2, 150–270 MHz (some P-band radars); Band 4, 0.5–1 GHz; and Band 7, 2.5–3.5 GHz. XCAP (expanded capability) added Bands 5, 6, 8, and 9 to deal with newer high-frequency fire-control radars that were important outside Vietnam. XCAP, entering service in 1973, also incorporated a digital recorder (for electronics intelligence). Computer memory was doubled, and new computer-operated modes allowed simultaneous automatic coverage of several enemy radars. Jamming was driven by a new exciter.

XCAP and earlier aircraft can be distinguished by a pair of spear antennas protruding from the outboard pylons. The right-hand antenna transmits, the left-hand receives. The antennas initially served the ALQ-41 and ALQ-100 self-defensive (track-breaking) systems.

In the XCAP version, ECMO 1 (in the front seat) and ECMO 2 operated the main jammer, with ECMO 3 (who was not always needed) assigned to the ALQ-92 communications jammer. ECMO 1 also served as navigator and, therefore, had a disproportionate work load.

ICAP-1 (1977) added digital receivers, which fed a computer display system, and an automatic carrier landing system (ACLS). Major changes in displays and cockpit layout considerably reduced the work load of the crew members. The entire track/jam function was moved to the after pair of seats. ECMO 1 became communications jammer (ALQ-92), navigator, and radar operator. ICAP Prowlers can be distinguished externally by the 2 antennas of their ALQ-126 defensive (and deceptive) ECM system, which replace the 2 spears of the earlier aircraft: a receiving antenna on the refueling probe at the nose, and the "tin can" receiving antenna on the after edge of the fin radome.

ICAP-2 introduced the AIL-developed universal exciter, and it could jam communications on a limited basis. ICAP-2 has an automatic signal processor and a mission planner, as well as the current CAINS. The Band 7 search-receiver coverage was extended to the lower edge of Band 8, at 4 GHz (rather than 3.5 GHz as before).

The universal exciter substitutes a computer-generated signal for the previous analog-processed threat signal. The antennas are electronically steered, and output is about 1 kW/MHz, with a 30-deg beamwidth. Frequencies can be mixed within any pod, weight varying according to the 2 transmitters carried (the older pods could jam only 1 band each).

As the threat becomes denser, the operator cannot initiate action quickly enough, and the computer becomes the initiator, the human operator the monitor. The original ALQ-99 was semiautomatic, partly because it appeared before computers had

become particularly reliable. Problems with operator speed were first noticed in ICAP-1 aircraft, and ICAP-2 introduces full automation, with a faster (AYK-14) computer.

The next version (Block '86, 1988) adds encrypted HF communications, enhanced signal processing and recording, and VHF/UHF communications. Like ICAP-2, Block '86 can fire HARM missiles.

Block '86 will be the last version to incorporate the ALQ-99 that marked the entire series. In 1991 advanced capacity (ADVCAP) Prowlers will begin to appear, built around an entirely new system, currently described only as the RPG (receiver-processor group). The RPG system will respond to considerable improvements in threat radars, such as more complex (coded) pulses, to overcome spot jamming, and pulse-to-pulse frequency agility. Successful jamming now requires an ability to analyze pulse and pulse-train patterns so that they can be mimicked. Moreover, radars can now tune over wider bands, so that jammers limited to specific narrow frequency ranges may no longer be effective. Hence the vital interest in a "universal exciter" and in faster scanning of the spectrum. Increasing civilian use of the electromagnetic spectrum increases signal density and also makes it easier for a jammer to be seduced into action against a nontarget signal.

The RPG has been in full-scale development since 1983 and will be combined with the ALQ-149 system for command-control-communications countermeasures, which replaces the earlier ALQ-92. The RPG will substitute a disk recorder in place of the current digital tape, for greater information density and higher speed. ADVCAP aircraft will probably also have a new radar, which cannot be the multifunction type now specified for the A-6F. A third display (for the front cockpit) will be added to the 2 displays currently in the 2 rear seats. The forward operator currently is underutilized, and as the electronics environment becomes more complex, this operator will become vital to the 2 NFOs in the rear.

Versions are distinguished as

ALQ-99(V) Original EA-6B version, covering Bands 1/2, 4, and 7. The pods have the following dimensions:

Band	Weight	Length	Height	Width
1/2	959 lb	185 in	26 in	24 in
4	929 lb	185 in	28 in	18 in
7	962 lb	185 in	28 in	18 in

ALQ-99A EXCAP version, covering 8 bands (1/2, 4, 5/6, 7, 8/9). A single TWT covered bands 5/6; and a single new tube, a major development, sufficed to cover all of Band 9. New pods were introduced:

Band	Weight	Length	Height	Width
1/2	959 lb	185 in	28 in	24 in
4	929 lb	185 in	28 in	18 in
5/6	969 lb	185 in	28 in	18 in
7	962 lb	185 in	28 in	18 in
8	953 lb	185 in	28 in	18 in
9	983 lb	185 in	28 in	18 in

These pods were used in all naval versions through -99E.

ALQ-99B Minor improvements for reliability and maintainability.

ALQ-99C Additional reliability and maintainability improvements, modifications to frequency-sector mode of operation.

ALQ-99D ICAP-1 system with digitally tuned receivers and fully integrated computer-controlled jamming.

ALQ-99E RF-111A system for the air force.

ALQ-99F ICAP-2 version with universal exciter. Each generic pod (185 × 28 × 18 in) carries any 2 transmitters; they vary only in weight (1014 lb, for 2 Band 4, up to 1089 lb, for 2 Band 9).

◆ ALQ-108

Magnavox's IFF deception set, for E-2C, EP-3E, and S-3A aircraft, originated in the early 1970s. Over 300 were manufactured; reportedly some are carried by West German F-4 fighters.

◆ ALQ-110

United Technology's radar signal-collection system (Big Look improvement program) is for EP-3 aircraft. Big Look was originally used to monitor North Vietnamese SAM activity. See ASQ-171.

◆ ALQ-123

The Loral pod-mounted IR jammer produces a modulated IR signal. IR guided missiles use a technique equivalent to conical scanning, i.e., the missile associates directional information with the timing of the IR signal it sees. A suitably modulated jamming signal thus provides false directional information and causes the missile to pitch up. The choice of modulation frequency (see the Sidewinder description for some typical figures) depends on the design of the target missile; in 1986 ALQ-123 was reportedly being modified to provide additional pulse rates to defeat newer Soviet missiles.

Dimensions are 10 in (diameter) × 102 in (378 lb). In 1982 ALQ-123 was upgraded and modified to meet additional threats. MTBF is 280 hr. This assumes that the lamp is not continuously lit, as lamp life is 150 hr. MTTR is 30 min. Power is provided by a ram air turbine.

ALQ-123 was one of the first IR jammers. It was developed on a crash (QRC) basis in 1972, as part of the CAIR program begun in 1971, winning over a Sanders prototype. It was approved for service use in FY73, and 60 were bought under the FY73 QRC program. Estimated unit cost was \$20,000. ALQ-123 was originally designed to defeat the Soviet AA-2 IR air-to-air missile. An improved IR lamp was tested under the FY80 program, and about 170 were manufactured. Users included the Israeli airline, El Al. Loral received an upgrade contract in August 1984. British Aerospace was licensed to produce this pod.

◆ ALQ-126/164

The defensive ECM (DECM) system of the F/A-18 Hornet is manufactured by Sanders Federal Systems Group. ALQ-126B, the current version, is the first U.S. Navy/Marine Corps reprogrammable DECM system. This system is also used on foreign-sales F/A-18s. It operates either autonomously or in concert with the ALR-45F/APR-43 or ALR-67 RWR, the ALQ-162 CW jammer, and the HARM missile.

In an F/A-18, the system incorporates forward high-band antennas just aft of the radome (above and below the fuselage), an aft high-band antenna atop the port fin, forward mid-band antennas above and below the fuselage just forward of the air intakes (starboard above, port below), aft mid-band antennas just forward of the vertical fins (above and below), and low-band antennas (positioned with the mid-band antennas, but on the other side of the airplane).

Total weight is 190 lb (2 units, upper and lower deck, connected by blind-mate connectors), and the maximum power requirement is 3 kVA.

ALQ-164 is the podded version of ALQ-126B, for the Marine Corps AV-8B Harrier. ALQ-126 replaced the Sanders ALQ-100, which had been the standard navy self-defense jammer from the early 1960s on. ALQ-126 was initially referred to as ALQ-100X. The pod weighs 350 lb (16 in × 85 in).

The original ALQ-100 contract was awarded in February 1963, and production ended in February 1967, 2500 having been made. It was an E- through H-band track breaker, providing 1 kW of peak power at a 4% duty cycle, pulsed with 50 W of CW. Techniques were range-gate pull-off (RGPO), inverse conical scan (ISC), main-lobe blanking (MLB), swept square wave (SSW), and velocity-gate pull-off (VGPO). Response time varied between 0.120 and 4 microsec. ALQ-100 was designed to fit an A-4 Sky-

hawk; volume was 2.44 ft³, and weight was 180 lb. Presumably, these considerations also shaped its successor, ALQ-126. Compared to ALQ-100, -126 emits over 1 kW/band, and coverage expands to the I/J bands. Available tactics match those of the earlier jammer, but one variant uses a transponder jammer technique. Typical response time is 0.1 microsec, with 4-microsec memory duration. Coverage is typically 60 deg beamwidth, pointed down at about 15 deg.

◆ ALQ-129

ITT Avionics' mini-track breaker (in X-band) for the F-14 fighter. Technology from this pocket was offered for the Belgian Mirage 5 ECM package, a contest won by Loral's Rapport.

◆ ALQ-130

The AIL communications jammer on EA-6Bs is an updated ALQ-92. ALQ-130 attacks missile-command links, using broadband noise. This jammer is internally mounted on board EA-6Bs.

◆ ALQ-142

Raytheon's ESM system for LAMPS Mk III helicopters is a repackaged version of SLQ-32(V)1/2 (ESM without jamming). The antennas are 4 Rotman-lens array units, and target bearing is measured on each pulse. The system's threat library is carried in the helicopter's AYK-14 computer. There is a patrol-airplane variant with extended frequency coverage. See the Antiaircraft Warfare section for SLQ-32 details.

◆ ALQ-144

Sanders's infrared countermeasure for helicopters consists of a cylindrical heat source surrounded by a modulator, mounted either on top of or under the helicopter. It is used on board army AH-1S and UH-60 helicopters and on board marine AH-1J, -1T, and UH-1N helicopters. ALQ-144 was mounted on board LAMPS I helicopters deployed to the Persian Gulf as a countermeasure against hand-held IR missiles. Versions are -144(V)1, (V)3, and (VE), the last for export. Together with ALQ-147, ALQ-144 comprises the "Hot Brick" IR countermeasure of the army OV/RV-1D reconnaissance and observation aircraft. ALQ-147 is a fuel-fired IR countermeasure originally intended to fit the after end of the OV-1 drop tank; later a stand-alone version was developed. Presumably, the combination of 3 separate (and separately modulated) IR sources was intended to counter the IR equivalent of monopulse missiles (the combination would be equivalent to the "cross-eye" technique used to counter monopulse radar).

Deliveries of ALQ-144 began in March 1981; by 1988 over 1200 had been produced.

ALQ-144A is an upgraded version covering the long- as well as short-wave IR bands. The heat source is a piece of electrically heated graphite in a glass tube. The beam is concentrated by a lens, and a rotating reflector projects a beam. Total weight is 28 lb, and ALQ-144A operates at 1200 W.

◆ ALQ-146

The Sanders IR countermeasure to protect CH-46D helicopters was tested in 1976 and first ordered in 1977. Each CH-46D carries 2 ALQ-146s, 1 above the cockpit and 1 above the tail doors. The crew selects the modulating frequency.

◆ ALQ-149

The new EA-6B tactical communications jammer, by Sanders Associates, is compatible with the existing ALQ-99 and uses cooperative jam/look-through cycles to allow simultaneous operation of both systems. ALQ-149 is also intended to detect, identify, evaluate, and jam enemy long-range early-warning radars. Presumably, those abilities mean that it operates at somewhat lower frequencies than ALQ-99, e.g., against shipboard P-band radars.

In 1988 it was reported that this program had been delayed

because of a combination of severe technical problems and legal disputes between the original joint venture partners, Sanders and ITT. The current partners are Sanders and Lockheed Electronics. Reportedly, part of the problem was overambitious specification in frequency range; that problem has now been remedied. As of the fall of 1988, Sanders had delivered 6 of the 7 engineering-development models on order. Because the Vietnam-era ALQ-92 was removed some years ago, EA-6Bs are limited in their capabilities. ALQ-149 was planned as part of the ICAP-2 EA-6B upgrade, but delays have made it part of ADVCAP instead (FY91 and beyond). ASQ-191 was purchased as an interim solution (see entry).

◆ ALQ-156(V)

In October 1988 Sanders Associates received an FSED contract for the ALQ-156 Missile Detector, Integrated Defense Avionics Program (IDAP), for use on various navy tactical aircraft. ALQ-156 is a short-range pulse-doppler radar, intended to detect incoming missiles (such as IR types) that do not radiate and that, therefore, cannot be detected by RWRs. The radar creates a warning zone around an aircraft, and it is triggered by the closing rate and radar cross section of a detected object. It in turn fires IR decoys. It uses 2 blade antennas. The system was originally developed in 1976 to protect helicopters and slow aircraft; now it is being adapted to fast attack jets. Adaptation is relatively easy because the system is built around a programmable signal processor. A new buffer box connects it to other aircraft avionics. A new planar antenna has been developed for attack aircraft such as the A-6E (helicopters typically use a blade antenna, and slow aircraft, such as a C-130, use a horn antenna). The FSED contract calls for the design and production of 12 sets of equipment; the contract is to be completed by September 1990.

In IDAP (for modernized A-6E aircraft), the ALQ-156's spare processor capacity is used to integrate the system's ALQ-126B jammer, ALQ-156 MAWS, ALE-39 chaff dispenser, and ALE-50 towed decoy.

ALQ-156 (in helicopter form, with 2 blade antennas) weighs 50 lb and has an MTBF of 300 hr (MTTR is 15 min); power requirement is 425 W.

◆ ALQ-157

ALQ-157 is the Loral IR jammer for large helicopters. Two emitters are mounted, 1 on either side of the vertical tail of the helicopter, and the pilot can choose 1 of 5 jamming modes. Production began in 1983, for CH-53 and CH-46E helicopters. The system weighs 220 lb, and MTBF is 215 hr (lamp MTBF is 330 hr). Loral has proposed installation on heavy-lift aircraft (P-3, E-2C, C-130) as well as helicopters. In such aircraft, the optics would be shaped to correspond to the aircraft signature. At present ALQ-157 is carried by at least some Lynx helicopters (users unspecified), as well as by SH-3 and H-53 helicopters and P-3C and C-130 aircraft.

◆ ALQ-162 (Shadowbox)

Northrop's CW DECM system is a receiver-jammer and, thus, does not require any separate RWR. However, Shadowbox is compatible with any RWR, pulse jammer, or expendable countermeasure. Total weight is 40 lb plus two 0.5-lb antennas and a 1-lb remote control unit; demonstrated MTBF is 335 hr (260 specified). ALQ-162 uses 2 vertically polarized antennas, covering 60 deg to either side in azimuth and 30 deg up or down in elevation; the system can also interface with other ECM antennas as required. In 2 NATO air forces, the system is actually installed in the underwing pylons of F/A-18s.

ALQ-162 has been under test since 1981 and is planned for (or installed on board) A-7E, F-4S, AV-8C, and NATO F/A-18 aircraft.

ALQ-162 was the Compass Sail Clockwise jammer, intended to complement the non-CW ALQ-126; Northrop beat ITT for this contract.

◆ ALQ-165

ITT/Westinghouse joint-services Airborne Self-Protection Jammer (ASPJ) is made for upgraded F-14s, F/A-18s, and A-6s. Work on this system began in the early 1970s, a specification being issued in 1976. The ITT/Westinghouse team was chosen in 1981, but work was delayed because of the severe weight constraints imposed by the F/A-18. The final (12th) prototype was delivered, 2 years late, early in 1986. At that time the navy was comparing ASPJ to a combination of 2 existing jammers: the Sanders ALQ-126B and the new Northrop ALQ-162, which are less expensive and simpler. ASPJ survived this comparison, and initial production contracts, for 96 systems from each consortium partner, were let in September 1987 (for delivery in 1989). The total requirement is about 2500 systems for both navy and air force.

ASPJ is to be carried internally, and the original navy requirement called for very dense packaging. As of 1984, the required frequency coverage was 0.7–18 GHz, with a system response time of 0.1–0.25 sec; these capabilities were to fit within less than 2.4 ft³. Required resolution was 5 MHz, with an instantaneous bandwidth of 1.44 GHz and a minimum receivable pulse width of 0.1 microsec (false alarm rate 5/hr or less). The associated jammer was to be capable of dealing with 16–32 emitters (noise and deception jamming), with an accuracy of ± 0.5 –20 MHz. Frequency coverage is to be extended to 35 GHz in the 1990s. Required MTBF is 140–190 hr.

The ALQ-165 version for the AV-8B Harrier is podded; it weighs 380 lb, compared to 225 lb for the basic version and 306 lb for the internal common version.

ALQ-165 is connected to the aircraft RWR (e.g., ALR-67). The basic unit consists of 5 elements (WRAs): 1 high- and 1 low-band receiver, 1 high- and 1 low-band transmitter, and a processor. The F-14 version adds a high-band transmitter and receiver for aft coverage. Each TWT transmitter can operate in either pulsed or noise mode. An enhanced ("common") version has an additional high-band transmitter and an additional (simplified) receiver, for better aft-facing coverage. The original design was criticized because it could not simultaneously jam enough radars, and the number of range-gate deception jammers (effective against "older pulse radars") has been doubled in the production version.

ALQ-165 was also criticized for its volume and for the difficulty of producing it. The original design used multichip (hybrid) microcircuits, with reliability and quality problems. Now about half the original hybrids have been replaced with monolithic gate arrays, for a considerable savings in volume.

The current preproduction version is also easier to manufacture. For example, a hand-soldered wire harness was replaced by a multilayer mother-board (this reduced assembly time from 6 weeks to 4 hr). Plug-in modules for microwave signals now use plug-in RF connectors.

ASPJ passed a critical design review in June 1989, following successful completion of operational flight tests in the spring of 1989. Initial production (100 in FY89) was divided between ITT and Westinghouse; the partners compete for shares of the 150 ordered in FY90. Full-scale production is to begin in FY92, and ALQ-165 is to enter operational service in 1992. As of 1989, the system had undergone about 8000 hr of tests, including 500 of flight tests. Delivery of 20 preproduction (production verification, or PV) units began in the fall of 1989.

The U.S. Air Force withdrew from the program in 1990, but that is not expected to increase unit cost by very much.

The ASPJ is a navy-led program, derived from the ALQ-129 of 1972–77 and from the ALQ-136 (for helicopters) of 1977–80. The latter actually entered production.

◆ ALQ-190

AIRBOC (Air-Launched Rapid-Blooming Chaff) is a fleet countersurveillance decoy deployed from aircraft. Unlike CHAFFBUOY (ALQ-39), AIRBOC deploys immediately upon being launched.

◆ ALQ-192

This passive MAWS was developed by Cartwright Electronics for the navy; ALQ-192 is being considered for adoption by the air force.

◆ ALR-42

General Instruments's self-protection receiver is the primary threat allocator for the ALQ-99 system of the EA-6B Prowler. ALR-42 concentrates jamming power against the most hostile threat to the airplane itself, in order of lethality. It monitors both the threat and the output of ALQ-99 transmitters, ensuring that the system reacts to the threat, rather than to some side-lobe or harmonic of its own transmissions. It can also activate the chaff system automatically and display threats to the air crew. ALR-42 receivers are located in the pod atop the tail fin. ALR-42 is an analog system and was produced only in very limited numbers; ultimately all will be replaced by ALR-67s.

◆ ALR-45/ALR-68

The standard navy threat-warning receiver by Litton supersedes the earlier APR-25, from which ALR-45 was developed. It operates over a wider frequency range (2–14 GHz) and incorporates a fast digital threat processor. The antennas are 4 planar cavity-backed spirals, covering 360 deg around the airplane; and the display is a strobe on the aircraft's PPI. This system has been in production since the mid-1970s, and it has been adopted by several NATO countries. The current version is ALR-56F.

The original APR-25 was conceived in the early 1960s and purchased on a crash basis beginning in November 1965 after the first 2 U.S. aircraft, an F-4 and an RA-5C, were shot down by North Vietnamese SA-2s. APR-25 employed 4 antennas, and crystal video detectors concentrated in the threat bands. The direction of the threat signal was obtained by vector resolution of the 4 signals from the antennas, and the device was, therefore, initially called Vector IV. The related APR-26 was a launch-warning receiver, first employed in 1966. Both devices were developed by Applied Technology, Inc., a firm that had previously specialized in strategic reconnaissance and intelligence.

ALR-45 was a navy development based in part on the newly perceived Soviet naval surface threat in the Mediterranean. Introduced to the fleet in 1970, ALR-45 was a digital system employing early hybrid microcircuits. By this time it was essential that even an RWR sort and prioritize hostile signals on a semiautomatic basis, in view of the sheer number of hostile or potentially hostile radars both in Vietnam and in the Mediterranean.

In mid-1972 Applied Technologies decided to modify ALR-45 by substituting a digital computer for a projected circuit board change; the result was Vector V. Given the programmable computer (called a variable programmer-alarmer), the device could analyze the received probability distributions of frequency, pulse repetition interval, PRF, pulse width, pulse coding, and other radar parameters. All of these data were probabilistic because the receiver could never be sure whether it was sorting out signals entirely correctly. Even so, it could guess radar identifications based on pairs of frequency and pulse repetition interval (the inverse of PRF). The next step was for Applied Technologies to develop its own computer, the first intended specifically for EW. The desired characteristics were a volume of 100 in³, a power consumption of 80 W, and a throughput of 250 kwords/sec. The machine, the Applied Technology Advanced Computer (ATAC), appeared in July 1973, with a volume of 96 in³, a power requirement of 45 W, and a throughput of 1.25 Mwords/sec. The computer was made part of Vector V, and this system in turn became the ALR-68 of the West German F-4 force and also the basis for the Enhanced Radar Warning Equipment of German Tornados.

In U.S. service, ALR-45 is being superseded by ALR-67. During ALR-67 development, it was decided to retrofit the programmable processor being developed for the newer system into ALR-45. An engineering-development model (EDM) was com-

pleted in May 1978 and delivered the following July. Systems changes were required to support HARM, ASPJ, APR-43 (Compass Sail/Compass Clockwise), and the updated ALQ-126.

The current navy version is ALR-45D. The improved ALR-45F is to be installed on A-7E and AV-8C aircraft. It includes a software reprogrammable analyzer and an alphanumeric display of threat bearing, weapons, craft, etc., as well as identification and interface with ALQ-126B, ALE-39, and ALQ-162. The processor is designated CP-1293. Total production: 1015 ALR-45D, 341 ALR-45F.

◆ ALR-47/76/502

IBM manufactures these systems, which combine the ESM, ELINT, and RWR functions. The design is optimized to detect short radar transmissions, such as the single-pulse mode a submarine might use. RWR features are an audio alert and outputs to control a countermeasures dispenser. For the other 2 roles, ALR-47/76 provides emitter identification, location, and parameters in a digital interface to other aircraft systems. The system uses an array of 4 cavity-backed broad-band spiral antennas in each wing tip. The aeriels are directed to achieve monopulse direction finding. Signals are fed into 2 narrow-band superheterodyne (tuning) receivers, for automatic signal processing under programmed control.

ALR-47 is on the S-3A; ALR-76 is an improved version for the S-3B, the ES-3, and the EP-3E. The entire system weighs about 88 lb, and ALR-47 costs about \$150,000. The improved ALR-76 costs about \$250,000. Compared to ALR-47, ALR-76 has an extended frequency range, and other improvements include automatic emitter classification and modular design for future growth. It continuously tracks an emitter to obtain better location data.

ALR-47 development began in 1969, and it was first delivered in 1971 for S-3As. It entered full-scale production in 1972. ALR-76 was developed under an S-3A Weapons System Improvement Program (WSIP); the contract was let in July 1983. It has been adopted for the S-3B program (a contract for 40 was let in December 1987). ALR-66 beat out ALR-76 and ALR-77 in the competition for the P-3 Update IV program (July 1987).

ALR-502 is a version of ALR-47 for the Canadian CP-140 maritime-patrol aircraft.

A target-acquisition console Mk 105, developed from ALR-47, was built for the *Asheville*-class gunboats, and an upgraded Mod 1 version was installed on board the *Pegasus*-class hydrofoils and on board some frigates and missile destroyers. These Mk 105s are programmable passive fire-control systems.

◆ ALR-50

Magnavox's SAM threat-warning receiver, developed from APR-27, is being replaced (in U.S. service) by APR-43 and ALR-67. It detects target-tracking and missile-guidance signals. Production began in the early 1970s, and very large numbers were ordered (e.g., 800 sets, for \$22 million, in 1972). Platforms included the EA-6A and EA-6B, the A-7, and the F-14. Estimated cost is \$15,000. It is being replaced by the APR-43 in A-7E and AV-8B aircraft, and by the ALR-67 in F/A-18s, A-6Es, and F-14s.

◆ ALR-52

The airborne version of WLR-11 (see the Antiaircraft Warfare section), by ARGOSystems, covers 0.5–18 GHz and uses separate octave modules. ALR-52 is carried by P-3s.

◆ ALR-58

Sanders's ECM receiver for the P-3B Orion is a precursor of ALR-66(V)2. It uses the APS-88 radar antenna to generate bearing strobes of threat radars on the radar's PPI. ALR-58 uses both a crystal video and an IFM receiver and display; it can display 8.5–9.6-GHz signals, or it can be limited to 9.2–9.6-GHz signals. Signals received by the radar antenna are passed through the crystal video receiver and PRF sorter to the radar PPI; a blanker protects the crystal video from the normal radar transmissions.

◆ ALR-59/73

The passive detection system (PDS) for the E-2C Hawkeye uses 4 antennas: 1 at the nose, 1 at the tail, and 1 at the tip of each horizontal tailplane. PDS can process signals from any 2 of its 4 bands simultaneously, and it increases its dwell time on any part of the spectrum that shows increased activity. The system measures direction of arrival, frequency (by superheterodyne rather than IFM), pulse width, amplitude, and scan rate. Emitter data are presented at the edges of the PPI displaying the main radar picture and also on a separate tabular display. Emitter position can be obtained either by correlation between 2 E-2Cs or by triangulation as the E-2C moves.

ALR-59 was offered as a major enhancement to NATO AWACS (E-3A) aircraft.

ALR-73 is an improved version of ALR-59. ALR-73 employs 4 groups of antennas, 52 in all, to cover 4 bands (500 MHz–18 GHz). Each antenna has its own IFM, and pulse trains are separated and analyzed by a central computer. Direction finding is by phase interferometry. Frequency-scanning is automatic, and each band is separately and simultaneously processed. Signal data (pulse width, PRI, frequency, pulse amplitude, special tags) are sent to the central processor of the airplane for identification. The system cuts its overall data load by eliminating redundant emitters for a programmable period. The large phase tolerance inherent in its binary beam allows for considerable radome distortion and aircraft reflection. Direction-finding accuracy is about 2 deg. ALR-73 was developed by Litton about 1980. The associated computer is AYK-14. Unit cost is about \$2 million. This system will also be installed (in modified form) in the EA-6B ADVCAP.

ALR-59 development began in 1970, and the first example was delivered in 1973. In 1974 Litton proposed a modified version for *Spruance*-class destroyers, but less than a year later it was canceled in favor of SLQ-32.

◆ ALR-60 (Deepwell)

GTE's computer-controlled multi-operator communications intercept and analysis system is for EP-3E Orions. Seven have been manufactured.

◆ ALR-66/79/80/606

General Instruments manufactures these threat-warning and ESM systems. They are particularly interesting because the same series includes both relatively inexpensive RWRs and quite elaborate ESM devices to support long-range missile attack by detecting targets well beyond the visual horizon, the latter in the form of ALR-66(V)3.

The original ALR-66 replaced ALD-2D and ALR-52 on P-3C and other maritime-patrol aircraft. It had a fully programmable crystal video receiver (covering the E–J-bands, extendable down to the C–D-bands) for radar warning, and digital output for library comparison. A typical version, the export ALR-66(VE), achieves a direction-finding accuracy of better than 15 deg and has an associated threat library of 1000 radar modes. Other versions have over 1800 radar modes in their libraries. The -66(VE) library can be reprogrammed on the flight line in 90 sec or in the air using a computer memory reloader.

Emitters are represented by 3 alphanumeric symbols: 1 for pulse width (N for narrow, W for wide), a number (1–9) for PRF, and frequency band (E, G, I, J). Thus N5J would be a narrow-pulse medium-PRF signal in J-band. The usual polar display is used, and the code flashes to indicate a tracking radar (i.e., an immediate threat); symbols for search radars are illuminated steadily. The system can detect and identify pulse doppler, CW, interrupted CW, LPI, 3D (short dwell time), frequency-agile, jittered/staggered PRF, and pulse compression radars. Total weight in the (V)1 version is 59.4 lb.

Versions:

ALR-66(V)1 SH-2 (Sea Sprite), SH-3 (Sea King) helicopters. In LAMPS helicopters, this set was replaced in the early 1980s by the (VE) version. ALR-66A(V)1 is the newest configuration of

the (V)1 RWR for the SH-2F (see below). DF accuracy was better than 10 deg (resolution 1.4 deg). The library contained 100 emitters, and 15 could be displayed simultaneously on a 3-in CRT. The processor contained 8 kwords of RAM/ROM and operated at 1.2 MOPS. Emitters were described by 24-bit words, which could be compared in 1.1 microsec, for quick library search. This set replaced the earlier ALR-54. The contract was awarded late in 1974.

ALR-66(V)2 Development of this version was occasioned by the decision, in the early 1980s, to provide P-3Bs with Harpoon missiles. Thus (V)2 was designed for OTH-T rather than pure radar warning. Therefore, it had unusually high sensitivity (to detect weak signals) and an expanded signal memory (since it had to accommodate characteristic warship signals as well as threat radars). It also had much finer directional accuracy. It was integrated with other aircraft sensors and had had an interactive display and control panel. (V)2 combined the existing (V)1 RWR with the P-3B wide-band high-gain APS-80 radar antenna (Little Look Program) and some new hardware and software. This combination in turn inspired the development of the ALR-66(V)3 described next. (V)2 was carried by P-3Bs and was bought as an interim installation on P-3Cs.

This and similar versions of ALR-66 seem to be unique among airborne radar detectors in sharing the main radar antenna with the on-board radar. They do not, however, appear to use this antenna for BRIGAND.

ALR-66(V)3 This set was bought in 1984 specifically to provide P-3Cs with an OTH surveillance and targeting capability; it replaced the ALQ-78. It is similar in concept to (V)2, using the main radar antenna (in this case APS-115 rather than APS-80) for high-gain direction finding. (V)3 uses 4 C/D-band and 4 E/J-band spiral antennas, all mounted at the wing tips, mounted in groups of 4 to give 360-deg coverage in azimuth and ± 45 -deg coverage in elevation. These antennas are used to achieve nearly wide-open coverage. Once a target has been detected, its direction can be measured more accurately (and tracked) by using a subreflector in the main nose APS-115 radar dish, which provides high-gain directional cover of the C- through J-bands.

For high sensitivity, the E-J-band crystal video amplifier-receivers are mounted in the wingtips, close to the spiral antennas there. These receivers are computer controlled to receive signals in 1 of 4 bands (E/F, G/H, I, J). There are also dual-band C/D-band receivers. The frequency measuring unit (FMU) mounted in the fuselage has dual channels, corresponding to the 2 sets of receivers (wing tip and nose). The 2 channels (and the RF bands within them) are sampled in sequence, cyclically. The order in which they are scanned, and the time allowed per band, are chosen for optimum probability of intercept, depending on the expected emitter environment and the characteristics of the modified APS-115 radar. The FMU in turn feeds video signals to the computer-converter, where they are digitized for analysis and identification (either automatically or by the operator). In the targeting mode, the system measures emitter frequency, angle of arrival, PRF, scan width, scan illumination, and beamwidth. Emitters are identified by a 2- or 3-letter alphanumeric code and displayed on a polar screen. Those that the system decides represent lethal threats trigger aural alarms. The system also tags the highest-priority emitter with its ELINT catalog number and displays PRF, pulse width, angle of arrival, and frequency. The operator can call up similar data on any other emitter displayed.

The high-gain channel (using the nose antenna) operates independently of the low-gain wing-tip antenna channel. ALR-66 adds an ellipsoidal subreflector to the main APS-115 antenna. One focus of this secondary antenna is at the focal point of the main reflector, the other at the phase center of the radar. This arrangement allows for simultaneous operation of the radar and the high-gain ESM. This is the same arrangement as in the (V)2 version, and it has also been applied to the LN-66 radar in the LAMPS I helicopter. General Instruments offers a similar modification in the ALR-606 export versions.

B-52 bombers equipped with Harpoon missiles have had this system installed, using their search radars as the high-definition DF receivers.

ALR-66(V)4 High-sensitivity version of (V)1 with upgraded software and improved direction finding, for the E-6A TACAMO airplane, covering the C- through J-bands. Total planned production is 16 systems.

ALR-66(V)5 P-3C Update IV. Dual-channel version with parallel processing (one for ESM, one for targeting). The reference to targeting suggests that this is an outgrowth of (V)3. Unlike (V)3, (V)5 uses separate modules for the 2 roles. (V)5 uses a multilevel pulse-separation scheme to operate in very dense pulse environments. Signals are channelized (within frequency bands) at the detection stage to limit the spectrum being processed at any time. High-speed pulse encoders convert video signals to digital form, even during pulse overlap, to reduce shadow time. The preprocessor uses frequency and angle of arrival to limit data density at the signal processor. The manufacturer claims that this system uses a unique parallel pipelined architecture, with multiple processors. General Instruments emphasizes the use of generic threat processing, which permits the system to identify types of emitters even though those emitters are not in the threat library. Generic processing is important because many Third World threat emitters (manufactured in the West or in the Third World itself) may not be carried in libraries filled with the characteristics of Soviet-made equipment.

Lancer, an export version with passive targeting capability, has been developed from (V)5.

General Instruments also offers LESM, a lightweight version of (V)5 designed specifically for shipboard helicopters such as the SH-60 series. Apart from the associated radar antenna, LESM weighs 38 lb. It can track 1000+ threats simultaneously. LESM can use the main radar antenna for precise tracking, and it can also use ESM data to cue that radar onto a target before turning it on, for a lower probability of counterdetection. It uses 3 different RF-detection technologies: IFM, superheterodyne, and amplified crystal video, and multiple 32-bit processors. Presumably these features also apply to (V)5. LESM can use a separate dedicated directional antenna in place of the helicopter radar antenna. LESM was to fly night trials late in 1990.

ALR-66(V)6 Shipboard ESM, for self-protection and targeting, derived from the ALR-66 airborne series, for patrol boats up through destroyers. It employs a spinning/scanning antenna in a radome plus 2 sets of fixed antennas, each consisting of 4 spirals in a radome. It can operate automatically, or it can display signals to a dedicated EW operator; and it can feed digital data into an ECM, chaff/flare, or fire-control system. (V)6 is installed on board U.S. PHMs.

ALR-66(VE) Export version, used by Venezuela and New Zealand (in A-4s) and also in LAMPS I helicopters. This version is related to (V)3. It uses 4 spiral antennas, with 4 receivers, a digital signal processor, and a digital display, to cover the E-J-bands (some versions extend to the C/D-bands). Receivers are crystal videos (with superheterodynes added in some versions), and directional accuracy is better than 15 deg. The associated processor carries out 1.2 million operations/sec, a figure dictated by the density of the modern pulse environment. It has a 72×3 -kbyte memory, and the associated library can hold 100+ radar types and 1000+ modes; it displays 15. MTBF is 725+ hr.

ALR-66(VC) Transport aircraft version.

ALR-66(V)A1 System for LAMPS I helicopters and foreign Sea Kings. It operates in 4 frequency bands (E-J-bands) against all pulse types, including CW, ICW, pulse doppler, LPI (pulse-compression), 3D (pencil beam), jitter/stagger agile, and frequency agile. Up to 15 emitters can be displayed, each being assigned up to 3 alphanumeric symbols. Symbol positions on the 3-in CRT indicate approximate range (based on radar identification and thus on a comparison between received signal

strength and known emitter power) and bearing (based on comparison between strength as received by the 4 spiral antennas). Direction-finding accuracy is described as significantly better than 15 deg. Antenna coverage is 360 deg in bearing, and ± 45 deg in elevation. Shadow time is less than 2 microsec. The associated digital processor has a total capacity of 68 kwords, of which 28k are EEPROM/ROM; it operates at 1.2 MOPS. The processor accepts up to 500,000 pps. The full library (1800+ modes) can be reprogrammed in 90 sec. It has an MTBF of 700+ hr. Total weight is 60 lb. The antennas are 2.41 in in diameter and 1.53 in deep. Optional improvements are high-sensitivity detection, in-flight data recording, dual displays, extended frequency coverage, IFM, frequency set-on receiver, and a customized I/O bus.

ALR-79 This is a version of the basic ALR-66 for some SH-2F (LAMPS) helicopters. This is an upgraded version, more sensitive than its predecessor, with an IFM, a frequency set unit, and an interface for jammer control. It operates in the E-J-bands. The antennas are in the nose and tail of the helicopter; total weight is 102.75 lb. ALR-79 is described as a classified (special capability) system. The jammer connection suggests that it is used to supplement shipboard jammers, perhaps for operational deception. It may use the helicopter's LN-66 radar antenna for high-definition direction finding.

ALR-80 For A-4, F-4, F-5, F-16, Mirage, and Jaguar. It was announced late in 1985, based on ALR-66(VE)1. It carries 1800 radar modes in its memory. This system covers the C-J-bands. ALR-80 is intended as a direct substitute for APR-36, -37, -39, ALR-45, -67, and -69.

ALR-85 This is an outgrowth of ALR-66, for transport aircraft. New features include an IFM/superheterodyne receiver (IFM/SHR) and a C/D-band direction finder. With the IFM/SHR it can combine wide and narrow instantaneous bandwidths, for high sensitivity and high-density operations. The IFM provides a frequency measurement of each pulse using a wide-bandwidth receiver in a high-density environment; the superheterodyne gives more sensitive performance over a narrower band for earlier detection, providing a range advantage against weaker emitters (such as pulse doppler and CW radars) operating on narrow frequency bands. Coverage is C-J-bands; the library contains 1800+ emitters, and MTBF is 750 hr.

ALR-606(V)1 Export version for helicopters and fighters. It has the same hardware as ALR-66(V)1 and is typically installed on Sea Kings, Super Pumas, and Gazelles. There are some software improvements.

ALR-606(V)2 Export version for maritime-patrol aircraft. In March 1989 Pakistan bought this receiver for its P-3Cs. This system can track 35 radars simultaneously, and it can display 15 at any one time. Direction-finding accuracy is better than 15 deg, and shadow time is 2 microsec. The associated memory is 68 kbytes. This version is described as a cross between ALR-66(V)2 and (V)3, presumably also using the airplane's nose radar antenna for high-definition direction finding.

ALR-606(VE) Export version of -66(VE) for fighters including F-4, F-5, F-104, A-7. It differs from -66(VE) mainly in data presentation and threat library.

SLR-600 Shipboard version; see the Anti-aircraft Warfare section for details.

Approximate unit cost: \$75,000 for the pure RWR, \$250,000 for the ESM version.

◆ ALR-67

Itek's RWR is made for A-6E, AV-8B, F-14D, and F/A-18 aircraft. It covers 1-16 GHz, using 4 spiral antennas. The receiver is a hybrid (superheterodyne and TRF), and the system uses a digital computer (Vector V threat processor) developed from ATAC, the first computer developed exclusively for EW. The system is programmable in the field. Applied Technology, by that time a

division of Itek, won the ALR-67 competition in 1975. The company became a division of Litton in 1983. ALR-67 is form-fit-function compatible with the older ALR-45. The ALR-67(V)2 version is used on board the AV-8C (modernized AV-8A), F-14A, F-14D, and F/A-18, a total of 616 aircraft.

A similar system, ALR-68, was developed as the West German Advanced Radar-Warning Receiver. It uses a special version of the Vector V processor, but the RF and microwave sections are similar to those of the U.S. ALR-67.

In September 1988 the navy issued an RFP for an advanced special processor (ASR) to upgrade ALR-67; this new device was also expected to be the basis for a common navy-wide RWR. Hughes/AEL won the competition. ALR-67ASR is intended to enter service in 1995.

The ASR is so significant an improvement over ALR-67 that OSD opposed ASR on the grounds that it was in effect an entirely new program. OSD suggested that the navy buy an existing recent air force receiver, the Litton ALR-74. The navy successfully argued that its 1983-84-era technology would be obsolete by the time ALR-67ASR became operational in 1995. The ALR-74 components in question were its EPROM memory, its power supply, its superheterodyne receiver, its computer processor, its special receiver, and its quad receiver. Moreover, the navy argued that to adopt ALR-74 would be a maintenance disaster, as the carriers would have to support both ALR-67 and -74, rather than just ALR-67 and some additional components.

The ASR modification replaces the signal processor and some antennas but retains other elements and fits the form, power, and cooling of the original ALR-67. The new receiver provides increased frequency coverage, sensitivity, DF accuracy, and signal-processing throughput. Even so, the result is still an RWR rather than an ESM set.

In 1990 Litton was proposing ECP-510, which would be half-way between ALR-67 and -67ASR. ECP-510 has an interface with the host aircraft's INS and increases detection range by a factor of 10. If successful, it will enter service in 1992.

◆ ALR-75(V)

Scientific Communications's surveillance receiver system (0.1-40 GHz) is in service with FEWSG's EC-24A, ERA-3B, and NKC-135A aircraft. The digitally controlled system can use any combination of 8 independent tuners, covering either several bands (each tuner can handle 1 octave) or several portions of a single band, or a combination. The output of each tuner is analyzed separately, and signals are identified by comparison with the system's memory. Displays are digitally refreshed. Outputs include PRI, PRF, pulse width, frequency, antenna beamwidth, scan type, and scan interval. This system also exists in a ground version.

◆ ALR-87

General Instruments's RWR, a form-fit-function replacement for the air force ALR-46, uses the same azimuth indicator. It is carried by some F/A-18s. It operates over the C-J-bands, using 4 quadrant antennas and channelized crystal video receivers with a combination of IFM and distributed narrow-band superheterodynes. Memory is 128k EEPROM and 162 kwords of RAM (16-bit words), and the mission data recorder has a memory capacity of 1 Mword. There are 3 MIL-STD-1750A microprocessors, programmed in JOVIAL. The manufacturer claims up to 4 times the pulse processing capability of other systems. Preprocessing (deinterleaving) is based on frequency and angle of arrival. Total weight is 74 lb, and power input is 580 W. ALR-87 has 50% memory and processing capability reserve.

This device was announced in 1990.

◆ APR-39

This simple RWR, originally for light aircraft and helicopters, is also used in fast patrol boats and gunboats. The original (V)1 version was developed by E-Systems, (V)2 by Loral, and A(V)1 by General Instruments. As of January 1988, 6000 had been delivered, and the system has been exported to West Germany

(for PAH-1 antitank helicopters). Although the contracting agencies are the U.S. Army and the U.S. Air Force, APR-39 has important naval applications (e.g., to helicopters and to fast patrol boats).

Versions:

APR-39(V)1 Covers the F-I-bands, plus most of J- and parts of C- and D-bands. It has 4 cavity-backed spiral antennas in hemispherical radomes, plus 1 omni antenna (a blade) and 2 dual video receivers. The usual visual display (bearing, identity, radar mode) is supplemented by an audio tone whose frequency is proportional to the PRF of the intercepted signal. The entire system weighs about 3.63 kg and can be installed either internally or in a pod.

APR-39(V)2 This version has a new processor (Loral CP-480/APR-39(V)) that sorts and identifies intercepted signals, presenting them on the cockpit display. Memory is 19k (EPROM), and the system can filter signals by angle-gating or by PRI. Total weight is 6.5 kg.

APR-39A(V)1 New version with synthetic voice alert. The digital display indicates whether a threat radar is searching or has locked on, and when radar lock is broken. Threats are prioritized for display. The digital display automatically separates threat symbols when they become too dense for the pilot to read. APR-39(XE-2) is a special version for the Marine Corps and army special mission V-22s. The antennas are C/D-band blades and H/M-band spirals.

APR-39A(V)2 Shipboard Integrated Electronic Warfare System (SIEWS). SIEWS may also designate a larger system that uses APR-39A(V)2 as its warning receiver. The system operates in E-K- and C-D-bands (E-M optional), and provides synthetic speech warnings and alphanumeric symbology (for a ship combat system). It can be connected to other elements of a ship combat system via a 1553B bus and is compatible with NVGs. General Instruments envisages a system in which a laser warning receiver feeds into the APR-39, and the latter feeds missile warning systems and countermeasures launchers. This is apparently the ESM system on board U.S. Patrol Boats Mk III and IV.

◆ APR-43

Loral's radar-warning detector is installed in aircraft such as the A-7E. It was developed under the Compass Sail Clockwise program to provide tactical aircraft with threat warning and direction finding against C- and D-band pulse and CW missile-guidance systems; it provides C/D-band CW warning for other RWRs lacking such capability. APR-43 employs a single multielement blade antenna, a crystal video receiver (against pulse radars), and a superheterodyne receiver (against CW radars). It has a direct interface with ALR-45/45F (ALR-67 processor) and with ALQ-126/162 jammers. It contains those ALQ-162 antenna output elements required for CW jamming.

Compass Sail was a program to detect and analyze SAM guidance beams to warn pilots that a missile was en route. APR-43 replaced the earlier ALR-50.

◆ APR-44

AEL's CW RWR is used by both the army and navy and is adapted from the earlier APR-42. The antenna, mounted on a horizontal surface, provides coverage of a 50-deg arc to the rear of the aircraft. The receiver triggers an audio signal, a lamp, and a flashing light. Bandwidth is selectable.

◆ ARS-5

Cubic's ARS-5 is a sonobuoy reference system, an interferometer normally used to locate the buoys of a field by measuring phase differences between signals received by antennas spread over an airplane. See the description of the S-3A tactical system in the Surveillance and Control section; ARS-5 is the version in the P-3C Update III. Unlike earlier versions, ARS-5 contains its own embedded signal processor. Therefore, it functions as

an interferometric VHF direction finder. Cubic claims that it is designed for expansion into the ELINT DF role. The company also offers a stand-alone sonobuoy reference system (SRS) with similar potential.

◆ ASQ-171

This electronic intelligence system for EP-3E Orions is described as covering the A-J/K-bands and is capable of detecting back-scattered transmissions at long ranges. It is probably a direct descendant of the BRIGAND program of the early 1960s, and it may be a replacement for an earlier ALQ-110 (Big Look) carried by EC-121Ms and then by early EP-3s. This is probably the device that occupies the belly radome of the EP-3E.

BRIGAND is a technique for detecting the signals reflected by objects near a target radar; in effect it picks up a distorted version of the target's own radar picture. The technique was originally developed by VQ-1 technicians in 1960. They used the highly directional antenna of an APS-20 (the belly radar in the EC-121) to feed a very sensitive radar receiver (an APR-9). The resulting device was code-named GRAY SHOE and was used operationally in September 1960. It was soon discovered that, when receiver gain was turned up, the receiver showed not only the pulses of the target radar but also the ground clutter around it, i.e., the reflections of the target radar's own pulses. In theory, a really sensitive receiver could see not only the ground clutter around the radar but also some of the targets the radar was detecting beyond the clutter. Initially the clutter itself was well worth detecting because it could be used to map the terrain immediately around the target radar, and thus to locate the target radar very precisely. However, other applications were soon found. For example, even if only 1 ship in a group was radiating, back-scatter revealed the others.

In 1963 the VQ-1 technicians built a special receiver to exploit this phenomenon, using the EC-121's APS-20 antenna. The acronym BRIGAND (Bistatic Radar Intelligence Generation and Analysis, New Development) was coined at this time. The early EC-121 installation covered the 50-4000-MHz band. It comprised modifications to the APS-20, plus omnidirectional stub antennas for VHF and UHF band antennas, and 2 horn antennas in the dorsal radome. Presumably ASQ-171 employs similar antennas. BRIGAND first flew in June 1963 and was first operationally tested in August 1963. Tests early in 1964 showed that BRIGAND could be effective against both airborne radars and IFF transponders.

The first EP-3Bs were modified from P-3A airframes in 1969; they were flown by VQ-1. They were followed by conversions to EP-3E (and the 2 original EP-3Bs were modernized to -3E standard), beginning in 1971-72. Lockheed received a contract

An EP-3E, showing its large belly radome. Japan is reportedly converting 4 P-3Cs to a similar configuration, for naval surveillance. (Lockheed Aeronautical Systems Co.)

in 1986 for 10 further P-3C conversions. The major EP-3E signals-intelligence programs are Aries, Big Look, and Deepwell.

The JMSDF is the only other operator of a P-3 SIGINT version; it is not clear to what extent its aircraft correspond to the EP-3E. The JMSDF's first EP-3, converted by Kawasaki, was rolled out in July 1990. It carries NEC's LF and Mitsubishi's HF systems. The EP-3 replaces the current EP-2J, covering a wider frequency range and, because it flies higher, a larger area. The JMSDF expects to buy a total of 6 to replace the 2 current EP-2Js (2 have been ordered so far, the second for delivery in mid-1992).

◆ ASQ-191

Rockwell/Collins's communications jammer was developed originally by Collins to test its own communications system. The jammer was first purchased by the Fleet Electronic Warfare Support Group (FEWSG) to equip aggressor aircraft for fleet training. ASQ-191 was adopted for operational use on the recommendation of CDR James Powell, Readiness Officer for Medium Attack Tactical Electronics Warfare Wing, Pacific Fleet; he had encountered this jammer when he was a student at the Naval Postgraduate School. FEWSG lent 3 ASQ-191s to the Pacific Fleet VAQ organization, and VAQ-135 was the first squadron to deploy with the jammer. They used it during the Persian Gulf battle of 18 April 1988, helping to neutralize the Iranian Silkworm threat to U.S. warships in the Gulf. When VAQ-135 rotated home from the carrier *Enterprise*, the squadron left its ASQ-191s on board for the next EA-6B squadron to use. Ultimately the navy hopes to buy 40 ASQ-191s for use until the more sophisticated ALQ-149 is ready.

ASQ-191 is small enough to fit easily into the EA-6B equipment bay, betraying its nonstandard origins in its requirement for a special control console (in front of the right front seat of the airplane). The jammer's reported unit cost is about \$200,000.

◆ AVR-2

Perkin-Elmer's laser-warning receiver, usually for helicopters, is integrated with the APR-39 RWR. AVR-2 employs 2 warning heads and a comparator, to estimate threat direction. Work is currently underway on a version for fast aircraft.

◆ DLQ-3C(V)

The Pacific Missile Test Center developed this jammer for training (i.e., threat simulation) purposes, but DLQ-3C(V) is available as a "tactical contingency asset." SH-2 or SH-3 helicopters typically carry this jammer. The designation suggests a missile or drone application.

◆ ULQ-16

Electronic Support Systems Inc.'s (ESSI) pulse analyzer for ESM in ASW aircraft accepts signals at 160 MHz (intermediate frequency, reduced from the actual signal frequency by mixing upon reception). There are 1 automatic and 5 manual modes (time base, delayed time base, single sweep, self-test, and falling raster). ULQ-16 measures PRF/PRI, pulse width, pulse amplitude, scan time/rate, illumination time, and bandwidth. As of 1989, over 600 had been procured, and over 400 were in service.

◆ BGPHERS

The E-Systems Battle Group Passive Horizon Extension System is a passive detection system (ESM) to be carried by ES-3 aircraft. BGPHERS supplements land-based EP-3s. The surface-ship terminal for this system is SLQ-50.

BGPHERS was conceived as a replacement for the carrier-based EA-3, which was aging badly by the early 1980s. Lockheed had proposed an ES-3 during the 1970s, and under the EX program such an aircraft competed successfully with an EW version of the Grumman C-2. Plans called for the navy to buy 8 EXs initially, and ultimately a total of 24. EX in turn was canceled in 1987 in favor of BGPHERS, which was originally a palletized EW system that could be installed in the bomb bay of an S-3 and

The ES-3A (BGPHERS) prototype. (Lockheed)

controlled entirely from the carrier. Its virtue was that the carrier would not have to support additional special-purpose aircraft and so draw down either its strike or its ASW force.

As BGPHERS developed, however, the remote-control concept became less and less workable. Ultimately the navy chose to modify existing S-3As as special-purpose platforms.

◆ ES-3A

The ES-3A is the airborne element of BGPHERS, the Battle Group Passive Horizon Extension System. Much of the equipment matches that on board an EP-3, but the concept is very different. The ES-3A is an extension of carrier ESM, transmitting its data down to the carrier via a special wide-band data link (Link 11 is also installed). In this the ES-3A is broadly analogous to a LAMPS helicopter. Operator interaction with the sensors is minimized since the system is controlled primarily from the carrier. The predecessor aircraft, the EA-3B, was largely self-contained and had a crew of 7, compared to the 4 on board the ES-3A (the EA-3B also lacked the degree of automation in the ES-3A).

Most of the new electronic equipment is installed in the former weapons bay, with other equipment in the rear fuselage. It is served by 3 AYK-14 computers, which replace the single AYK-10 of the S-3A. All of the original ASW equipment is removed. The copilot's station is replaced by tactical displays for the NFO acting as EW combat coordinator. There are 2 EW operators, replacing the 2 acoustic-sensor operators of the S-3.

The S-3B imaging radar (APS-137) and FLIR (OR-263) are retained, as is its ALR-76. A fully passive navigational system, GPS, is installed for this passive sensor platform; this installation is part of a wider program to eliminate TACAN by 1997. Mission equipment includes signal analyzers and direction finders (covering all bands). A canoe radome is added along the spine of the airplane, and 2 circular radomes probably house very precise direction-finding antennas. It seems likely that the APS-137 radar is modified for BRIGAND operation. EP-3 digital processing and display systems are added (computers, mass memory, digital tape, color displays, and keyboards with trackballs). The net effect of conversion is to exchange nearly 6000 lb of new electronics for 3000 lb of ASW equipment. The new electronics spaces are air conditioned, which adds more weight.

Sixteen conversions are planned, under a 4-year contract. The first S-3A was delivered to Lockheed in 1988 and flew in 1989. Mission software was to be delivered at the end of February 1990, and the test program is to be completed in May 1991. Two squadrons will be formed, VQ-5 and -6, based at Rota and Guam, with 8 aircraft each. They will supply 2-aircraft detachments for carriers.

◆ FAEWS

These training EW systems are used to simulate enemy jammers. They are significant here for 2 reasons. First, the array of systems gives some idea of what Soviet-bloc jammers can be expected to do. Second, some of the training devices, such as

ASQ-191, have been used operationally. FAEWS is the FEWSG Airborne Electronic Warfare System; FEWSG is the Fleet Electronic Warfare Support Group. FEWSG flies ERA-3B Skywarriors and EA-7L Corsair IIs; it consists of 2 squadrons, VAQ-33 for the Atlantic Fleet and VAQ-34 for the Pacific Fleet.

The ERA-3B carries FAEWS, consisting of the ALT-40 noise jammer (0.1–17 GHz), the ALR-75 superheterodyne pulse-analysis receiver (100 MHz–18 GHz), the OE-320 direction finder (0.3–18 GHz), the DLQ-3 noise/deception jammer (0.4–11 GHz), and the ALE-39 chaff dispenser. The ALR-75 and OE-320 feed an HP-9826A computer, which in turn controls the ALT-40 jammer. The ERA-3B can also carry the ALQ-167 pod and the ALE-43 bulk chaff dispenser. The latter can lay a corridor 92 miles long. VAQ-34 was formed in March 1983, and the FAEWS system became operational in 1984. It replaced combinations of jammers carried aboard a variety of aircraft, including the last operational example of the B-47 Stratojet.

The EA-7Ls carry ALQ-167 pods and ALQ-170 pods that simulate the homing heads of antiship missiles. They also carry ALE-41 bulk chaff dispensers.

Other aircraft used for fleet training include A-4s used to simulate antiship missiles.

◆ Fly's Eye

This IR missile launch-warning system has been under development by the Naval Research Laboratory since 1983. It uses a set of wide-field of view indium antimonide focal-plane arrays (4–5-micron staring sensors) to achieve hemispheric coverage. Fly's Eye uses 2-color spectral/spatial/temporal processing to reject clutter and, thus, to detect the thermal plume of a missile being boosted into flight. Although the processing load is quite heavy (a 128×128 array typically produces more than 16 Mbits/sec of data), the program has been able to find a suitable processor developed for another program. NRL rejected a scanning approach because dwell times were short and because the associated software had to reconstruct the associated background seen by a staring sensor. As of 1990, Fly's Eye was still some years from the prototype stage.

The parallel air force program is SAWS (silent attack-warning system), using a scanning IR array. Its software uses multicolor spectral and track processing to reject clutter. Tests against a ground-based SAWS were scheduled for the spring of 1990, and an airborne version should begin flight tests in April 1991.

Both systems would replace the current electro-optical (uncooled sensor) AAR-47, which uses photomultiplier tubes to detect the radiation from a booster rocket.

◆ IDAP

The Integrated Defensive Avionics Program is built out of off-the-shelf items. An advanced development model has been mocked up and flight tested aboard an A-3 at China Lake. IDAP includes a missile detector and towed decoys. As of late 1989, tests against live missiles were expected in January and February 1990. IDAP is proposed for the Block-III A-6E upgrade, planned for FY91. The IDAP missile attack-warning system is the Sanders ALQ-156(V)N (see above).

◆ INEWS

Integrated Electronic Warfare System is the planned next-generation joint-service defensive ECM suite. The joint-venture team is Sanders/GE, augmented by Motorola and HRB-Singer. INEWS incorporates VHSIC technology. This program is led by the air force, and the planned applications are the next-generation tactical aircraft (ATF, ATA, and possibly ATB).

INEWS will differ from existing systems in that it will be an extension of the planned ICNIA (Integrated Communications/Navigation/Identification) suite that is to replace separate dedicated systems in future U.S. tactical aircraft, and that will be the most radical systems integration to date. Twenty separate systems, which together occupy about 8 ft^3 (600 lb), will be repackaged into a single box (4 ft^3 , 230 lb). Promised improvements in reliability will stem partly from a drastic reduction in

connectors and plugs between boxes. ICNIA was scheduled for flight testing in 1988. Integration of INEWS with ICNIA suggests that both systems will share common antennas and, indeed, that the total number of antennas on board the aircraft will be drastically reduced. That reduction should be possible partly through the increased use of electronically scanned arrays, e.g., in the aircraft skin ("smart skin").

Because INEWS will share antennas with ICNIA, the former will be able to detect and jam communications links, e.g., between fighters and airborne control aircraft. In theory, INEWS will cover the entire frequency range from HF up through infrared and laser.

◆ New Radar Warning System

For FY90 the Marine Corps plans to begin development of a new radar-warning system for its AV-8B Harriers. Unlike the current ALR-67, the new system would automatically begin defensive reaction. In addition, the new system is to be able to detect incoming infrared missiles as well as active and semi-active radar-guided weapons. No designation has been assigned. The initial requirement is for 160 such devices, with 70 more required later. Reportedly, the British are already installing such a system on their own Harriers.

◆ Boeing VJS/G-String

Boeing's Ventriloquial Jammer System was the unsuccessful alternative to the U.S. Navy (Raytheon/Hughes) AAED; G-String was the navy developmental name. VJS may be test-flown on a Canadian F/A-18. A jammer in the towing airplane feeds a simple conical reflector and polarizer towed on the end of a 90–150-m line. The result is a power centroid representing a virtual target; the line is (in effect) a high-grade video cable with the outer layer stripped off. The line and reflector cost \$500 and are jettisoned after a mission (the airplane cannot land with it). Boeing claims that 600 AAEDs, for A-6s, will cost \$255M, compared to \$30M for its VJS. The Boeing estimate does not include the cost of aircraft modification.

◆ Challenger

Loral's helicopter IR countermeasure is in service on board at least 1 country's Lynx helicopters. It has Matador and ALQ-157 features. Each system uses 1 or 2 transmitters, with multithreat jamming codes. Loral is marketing it for installation on Atlantic and Super King Air 300 maritime-patrol aircraft.

◆ EW-1017/ARI 18240/1

Loral's ESM system for maritime-patrol aircraft was adopted for the British Nimrod MR.2 under the designation ARI 18240/1. EW-1017 is on board German Atlantic maritime-patrol aircraft and also the British version of the U.S. AWACS (E-3). This system uses 16 cavity-backed spiral antennas in wing-tip pods, with front-end receivers also in the pods. The antennas form 2 sets (8 each) for high- and low-frequency bands; system coverage is probably 2–18 GHz. The associated receiver is a hybrid superheterodyne, operating broad-band for acquisition and then narrow-band for identification and direction finding. The system uses several parallel processors to deal with large numbers of pulses.

◆ Loral Advanced IR Countermeasures

In 1989 Loral announced that it was working on 3 categories of advanced IR countermeasures, all of them potentially applicable to naval aircraft.

Laser Jammers Loral is working on an air force program, Have Glance, for a laser-based IR countermeasure. It seems likely that Have Glance would use a laser to find a hostile IR sensor (by reflection in the appropriate frequency band), and then increase power to blind the sensor. Such operation would be analogous to several current or proposed laser anti-optics weapons. The company may also be working on direct counters to laser-guided missiles such as the Swedish RBS 70.

Pointable IRCM This is a counter to all-aspect IR missiles, such as the later versions of Sidewinder. Pointability is required because existing sources are not sufficiently intense when operated to cover all directions.

Advanced Expendables Loralei is a family of forward-fired expendables with multispectral emulators and aerodynamic maneuverability, i.e., a counter to future more intelligent IR seekers that can measure target motion and target spectrum.

Although these are largely proprietary Loral programs, they are interesting as indications of current trends.

◆ Matador

Loral's modular IR countermeasure is for large aircraft, such as Boeing 747s. Installations include dual sources aft (shown on a BAe 146), a single source forward, and sources underwing, in the slipper pylons carrying jet engines. A single control can handle 1–5 transmitters, each emitting 4–12 kW of IR energy. A standard transmitter can emit sufficient energy to overcome the emissions of a TF-33, JT3D, or CFM-56 jet engine. Current installations include the Lockheed L-1011, the VC-10, the Boeing 707, and the Boeing 747; this is probably one of the countermeasures protecting U.S. presidential and national-command-authority aircraft, and it is the sort of countermeasure likely to be applied to the E-6A.

◆ Peace Peek

E-Systems's SIGINT system was supplied for 5 German navy Atlantic aircraft.

◆ Varo LWS

The U.S. Navy is now testing this Laser-Warning System (reportedly for the 0.1–0.4-micron band).

EXPENDABLES

In 1986 the U.S. Navy was experimenting with semiexpendables, small radar repeaters towed on cables. Compared to full expendables, these repeaters could provide long-term coverage (whereas the launch of an expendable must be accurately timed).

◆ AAED

The next-generation active expendable is under development by Naval Research Laboratory. There are 2 versions. One is a forward-fired version, based on the 2.75-in rocket, that is intended to use an autopilot to fly relatively slowly ahead of the airplane. The other version is towed on a cable, probably powered by the airplane. Naval Air Systems Command is developing a 600-lb pod (based on the current 2.75-in pod) to carry both AAED (forward-fired) and chaff/flare decoys.

In 1989 a Raytheon-Hughes team was selected for 2-year full-scale development of the towed decoy. NRL remains the prime contractor for the forward-firing decoy, with a Teledyne CME payload, Garret guidance, and Atlantic Research propulsion.

◆ GEN-X

Texas Instruments's generic expendable jammer is to be carried in existing chaff/flare dispensers. In 1986 the design objective was a unit price of \$3000. The standard expendable size is 1.63-in diameter $\times$ 5.8 in (the air force cannot use navy expendables because the air force's chaff chutes are rectangular in section). Compared to POET, GEN-X can operate over several frequency bands. Thus an airplane need not carry many different types of active expendables and can devote valuable chute space to chaff and flares.

In September 1987 the Naval Air Development Center awarded Texas Instruments a contract for 288 of these decoys, to be delivered by September 1989 (\$19 million). The navy has an option for up to 30,000 such jammers. As of September 1987, Texas Instruments had already delivered 25 test decoys, as part of the competition leading up to the 288-decoy award.

Raytheon was selected as second-source in May 1988. Production is expected to begin in 1991.

GEN-X expendable jammer in combat. (Texas Instruments)

◆ POET

Sanders's Primed Oscillator Expendable Transponder (AN/AM-6988/A) is a small active system. POET was developed in the late 1970s in response to a suggestion by the Defense Science Review Board that the navy take the lead in developing expendable microwave decoys; POET was one of the first active expendables. It is launched via the standard chaff/flare dispenser. POET has a single antenna and is limited in frequency coverage. As of 1986, POET was the only expendable jammer in the U.S. inventory and was being manufactured at the rate of 2300 per month. POET fits within standard expendable dimensions, 1.4 in (diameter) $\times$ 5.8 in.

POET is to be replaced by GEN-X.

POET is the culmination of several earlier programs. In the mid-1970s Tasker Industries developed a low-frequency (A-band) expendable noise jammer, T-1219 (output 10 W, endurance 5 min), which could be ejected from standard chaff dispensers (and which was suspended from a parachute), and an adaptive expendable jammer to be carried by a Zuni or 2.75-in folding-fin rocket (in I-band). Bowmar/TIC developed a high-powered E/F-band expendable jammer, and Raytheon conducted a design study of a high-powered expendable TWT for I- and J-bands. Of these projects, the E/F-band jammer had been delivered by early 1975, and 250 T-1219s were scheduled for delivery by mid-1976. The Bowmar/TIC jammer was a fixed-tuned 55-lb device developed under a program called Tree Moth; output was 1 kW and endurance was 10 min (parachute descent). By early 1975 Tree Moth had been used in exercises, against ground-based S-band radars. At this time there was considerable interest in small jammers that could be carried on board RPVs, a theme that was revived in the 1980s. In the mid-1970s the primary sponsor was DARPA. For example, the navy tested the Tacit Rainbow (loitering ARM vehicle) concept in the form of PARM (persistent ARM), a Motorola radar seeker on board an MQM-74 Chukar drone, which could loiter over a presumed radar. DARPA and the air force were working on a complementary very low cost harassment vehicle.

◆ Samson

Samson is the expendable decoy developed by Brunswick and produced by Israel Military Industries (IMI). Samson's success in the Bekaa Valley in 1982 prompted the U.S. Navy to buy 100

The SAMSON decoy, predecessor of TALD. (Brunswick)

SAMSON being launched. (Brunswick)

for operational evaluation. The decoy is a glider, carried on a standard aircraft hardpoint, that dispenses chaff or generates false targets as the plane flies toward the target. This decoy was the outcome of a series of studies and prototypes for the U.S. Air Force; when U.S. support ended, the Israeli Defense Ministry took over.

Brunswick developed the Model 150 Maxi Decoy (tested 1973) for carriage, with folded wings, in the external-stores rack of a strike aircraft. Three Maxis could be carried in each of a Phantom's Sparrow-missile positions, and 2 could be carried on a 750-lb hard point. Maxi was a high-subsonic glider, but Model 290P (1974) was self-propelled, with a circular rather than square-section fuselage. That model in turn led to the design of the cylindrical-fuselage unpowered Samson 1, manufactured under license by IAI. The U.S. Navy bought 100 Samsons in 1985, for further operational evaluation, and in 1987 bought another 1000, plus 1500 of the improved TALD.

◆ TALD

The Tactical Air-Launched Decoy was developed from Samson and shown for the first time in 1986. TALD carries emitters, mimicking fighter radars and ECM systems, in its nose and dispenses chaff from its belly. The navy ordered its first batch of 500 TALDs from Brunswick in December 1985. In November 1987 the navy ordered another 600, with an option for 1000 more, production to be split between IMI and Brunswick. TALD reflects Brunswick experience in decoy design under the air force Maxi program (1973). Brunswick was also involved in an air force powered-decoy program in the late 1970s. The TALD development contract was let in December 1985.

The decoy can dispense chaff, either continuously or in packages, from its tail. It weighs 450 lb and achieves a 10:1 glide ratio, so when it is launched from 40,000 ft at 250 kt it flies for 68 nm. Launched from 2000 ft, at the same speed, it flies 14 nm. The manufacturer claims that 1 TALD costs about one-thousandth as much as a combat airplane, which probably means much less than \$50,000 each.

Both TALD and Samson are carried like 500-lb Mk-82 bombs, their swept wings folded back; over 20 can be carried in the multiple ejectors of a typical attack bomber or fighter. The decoy carries an autopilot, which can be programmed with launch altitude and flight profile (and, presumably, deception program)

The Brunswick TALD decoy. (Brunswick)

TALD under the wing of an A-7E of VA-76. (U.S. Navy)

before takeoff; no special on-board control equipment is required.

Compared to Samson, TALD has a square (rather than round) cross section for greater chaff capacity, a better active emitter, a better chaff dispenser, and a wider carriage-and-release envelope. There are several different versions. RF TALD has active radar amplifiers and a "reflective lens" system. Chaff TALD is for force masking, ejecting chaff from its rear in 40 increments. IR TALD is for IR-missile training. TALD has been in service since 1986, and 2900 are scheduled for delivery by the end of 1991. Brunswick has proposed (and displayed at Farnborough in 1990) an Improved TALD with turbojet power (with an improved IR signature and a more realistic flight profile); range would be about 125 km [68 nm] at M 0.8 at 20,000 ft. This ITALD is now in development.

The FY91 defense-appropriations conference's report calls for development of a TALD variant for defense suppression, with a seeker and a warhead. Feasibility studies are currently underway. There is some question as to whether any version of TALD could duplicate Tacit Rainbow's capabilities, and as of late 1990, it seemed likely that the navy would rejoin the Tacit Rainbow program in FY92. The FY91 report called upon the navy to accelerate work on the powered ITALD by using unspent FY90 money as well as FY91 R&D money.

◆ Tracor's Smart Expendables

In the fall of 1990 Tracor was reportedly working on 3 new expendable decoys. They are probably typical of next-generation concepts. Two are free-flying IR decoys: one is a free flier that uses its own heat (pyrotechnic) source both to generate a signature and to propel itself, and the other is a towed decoy that carries a burner heating a bulb tuned to the airplane's IR signature. The fuel and bulb coating can be varied to suit the towing airplane. Both concepts are intended to defeat IR missiles that can measure the spectrum of the emitter (mainly using 2-color seekers) and missiles that measure an emitter's dynamics to reject unpowered decoys (mainly using gyros for proportional navigation). Tracor is also developing an expendable RF emitter, the Straight Through Repeater Antenna Performance (STRAP) decoy. The company is developing a short-life TWT amplifier for future active RF decoys.

ANTIAIRCRAFT WARFARE

Naval air defense is directed both against missiles fired at warships and against enemy aircraft. The same systems that can deny an enemy access to a fleet can also help cordon off an area some distance away in which friendly aircraft may be operating, e.g., while they attack shore or surface targets or pursue submarines. In peacetime or cold war, naval air-defense systems may be naval air-control systems, supporting surveillance or examining potentially unfriendly aircraft. Thus U.S. naval air defense, in the form of F-14s controlled by airborne radars (on board E-2C Hawkeyes), was able to identify and then to force down the Egyptian airliner carrying the hijackers of the *Achille Lauro* in 1985. The same air defense was able to isolate strike zones in Libya in 1986 so that A-6 Intruders could attack without fear of Libyan air attack. In Vietnam, naval surface-to-air missiles offshore actually shot down enemy fighters attempting to engage U.S. strike aircraft.

Because modern aircraft are so expensive, they cannot be produced in vast numbers, and naval air-defense systems can help to achieve air superiority by the destruction of enemy aircraft. Such air superiority would result, for example, if the air defenses of American carrier battle groups destroyed a significant fraction of attacking Soviet bombers. In this case, defense would be transformed into an offensive means of gaining sea control (maritime air superiority). On the other hand, shorter-range missile systems almost certainly would not be positioned well enough to engage the bombers but would find themselves defending the carrier and her consorts from whatever missiles the Soviet bombers managed to fire.

Modern naval air-defense systems divide naturally into long (area), short (point), and very short (close-in) ranges, with systems straddling each of these divides. Really long ranges become more difficult to achieve as incoming targets approach at higher speeds, since the fundamental limits of all air-defense systems include reaction and, therefore, detection times. At very long range, moreover, air defense can turn into an attack on the platforms from which the original attack is launched, be they aircraft (missile-carrying bombers), ships, or shore launchers. Only in the case of the bombers is this end of the air-defense spectrum included in classical anti-air warfare measures.

Thus, the longest-range anti-aircraft weapons are the long-range missiles carried by naval-defense fighters. For the purposes of this book, these defenders are carrier-based fighters, which are operated by only a very few navies. Land-based fighters, generally not under naval control, can, of course, contest the passage of antiship bombers. However, the historical record strongly suggests that such fighters often cannot appear in time to engage passing bombers, especially if the bombers can evade over enormous sea areas. The advantage of the carrier-based fighters is that their bases are in the bombers' target areas, so the bombers must necessarily fly toward them.

All long- and medium-range weapons are necessarily terminally guided. At shorter ranges, however, unguided gunfire can be effective, particularly if produced in sufficient volume. Missiles are generally limited not only in maximum but also in minimum range, as they require time to accelerate to a speed at which sufficient air is flowing over their fins for effective guidance. In contrast, guns can be aimed down to zero range.

Maximum effective gun range is largely determined by how well the target's future position can be predicted, since the shell travels to an aim point computed slightly before the gun is fired. Any error in aim point against an air target will cause a shell to miss. Proximity fuzes make up for such errors by exploding a shell near a target, and in such cases maximum effective range is determined by the maximum miss range within which the proximity-fuzed shell is still lethal. That range depends on the speed of the target and on the average speed of the shell, since the miss distance will increase over time. Effective range also depends on how quickly the associated fire-control system computes a solution; the faster the computation, the less outdated the data on which firing must be based. The faster the shell, the less a target can move while the shell is en route, and thus the lower the chance that the fire-control solution will be wrong

by the time the shell arrives near its target. Hence the current U.S. interest in exotic high-velocity weapons such as rail guns. For a gun firing against a surface target, maximum range is determined by the steepness of the trajectory. A flat-trajectory shell will pass through a target even if the aim point is slightly in error. A steeply falling shell, however, will pass in front of or beyond a target. The tolerable miss distance corresponding to a given range is the danger space associated with the gun.

For all air-defense systems, there is a minimum acceptable kill range, since even a badly damaged missile may well follow a ballistic trajectory into a targeted ship, and since the fragments of a severely damaged missile will continue along its original path. Weapon lethality is, therefore, a very important issue. Proponents of very small caliber weapons, such as Phalanx, rely heavily for the physical destruction of an incoming missile on the fuzing of its warhead as a result of penetration by 1 or more projectiles. If the warhead is not fuzed, the missile may well continue into the ship. For example, in a 1986 U.S. Navy incident, a self-propelled Chukar target was hit by USS *Antrim* and scored as killed. It flew into the water but glanced off and continued into the ship, killing a man and severely damaging the ship's unarmored combat information center. Proponents of larger-caliber weapons (such as the Bofors 40- and 57-mm guns) claim that, although shots are much fewer, each is far more lethal, as its fragments can fatally damage a missile.

Thus, even if an air-defense system defeats all the missiles attacking it, those missiles may still do some damage. The lesson would seem to be, not that active defense is pointless, but rather that it must generally be combined with some form of passive defense: ships will be damaged, but they must remain afloat and at least partly effective. Most passive-defense issues are outside the scope of this book, but one is very important: the rise of distributed rather than centralized combat systems. To the extent that a combat system (and its power supply) can be spread over the length of a ship, the system cannot be eliminated by a single concentrated hit. Here the key technologies are probably data busing (so that several widely distributed computers can maintain the same current combat data base) and relatively inexpensive high-density electronics (so that there is no need to concentrate the combat system in a single central computer, either to provide enough computing power or to provide that power at a reasonable price). If a ship and her combat system can survive several hits, an increased burden will fall on the attacker, who must launch more weapons (of individually greater power) and who, thus, may find it difficult to deal with as many separate ships. Survivability may make decoying more effective or may force the attacker to concentrate an attack (e.g., to fly several aircraft together) in a manner increasing vulnerability and reducing saturation.

Lethality issues also apply to missiles. Very few missiles can be expected to actually hit small incoming targets. Rather, most will employ proximity fuzes to convert a near miss into a hit. The proximity fuze is triggered by the nose of the missile, and defending and attacking missiles may well be passing each other at or above Mach 4. There is a finite time lag while the proximity impulse activates the missile's fuze. Then there is also a finite interval while the explosive effect of the defending missile propagates to its target. Mach 4 is approximately 4000 ft/sec, and this speed leaves very little time to destroy a missile less than 10 ft (i.e., less than 1/400 of a second) long.

This problem explains the decision to abandon continuous-rod warheads in the U.S. and British navies. Continuous rods were adopted after World War II as a means of cutting through the airframes of large bombers and thus inflicting fatal damage; these warheads consist of rods joined together at alternating ends, wrapped around explosives. When the warhead detonates, the rods are forced apart into an expanding ring, which eventually breaks apart. The rods have considerable inertia and cannot move very fast. An alternative is pure blast-fragmentation, which may not chop up a bomber as effectively as a continuous rod but which propagates much faster. Presumably, the ultimate

warhead would employ a shaped charge focused in one direction; the missile would roll toward its target before bursting.

The air-defense missiles described here vary considerably in guidance, ranging from self-guided (by infrared or active radar) to semiactive (homing on a signature imposed on the target) to command-guided (following decisions made externally). Each type of guidance has its own advantages. Self-guidance minimizes the load on the launch platform. In an airplane, self-guidance means fire-and-forget operation, allowing a fighter to engage multiple targets in quick succession. Similarly, in a ship, self-guidance helps counter saturation. However, because the intelligence that can be packed into a small missile is necessarily limited, the missile may be unable to overcome target countermeasures. In theory, the greater the intelligence that can be incorporated in a fighter or a ship, the greater that platform's abilities. However, pure command guidance necessarily becomes less accurate as range increases, since any particular angular error equates to a greater and greater miss distance (and ultimately to a miss distance beyond the lethal radius of the missile). Semiactive guidance is a compromise: the ship or airplane imposes a signature on the real target (and so limits the efficacy of countermeasures); but, homing on reflected energy, the missile, in theory, gains accuracy as it approaches the target. Semiactive guidance, however, requires that the weapons system dedicate a guidance illuminator to one target throughout the flight of the missile or missiles. For a ship, the number of such illuminators is limited by topside configuration. No airplane can afford more than a single illuminator. Thus, systems designed to defeat saturation are driven toward some mixture of command and self-homing. Command guidance has the additional advantage of extending a missile's range by flying the missile along an energy-efficient path. In contrast, semiactive guidance requires some type of pursuit path, which is inherently inefficient.

For the present, perhaps the single most important question is the extent to which shipboard systems can continue to provide area defense against faster and faster incoming attackers, i.e., in the face of shorter and shorter warning times. Without some form of area defense, each ship (and, ultimately, each merchant ship) needs its own point defense. On the other hand, if even modest area defense becomes sufficiently expensive, navies will be unable to field sufficient numbers of effective warships. One possibility is that missiles as they are currently understood will be superseded by lasers or other exotic directed-energy weapons, for which time of flight will no longer be a meaningful limitation.

This section includes a wide variety of shipboard missile countermeasures, both active (jammers) and passive (decoys). Often they are associated, the jammers pulling an incoming missile off into the cloud of chaff. One problem with such systems is that the missile is unlikely to detonate in the chaff cloud. The missile may emerge from the cloud only to begin a target-reacquisition routine; and the missile, if it still has sufficient fuel or energy on board, may then find the original target. That scenario would be most probable for missiles that hit their targets at very shallow angles, such as most sea-skimmers; missiles designed to make terminal dives may well dive through a chaff cloud into the sea. Thus, the best defense against a sea-skimmer may include some means of triggering the missile after it has been decoyed. One possibility would be to fire shells into the sea under the chaff cloud, to create a wall of splashes into which the missile would fly (or that would, at the least, trigger its fuze). No system integrating chaff and jammers and medium-caliber guns currently exists; but as combat systems become more fully integrated, such tactics would seem to be very easy to implement.

This section also includes submarine periscopes, with an emphasis on optronic devices. Because sonar may be limited in its ability to detect and track surface craft, periscopes are often the submarine's primary surface-search sensors and, thus, are in the same category as the submarine radars listed and described here.

Moreover, the newer optronic (or photonic) periscopes share the technology of the optronic sensors and fire-control devices described in this section.

Periscopes are changing radically. Until the last decade, they were all optical, and most submarines had 2 types, a wide-angle search periscope and a narrow-angle attack scope, the latter intended to leave the narrowest possible wake so as not to reveal too easily the position of the submarine. A submarine commander would obtain a surface picture by making a quick sweep with the search periscope, the duration of the sweep determining both the quality of that picture and the extent to which there has been exposure to detection. Much of the submarine officer's training (for example, in the British "perishers' " course) was devoted to forming a coherent surface picture after the briefest sweep.

As for the technology, very compact optics was developed to provide such facilities as alternative air and surface search in the same narrow tube, as well as stadimetric range finding. A stadimeter measures the angle between the horizontal and the observed height of an object; if the height (usually the masthead height) is known, the range can be calculated. From a submarine's point of view, the advantage of stadimetry is that the baseline is the object being measured, rather than the range-finder (which must be quite small, so as to be unobtrusive). The horizontal equivalent of stadimetry, using the observed length of the target, is impractical because most targets will not be at right angles to the line of sight of the periscope.

There are also special night periscopes with greater light-gathering power. Some search periscopes are binocular, with duplicated windows at the top. At one time many search periscopes provided for air search, but now air warning is more usually the function of a radar-warning receiver found atop the search periscope.

Two major developments are associated with the post-1945 revolution in submarine design and performance, the combination of high underwater speed and indefinite submerged periods (snorkeling when required). The first development required search and radar periscopes that could be extended at relatively high speeds (the U.S. Navy called for periscopes that were extendable at 14 kt). High speed in turn induced severe vibration, and images had to be specially stabilized. The second development required sextants for taking navigational fixes to be incorporated in search periscopes. Conceivably, this requirement will lose its urgency with the rise of very accurate and universally available satellite navigational systems such as GPS, but surely the sextant will always be desirable as a backup against the destruction of the satellites.

Optronics is an outgrowth of television and thermal (IR) imaging technology. Periscopes were initially provided with these sensors, such as image intensifiers (low-light-level television, in effect), to extend the periscopes' usefulness to lower light levels. However, as with surface-ship and aircraft applications, the potential of converting the image into an electromagnetic signal is much greater since the image itself can be processed. In surface or air applications, the emphasis is usually on processing for tracking. In a periscope, the emphasis is more on processing the image to extract all of its information content and even to merge it with other relevant data.

The 2 applications of such cameras are quite different. A conventional or LLLTV camera can be inserted in the bottom of the periscope, taking the same image as the periscope's eyepiece, on much the same principle as a single-lens reflex camera. However, an infrared sensor is best placed at the top of the periscope since thermal photons traveling all the way down the tube (e.g., to a camera at the base of the periscope) would suffer from added noise. Moreover, the optical components of the periscope will not focus or reflect infrared radiation as they do light itself. Thus, a conventional periscope cannot be converted to infrared operation by simply installing a new crosshead, whereas that periscope can relatively easily be provided with an image intensifier.

Infrared operation requires installation of a thermal camera at the head of the periscope. The IR sensor must be cooled, and the coolant led up a very narrow periscope tube (or else a very compact refrigerator must be incorporated in the small periscope head).

Existing optronic periscopes employ a camera analogous to the window of a periscope, fixed rigidly to a tube that the observer rotates. However, there is no reason for the observer to memorize the scene as quickly as the periscope is turned. In principle, the sensor can make a very quick scan (or even look simultaneously in several directions), and the image can be stored either digitally or in a video recorder, for display as desired on a CRT. The newer sensors can provide images of optical-periscope quality. That capability, in turn, opens up some very interesting possibilities.

The exposure associated with a periscope depends on 2 factors: the sheer size of the head and the time during which the head projects above water. Optonics probably always requires more space than simple optics, but optonics can also greatly reduce exposure time, since observation need not coincide with exposure. The submarine commander can view the resulting images for a protracted time, well after they have been created. Modern digital CRTs can display these images alongside other sensor data, such as ESM data collected at the same time by the same mast. The officer viewing such a windowed CRT can fuse the data from these various sources to form a much better tactical picture. In theory, the same CRT could also display relevant sound data, again adding to the overall tactical picture in a way impossible for a conventional optical system.

Perhaps at least as importantly, the commander of the submarine would no longer have to be the operator of the periscope sensor, just as the commander is not the operator, but rather the supervising user, of the various other acoustic and non-acoustic sensors on board a submarine. The skipper could obtain the full tactical picture without having to concentrate on the necessarily fleeting periscope image. Those manufacturers offering digital optronic or photonic periscopes, such as Dowty and Plessey, tend to suggest radically revised arrangements for submarine control rooms or operations rooms, in one case with the periscope image on a large screen on one bulkhead, surrounded by relevant data-base readouts (e.g., the characteristics of the ship shown on the screen, to the extent that the expert computer system connected to the data can identify the contact).

An optronic sensor unit might also be far lighter than conventional periscope-head optics and, thus, might be much easier to stabilize and even to control in an autotrack mode.

Moreover, there is no reason why an optronic or photonic sensor must be mounted on a mast penetrating into the control room of the submarine. In some submarines, such as the German IKL designs, all masts other than the periscope are already nonpenetrating; they telescope out of the sail of the submarine. Nonpenetration reduces structural stress in the submarine's hull and can simplify mast design, since the body of the mast no longer needs to be pressure tight. Instead, most of the mast can be free flooding. That design would allow the use of non-metallic (i.e., non-radar-reflecting) materials. Moreover, there are considerable advantages (both in drag and in radar cross section) to be gained by using a noncylindrical mast (which is acceptable if the head, rather than the entire mast, rotates).

A control room or CIC served by an optical periscope must be directly under the sail, and that requirement complicates the arrangement of the submarine. For that matter, the central position of the optical periscope greatly complicates the internal arrangement of the control room or CIC; in theory, a much more efficient arrangement is possible. Presumably, the ultimate simplification would be to eliminate the mast altogether, placing the optronics and other sensors in a towed body that the submarine could launch and recover and that would use some inertial device (such as a ring-laser gyro) to locate itself relative to the hull of the submarine. In theory, such a devel-

opment would greatly reduce the drag and noise of the submarine's hull, and the submarine could remain much farther below the surface at what would amount to periscope depth.

In practice, submariners have resisted total dependence on any form of electronics; an optical periscope will still work even if electrical problems have put computers and displays out of action. Attempts to eliminate the submarine's sail altogether have been quite frequent, at least in the U.S. Navy, but have generally failed because the sail is needed for some other quite essential purposes: for good depth keeping near the surface in relatively shallow water (but this requirement does not apply to a submarine with her foreplanes on her hull); for navigating on the surface, e.g., when entering port; and for supporting the snorkel.

It would be impractical to convert an existing optical periscope to optronic or photonic operation because considerable information is lost between the lens at the top and any sensor inserted at the bottom, particularly with infrared images. On the other hand, periscope photography, which is a sort of predecessor to optronics, has been common for many years.

SHIPBOARD RADARS AND FIRE-CONTROL SYSTEMS

CANADA

RADARS

◆ SPG-515

Band: X (8.5–9.6 GHz) **Beam:** 2.6 deg **Peak Power:** 250 kW
Gain: 39 dB **Pulse Width:** 0.25 microsec **PRF:** 1000 ($\pm 10\%$)
Scan Rate: 29.2 Hz in conscan or spiral scan
Scan Angle: 4.1 deg conscan, 12.6 deg spiral scan; beam shift 0.5 deg in conscan, 0.5–5 deg in spiral scan
Antenna Dimensions: 40 in diameter

SPG-515 fire-control radar (MK 60 director) on board the Canadian destroyer *Annapolis*, 1989. (G. Till)

This new solid-state Norden radar replaces the U.S. SPG-48 on board Canadian destroyers (frigates); the modified FCS is designated Mk 69 Mod NC6 (not Mk 60, as sometimes reported). The new FCS is said to show a 40% improvement in accuracy against moving, incoming targets. Mod NC6 is a digital version of the old U.S.-supplied Mk 69 analog system. Additions include an angle-error indicator and a digital range computer.

The original SPG-48 was a repackaged Mk 35, using the 250-kW transmitter and reflector of Mk 25. Maximum target range was 40,000 yd, and acquisition range was 25,000 yd.

◆ SPS-501

This radar is essentially a Dutch LW-03 antenna combined with a U.S.-type SPS-12 transmitter. In 1984 a Canadian company, SPAR, marketed a new solid-state receiver for SPS-12 radars,

presumably intended largely for the modernization of existing Canadian SPS-501 radars. The company also improved range resolution (to 200 m in wide-band/short-pulse mode, and to 800 m in narrow-band/long-pulse mode). Specified MTBF was over 10,000 hr. The modification kit was also much smaller than the original SPS-12 receiver.

◆ SPS-502

Cardion Electronics's solid-state surface-search radar, although using the SPS-10 antenna, has more than 95% of its parts compatible with the company's SPS-55.

◆ SPS-503

Band: S (2.7–3.2 GHz, i.e., frequency-agile over 500 MHz)
Beam: $1.5 \times \csc^2$ to 40 deg
Peak Power: 20 kW (average 800 W) **Gain:** 30.75 dB
Pulse Width: 54 microsec (0.6 microsec subsidiary pulse)
PRF: 739 pps (stagger, plus or minus 12.5%)
Scan Rate: 10 or 20 rpm **Antenna Dimensions:** 4.7-m width
Antenna Weight: total system weight 1300 kg [2865 lb]; antenna 490 kg [1080 lb]

SPS-503 and (above it) SPS-10D radars on board the Canadian destroyer *Annapolis*, 1989. The director atop the bridge carries an SPG-515 radar. (G. Till)

This air/surface-search radar, by Canadian Marconi Radar (CMR), is made for the modernized frigates (DELEX program) and replaces the older U.S. SPS-12. An adapted Marconi S1821, SPS-503 is a pulse-compression radar using a coherent transmitter (providing digital MTI); it has both MTI and non-MTI channels. The SPS-503's antenna is that of the Plessey AWS-4. This radar can employ either linearly or circularly polarized radiation, the latter being useful in severe weather. There is an

SPS-503 radar antenna at the Canadian Marconi plant, Kanata, Ontario. (Canadian Marconi)

alternative 2.44-m stabilized antenna in a radome, providing a beam of $2.8 \times \text{csc}^2$ to 30 deg, with a total weight of 500 kg and a scan rate of 12 and 24 rpm. Gain is 28.5 dB. Signals are horizontally polarized. The basic radar using the alternative antenna is designated CMR-1 (a Canadian Marconi designation).

Canadian Marconi also offers a version using an unstabilized planar-array antenna (3.5-m aperture, $2.1 \text{ deg} \times \text{csc}^2$ to 40 deg beam, 29.8-dB gain, 10/20 or 15/30 rpm scan). Signals are vertically polarized.

SPS-503 uses 2 TWTs driven in parallel (with output phase matching) by a solid-state frequency synthesizer. Transmission modes: pulse-to-pulse frequency agility among 16 frequencies (non-MTI), block-to-block (3-pulse) frequency agility (MTI), and fixed-frequency (MTI). PRF can be staggered to protect against lock-on jamming, and a jamming-strobe indicator alerts the operator to the presence and azimuth of noise jammers. The transmitted pulse consists of a 54-microsec chirp (which is pulse-compressed) and a short (0.6-microsec) unmodulated pulse, the latter for short ranges, to reduce energy on target (and thus the reflected energy from nearby clutter). The receiver compression ratio is 207.7:1, and the range cell is 39 m (minimum range is 200 m). The first blind speed is 1700 m/sec (3300 kt). Rated ranges against 4-, 1-, and 0.1-m² targets: 152, 108, 61 km (126, 90, and 51 km, respectively, with the 2.4-m antenna). Instrumented range is 160 km. Accuracy: 2.5 m in range, 0.29 deg in azimuth. Resolution: 39 m, 1.5 deg. Rated reliability: 305 hr MTBF, 1.0 hr MTTR.

A related radar, CMR-4, uses the 2.4-m antenna also, but at C-band (5.4–5.9 GHz), with a single TWT, the same transmission modes as CMR-1, and peak power 14 kW (mean power 330 W, PRF 1600 pps). Rated ranges against 4-, 1-, and 0.1-m² targets are 74, 52, and 30 km, respectively.

◆ LN-66 (CMR-85, SPS-59)

Band: X (9375 MHz) **Beam:** $2.5 \times 22 \text{ deg}$ **Peak Power:** 75 kW
Gain: 30 dB **Pulse Width:** 1.0 or 0.1 microsec
PRF: 500 or 2000 pps **Scan Rate:** 22 rpm
Antenna Dimensions: 36 in
Antenna Weight: total weight 22.9 kg

Data in this table refer to LN-66 HP, the search radar of the U.S. LAMPS I helicopter.

This surface-search radar, built by Canadian Marconi, has been very widely exported, both in its shipboard version and in a related helicopter version (on board U.S. LAMPS I helicopters). A related radar is used for submarine navigation (U.S. *Ohio*-class submarines), on board U.S. LCAC landing craft, and also on board U.S. small combatants such as the SEALs' Seafox. In the 75-kW version described above, range discrimination is 18.3 m. Range scales are 1, 2, 3, 12, 24, 48, and 72 nm.

LN-66 occupies the small radome halfway up the mast of the USS *Barnstable County*, 1986. The masthead antenna is SPS-10, and the "washtub" in the foreground is the OE-82 satellite-communications dish. (S. Terzibaschitsch)

The 75-kW version of the LN-66 radar. A modified form is installed on board U.S. Navy LAMPS helicopters. (Canadian Marconi)

The basic 10-kW version is designated SPS-59(V)1 in U.S. Army service. 59(V)1 uses a 5-ft slotted-waveguide antenna (AS-3146). A current solid-state version of the basic radar increases power to 12 kW. These radars can also be used with a 3-ft (radome-enclosed) or 8-ft slotted waveguide. This 3-ft antenna, not described above, produces a $2.7 \times 26 \text{ deg}$ beam (gain 26.5 dB). Pulse widths are 0.5 and 0.09 microsec (PRFs 800/1250 and 2500 pps, respectively). Minimum range is 20 yd, and range

scales are 0.25–48 nm. There are also 5-ft (60-in) and 8-ft (96-in) slotted-array antennas used with the 75-kW transmitter described in the table. The 60-in version has a 1.6×19 -deg beam (gain 29 dB) and scans at 24 rpm. The 96-in version has a 0.88×19 -deg beam (gain 31 dB). A version with a dual-display is used as TPS-66 in the U.S. Navy AN/TSQ-108 Radar/Sonar Surveillance Center.

As of 1988, Canadian Marconi was offering a 90-kW version of the basic radar to replace the 75-kW version. The former has the same pulse widths and PRFs as the 75-kW version.

In addition, there is LN-66 SP, a 6-kW version for submarines and small craft, that uses either a 3-ft radome antenna or a 4-ft detachable slotted waveguide (1.9×26 -deg beam, gain 28 dB). Pulse widths are 0.5 and 0.12 microsec (PRFs 1200 and 3000 pps). Minimum detection range is 25 yd, and range scales are 0.5–32 nm. About 1988 the LN-66 SP was redesignated CMR-85. Despite the official AN/SPS-59 designation, LN-66s in U.S. naval service are almost invariably called LN-66.

◆ Sperry Mk 127E

Band: X **Beam:** 1 deg **Peak Power:** 25 kW
Pulse Width: (i) 0.05 (ii) 0.025 (iii) 1.2 microsec
PRF: (i) 4000 (ii) 2000 (iii) 500 pps

A Canadian *Annapolis*-class destroyer shows, top to bottom, SPS-10D (turned toward the mast), SPS-503, and Mk 127E (the slotted waveguide at bottom), with SPG-515 below atop the director. (G. Till)

Mk 127E is now the standard Canadian naval navigational radar, superseding Sperry Mk 2. It was introduced about 1983. Range accuracy is about 1%. Range scales: $\frac{1}{4}$, $\frac{3}{4}$, 1.5, 3, 6, 12, 24, 60, 120 nm. This radar supplements SPS-502/SPS-10.

OPTRONICS

◆ SAR-8

The Advanced Development Model of the SAR-8 IR search-and-tracking sensor. (SPAR Aerospace)

The General Electric/SPAR infrared-search and target-designation (IRST) system was a joint U.S.-Canadian project. SAR-8 was tested at sea in 1978 on board HMCS *Algonquin* and in 1979 on board USS *Kincaid*. Full-scale engineering development began in FY84.

SAR-8 is a cylindrical mechanism gimbal-mounted for stability, continuously scanning for a 2-sec data rate (track-while-scan). This system can passively detect both air and surface targets, using a signal processor to detect small targets in heavy clutter. The surface display provides both a 360-deg panoramic view and an expanded display of any selected sector, for target identification. The published description suggests that SAR-8 is able to detect incoming air targets by the glint on their forward surfaces or by the aerodynamic heat generated on the targets' bodies. This type of system can also detect incoming missiles beyond the horizon by sensing their exhaust plumes. Although generally not precise enough for missile counterbattery fire, such detection can be used to trigger countermeasures under EMCON conditions.

Total weight is about 6500 lb, of which 1350 lb is above decks. The ship provides heading, speed, and altitude data, and SAR-8 scans at 0.5 revolutions/sec. Power requirement is 25 kVA, and above-deck volume is about 150 ft³. The associated computer is the new standard UYK-44. A combination of filters (spatial and temporal) and tuned algorithms is applied to the scene as observed; each source is analyzed to determine whether it is either (i) an airplane or missile or (ii) clutter. Any source classified as (i) has its bearing, elevation angle, and track data transmitted directly and automatically to the combat system. This point-source processing is supplemented by a panoramic image of the surrounding ships and other surface features, which is provided to the operator.

SPAR Aerospace developed its first infrared search-and-track system in the early 1960s, and between 1962 and 1967 developed an infrared acquisition system for the abortive U.S. Mauler point-defense missile. In 1968–70 the company developed and tested an Infrared Electronic Warfare System (IREWS) for the U.S. Navy, and this system was further modified in 1971–73.

The prototype SAR-8. (SPAR)

In 1974-77 the Canadian Navy sponsored the development and test of a Shipboard Passive Surveillance-and-Detection System (SPSDS). That project in turn led in July 1976 to a U.S.-Canadian MoU and Joint Project Agreement to develop an advanced development model of the IR Search-and-Track System (IRST), which became SAR-8. The Joint Agreement for Engineering Development of SAR-8 was signed in January 1983, and SPAR was selected as prime contractor in August 1984.

Full-scale development should have begun under the FY81 program, but Congress decided that the more sophisticated U.S.-built Seafire was superior. Work on SAR-8 was, therefore, suspended, while Seafire died of gross cost overruns. SAR-8 was then revived, and the prototype was scheduled for land tests at Port Hueneme through mid-1990, followed by shipboard tests in 1990-91, followed by production in 1991 and installation on board *Spruance*-class destroyers beginning in 1993. SAR-8 will probably be installed on board later *Wasp*-class (LHD 5-7) and *Arleigh Burke*-class ships. The U.S. Navy also evaluated the French VAMPIR but decided that its signal-processing capability was less than that of SAR-8. Meanwhile, work is proceeding on integration with other systems. The 1990 tests included operation with the Mk 23 Target Acquisition System, to support Sea Sparrow missile operation, and there were also efforts to integrate SAR-8 with the Aegis combat system and with the evolving NAAWS system. Follow-on work is scheduled for integration with ACDS and with SLQ-32.

CHILE

The ASMAR national shipyard exhibited several radars at the 1984 Feria Internacional del Aire (FIDA) at Santiago. Foremost among them were a dual-band (S and X) shipboard fire-control radar (6 of which had been produced) and a containerized S-band air-search radar.

The radar development group dissolved soon after, and it was being revived, on a more modest scale, in 1989.

CHINA (PRC)

SEARCH

◆ Bean Sticks/Pea Sticks

This *Luda*-class destroyer carries a Bean Sticks long-range air-search radar (4 × 4 array of yagis) just forward of her after funnel. The foremast radar is an Eye Shield (MX-902) short-range (target-indication) air-search set. The forward end of the platform carries a surface-search radar. The secondary battery consists of twin 37-mm and 25-mm machine cannon, and she carries 2 triple missile launchers. (U.S. Naval Institute)

This *Luda*-class destroyer carries a Pea Sticks long-range air-search radar. (U.S. Naval Institute)

The 2 names indicate alternative antennas for the same P-band early-warning radar, in *Luda*-class destroyers. Bean Sticks consists of 4 bays, each with 8 yagis.

◆ Eye Shield (MX-902)

An Egyptian *Jianghu*-class frigate shows, on her mast, an Eye Shield air-search radar at top and a Square Tie missile target-designator 2 levels down. One of the slotted waveguides is a Decca radar; the other is a Chinese Type 756. The director carries what appears to be a yagi array (like that of the old British Type 285) on its roof. The twin 37-mm guns are locally controlled. (U.S. Naval Institute)

A Chinese *Jianghu*-class frigate shows an Eye Shield radar at her mast-head, with a Type-756 navigational radar (the slotted waveguide) and Square Tie (missile fire control) below it. (U.S. Naval Institute)

Eye Shield is the air-search radar in *Jianghu*-class frigates. The antenna is a long, slim paraboloid, similar in overall shape to such Soviet radars as Slim Net and Head Net A, except that the Chinese antenna is of solid rather than lattice construction. (Slim Net is still in Chinese service on board 4 Riga-class frigates built in Chinese yards [with Soviet parts] in the late 1950s.)

The Chinese designation for Eye Shield is MX-902.

This radar is also in service on board the Chinese frigates transferred to Egypt.

◆ ESR-1

Band: S **Beam:** 2×10 deg (dual-beam pattern) **Gain:** 33.5 dB
Scan Rate: 30 rpm **Antenna Weight:** 350 kg [770 lb]

This low-altitude air-search radar was displayed at the ASIANDIX exhibition in Beijing in the fall of 1988. The antenna is roll-stabilized, and the 31-cm [12-in] PPI is arranged for plot extraction by roller-ball. The scope can also display synthetic video, and the radar can extract moving targets. The MTI improvement factor is 22 dB. The manufacturer, the China Shipbuilding Trading Co., claims that ESR-1 can detect a 0.1-m^2 sea-skimming missile (flying at a height of 8 m) at a range greater than 12 km [about 13,000 yd].

The data above are taken from the manufacturer's brochure. No power or pulse data were given.

◆ Rice Screen (Sea Eagle)

Band: C (described as upper end of G-band)
Beam: 2.7×1.4 deg **Peak Power:** 150 kW
Pulse Width: (i) 40 (ii) 20 microsec (compressed to 1 microsec)
PRF: (i) 370 (ii) 730 (average power 2.2 kW) pps
Scan Rate: 5 rpm

This planar-array 3D pulse-compression radar entered service in the mid-1980s and was publicly displayed (with the data given above and below) at the ASIANDIX 1988 exhibition in Beijing. Rice Screen is marketed for export by the Nanjing Marine Institute.

There are 2 types, with larger and smaller antennas. The data above refer to a large antenna, much taller than it is wide. A smaller type is reportedly 2.3×3.0 m, which would not quite correspond to the beam figures above. However, the beam figures come from the claimed resolution performance, and the resolution in azimuth may be degraded somewhat as the beam sweeps up while the radar turns. The radar antenna shows a prominent fin on one side, presumably carrying a serpentine (frequency-scanning) waveguide. Phase shifters are presumably used to allow the radar to sweep in frequency (both for pulse compression and for frequency agility) without sweeping its beam up and down.

This radar can semiautomatically track 10 targets simultaneously, using what the manufacturer calls an extraction PPI operating semiautomatically. Probably the operator designates the targets to the associated computer. Two or more entries of the same target (on subsequent scans) provide the computer

Rice Screen (top), Type 756, and Fog Lamp (bottom) on a *Jiangdong*-class frigate. (U.S. Naval Institute)

with a track. The operator then monitors later detections of the same target to see whether it remains on a constant course and speed. The target's altitude may be as high as 25,000 m [82,000 ft]. There are 2 operating modes: low angle (up to 7.2 deg in elevation) to a maximum tracking range of 180 km [197,000 yd], and high angle (to 28.8 deg) out to a maximum range of 120 km [131,000 yd].

The transmitter is a TWT CFA chain, and reception is coherent, with an MTI improvement factor of 30 dB. Accuracy is 100 m in range and 0.8 deg in azimuth and elevation. Resolution is 200 m in range. Operation is over a wide band (10% of frequency), with adaptive frequency selection on a pulse-to-pulse basis.

◆ Type 354

Band: C **Beam:** 1.2×5 deg **Peak Power:** 500 kW
Pulse Width: 2 microsec **PRF:** 400 or 800 pps
Scan Rate: 4–10 rpm

This low-altitude air-search radar is used for target acquisition on board missile frigates. The antenna is roll- and pitch-stabilized. Claimed range on a 10-m^2 target is over 50 nm, accuracy is 5 m in range and 5 mrad in bearing, and resolution is 300 m in range and 1.3 deg in bearing.

◆ Type 756

Band: (a and b) X (c) S
Beam: (a) 1.3×20 deg (b) 0.8×18 deg (c) 2×22 deg
Peak Power: 50 kW **Gain:** (a) 30 dB (b) 32 dB (c) 27 dB
Pulse Width: (i) 0.08 microsec (ii) 0.5 microsec (iii) 1 microsec
PRF: (i) 2000 (ii) 1000 (iii) 500 pps **Scan Rate:** 18–22 rpm
Antenna Dimensions: (a) 2 m (b) 3 m (c) 3.8 m

This navigational radar uses a slotted-waveguide antenna. Range scales are 0.5, 1.5, and 3 nm with short pulse; 6, 12, and 24 nm with 0.5-microsec pulse; and 48 and 96 nm with long pulse. The complete system uses both X- and S-band antennas for all-weather performance. Minimum range is about 30 m (mast height 15 m), and range discrimination is 25 m. Accuracy is 1% of range or 0.02 nm (whichever is greater) and 1 deg.

FIRE CONTROL

◆ EFR-1

The China Shipbuilding Trading Co. displayed this new naval radar fire-control system at the ASIINDEX exhibition at Beijing in November 1988. EFR-1 is a radar fire-control system externally similar to the French Castor series (i.e., with a Cassegrain antenna), with a television camera and a laser alongside the radar. EFR-1 was described as operating in X-band, with MTI processing, and was credited with the ability to acquire targets with cross sections of less than 2 m^2 at ranges beyond 30 km (and small sea-skimming missiles at 13 km).

EFR-1 is being offered as a feature of several new warship designs being offered for export; presumably this system is planned for a new generation of Chinese warships.

◆ Fog Lamp

This radar is the H/I-band SAM fire control for the HY-61 missile.

Top to bottom: Rice Lamp, Fog Lamp, and a twin HQ 61 missile launcher on a Zhongdong-class frigate. (U.S. Naval Institute)

◆ Rice Lamp

This radar is an X-band gunfire-control radar.

◆ Coastal Radars

Details of 4 types of coastal radars have been published. Type 404A is an X-band set with a solid elliptical antenna similar in shape to that of Eye Shield. Claimed accuracy (resolution): 100 (200) m, 0.35 (0.8) deg. The second type is an otherwise undesignated X-band coastal tracking radar, using a 200-kW transmitter (pulse width 0.2 microsec), and a 1×2 -deg beam antenna. Claimed range on a 7500-ton target is 60 nm; accuracy (resolution) is 30 (60) m and 1.5 (20) mils. The third type is the Eagle coastal radar, a mobile (truck-mounted) X-band radar. A published photograph suggests that the radar proper is radome-

mounted, with a large colocated IFF antenna (which itself resembles a radar antenna but has far too thin a mesh to work at X-band). Claimed range is 50 km on a 1000–2000-ton ship, and accuracy is 15 m in range and 0.09 deg in bearing.

In addition, at the Paris Air Show in 1989, CEIEC (China National Electronics Import & Export Corp.) announced a new JY-9 low-altitude search radar, which could also be used for coastal defense. It operates in S-band, using a dual-beam low-sidelobe antenna ($4.2 \times 7.5 \text{ m}$, for a 1.3×40 -deg beam; the upper and lower beams cross at 4 deg of elevation). The transmitter is pulse-to-pulse frequency agile and coherent, for doppler MTI, and the radar automatically detects and tracks targets. The antenna can be erected on a lattice mast for better low-altitude coverage. The radar can be set up or dismantled by 4 operators in 20 min.

DENMARK

The Royal Danish Navy uses a variety of British radars under its own designations. CWS-1, -2, and -3 are Plessey AWS-1 with different antennas (CWS-2 and -3 use Selenia reflector antennas; CWS-1 uses a slotted waveguide similar to one of the AWS-6 antennas). NWS-3 is Terma 20T48, a Decca 1629 built under license. NWS-1 is presumably an earlier Decca slotted-waveguide radar.

◆ Terma GCA Radar

Band: X (9.0–9.2 GHz)

Peak Power: 80 kW

Pulse Width: 0.18 microsec (± 0.02 microsec)

PRF: 3500 pps

This radar has been adopted (in navalized form) for the Brazilian carrier *Minas Gerais*. The data above refer to the land-based version. The radar uses 2 separate antennas for elevation and azimuth, as in the U.S. SPN-35 and the Italian SPN-720. Both outputs are displayed together on a 16-in CRT (elevation above, azimuth below, both in expanded form: $8 \times$ elevation, $3 \times$ azimuth). The range scales are 10 and 15 nm (range markers at 1-nm intervals). Electronic cursors on the elevation display show glide path and maximum permissible downward deviation (safety cursor). Typically, the elevation display shows alignment lines at 6, 3, and 1 deg, and the azimuth display shows similar lines at 15, 5, 0, and -5 deg. These data apply to a GCA-radar modernization program offered by Terma for any of a range of standard GCA radars. The beam characteristics are probably similar to those of the U.S. SPN-35.

◆ Terma Skanter Mil Radars

Band: X (9 GHz) or S (3 GHz)

Beam: 1 deg (horizontal beamwidth) at X-band (2 deg for S-band version)

Peak Power: 20 kW **Pulse Width:** (i) 0.06 (ii) 0.6 microsec

PRF: (i) 4400 (ii) 2200 pps

Gain: greater than 30 dB (X) or 28.5 dB (S-band)

Scan Rate: 24 or 48 rpm (60-Hz power; 20 or 40 rpm using 50-Hz power supply)

Antenna Dimensions: 2.1 m (X-band), 4 m (S-band)

Terma Elektronik AS, a Danish company, has developed several slotted-waveguide surface-search and navigational radars for the Danish and Swedish Navies. The Danish designations are NWS-1, -2, and -3; the standard Swedish unit is Skanter 009. The published data above refer to a radar whose development was completed in 1972. The transmitter is a magnetron, and the system as a whole can accommodate either S- or X-band operation, or a combination of the 2 (using different transmitters and antennas, feeding a common display). All displays are raster rather than rotating scan and are usable in daylight; they are adapted to show tactical system symbology and to operate with automatic tracking.

FRANCE

All French shipboard naval radars are products of Thomson-CSF. TRS numbers in parentheses are the commercial designations.

nations, where they apply. Many directors are produced by CSEE.

RADARS

◆ DRBC 32

DRBC 32 is an X-band monopulse pulse-compression radar designed specifically to control the 100-mm automatic gun. Its beam is 1.5 deg wide. Targets are automatically acquired, and all processing is digital.

This series was begun in 1961. DRBC 32A is on the *Suffren* class, some frigates, the *Jeanne d'Arc*, the *Clemenceau* (replaced by 32C in the *Foch*), and the *La Galissoniere*, and the T-47 ASW destroyers. DRBC 32B is on the *Aconit*. DRBC 32C is on the cruiser *Colbert*, the *Foch*, on *Commandant Rivière*-class frigates, and on some A69-class corvettes. DRBC 32D is on the *Tourville* and *Georges Leygues* classes (the 3 last ships of the latter class have DRBC 33 instead). DRBC 32E is on the *d'Estienne d'Orves*-class corvettes. DRBC 33 is replacing the DRBC 32 on the *Suffren* class.

The DRBC 32A and 32B versions both employ Cassegrain antennas; the others are all lightweight dishes with offset feeds. Originally DRBC 32 was always mounted on a quadraxially stabilized director carrying a stereo range-finder, designated TT type A (as installed on board the frigate *Aconit*); approximate weight is 11 tons. The director (*télépointeur*) was initially to have had a crew of 3, but that was reduced to 2 (pointer and observer/range-finder), at least in the case of the *Aconit*. Presumably, earlier versions had pointer, trainer, and range-finder operator. In this type of director, 2 of the axes are used to stabilize the platform of the director, and the other 2 point it at

DRBC 32C radar/optical director on board the carrier *Clemenceau*. (L. van Ginderen)

DRBC 32E fire-control radar on board the corvette *d'Estienne d'Orves*. (U.S. Naval Institute)

the target. Elevation limits: +80/-2 deg. A new lightweight unmanned biaxially stabilized radar-only director was developed for the *Tourville* class, based on the Masurca director. It is used with DRBC 32D and 32E, and with some 32Cs (the *Commandant Rivière* class retains the earlier manned director).

In the A69-class corvettes, the associated fire-control system employs a hybrid (analog-digital) computer.

Of the earlier fire-control sets, DRBC 31 survives to control 57-mm guns in the *Colbert* and the *Tartar* destroyers.

The first postwar French fire-control radar was ACAE (*Artillerie Contre Avions Éloignés*), which appeared about 1950. It employed 2 dishes side by side. ACAE was apparently a CW radar, since a recent French account notes that it could automatically generate height and bearing information, but not range. ACAE was installed on board the battleship *Jean Bart*, on the antiaircraft cruisers, and on the *Surcouf*-class destroyers. It was later replaced by the more conventional single-antenna DRBC 11. This radar was roughly contemporary with DRBC 10A (first tested 1955), the main-battery fire-control radar of the *Jean Bart*, which had an effective range of 25,000 m against surface targets. It used a "double cheese" antenna. The other fire-control radar of this generation was DRBC 30, a stabilized blind-fire radar director similar in concept to the U.S. Mk 63, used to control the standard twin 57-mm gun mount. It was succeeded by DRBC 31.

◆ DRBC 33 (Castor II: TRS 3203)

Band: X Beam: 2.45 × 2.3 deg

Peak Power: 30 kW, 120 W average **Gain:** 36 dB

Pulse Width: 0.5 microsec

PRF: computer controlled between 4000 and 8000 pps

Antenna Dimensions: working circle 1.6 m; dish diameter 1.053 m

Antenna Weight: total director weight 620 kg

Data are for the Castor IIC version. The original Castor II may have used 4-microsec, 80-kW pulses.

Reportedly capable of acquiring and tracking a 0.1-m² target at 8 nm, this radar is built both for the French navy and for export.

Castor II is a monopulse tracker using a Cassegrain antenna. Tracking includes multigate doppler filtering (900 m) using an 8-point FFT; the fully coherent transmitter is a TWT that can produce numerous computer-chosen frequencies over a 700-MHz bandwidth, somewhat less than 10% of base frequency. Tracking range is 500-30,000 m, and the first blind speed is at or beyond Mach 2. Elevation limits are -25 and +85 deg.

Acquisition is automatic, for very quick reaction, at ranges up to 25 km on a fighter and 15 km on an antiship missile. To ensure accurate tracking, the radar operates in short bursts (1.5 msec) at constant frequency, associating frequency agility and doppler processing; the radar can also jump from frequency to frequency on a pulse-to-pulse basis. Castor II can also passively track a jammer using range information from a tracker linked to a search radar. When directing shellfire, this system can display the angular error between shell and target. The radar can also be used for autonomous surveillance, scanning at a fixed elevation.

Castor IIB (TRS 3200) is a somewhat less sophisticated radar using the same antenna as II, but with single-knob tuning within the 700-MHz band. Pulse width is set at 0.4 microsec and PRF at 3600 or 7200 pps (with staggering). MTI processing uses a 3-memory filter. Compared to Castor IIC, IIB's sea clutter rejection ratio is 30 rather than 40 dB, and the transmitter weighs 80 kg rather than 200 kg.

Castor IIC limits: tracking range 0.5-27 km, radial speed 1000 m/sec, maximum train (elevation) speeds 1 (1.5) rad/sec. The probability of automatic acquisition in free space, for a 2-m² target, is 80% at 25 km. Clutter cancellation ratio is 40 dB for ground clutter, 35 dB for sea clutter. The associated TV/IR camera (TRAKIR) can place extraction gates (2.2 × 1.7 or 4.4 × 3.4 mrad) around a target, for tracking. The camera has a 35 × 27 mrad field of view.

Castor IIC. (Thomson-CSF)

Castor III. (Thomson-CSF)

Castor III is a J(Ku)-band radar/TV/IR director, designed as the basis of an all-weather antimissile system. This radar is specially designed to track in a cluttered and jammed environment, even at low altitude. Castor III uses a Cassegrain antenna (gain 43 dB, beam 1.5×0.67 deg) and a TWT transmitter (pulses 7.5 microsec). As in Castor IIC, there is an associated TRAKIR TV/IR tracker. Total height above deck is 2.422 m. The associated software uses a special low-altitude tracking algorithm that compensates for the image (multipath) effect of the sea's surface. In tests at Gavres in 1987 (see also the entry for the SATAN close-in weapon) the target, flying at an altitude of 7 m at 300 kt, was tracked with a standard deviation of 0.3 mrad (about 35 cm) at 1000 m range. Operational limits: tracking range 0.35–30 km, elevation $+85/-25$ deg, maximum speed 1000 m/sec. Acquisition time on an air target, with 90-deg bearing-slewing angle and 5-deg elevation search, is 2.8 sec; if identified as a sea-skimmer, 1.75 sec. The probability of automatic acquisition in free space (1 false alarm/min) is 90% at 18 km for 0.1 m^2 and 90% at 30 km for 2 m^2 : both figures are calculated for Swerling class 3.

Castor II is used with Vega fire-control systems in fast minor craft, including West German fast attack craft.

◆ DRBI 10

Band: S **Beam:** 2×2 deg **Peak Power:** 1000–2000 kW
Gain: 37 dB **Pulse Width:** 4 microsec **PRF:** 500 pps
Scan Rate: 4 rpm (vertically: 800 scans/min)
Antenna Dimensions: 3.4×3.4 m

The French carrier *Clemenceau*, 1972, shows typical radars: from top to bottom, they are: TACAN, IFF Mk 10, DRBV 22, DRBV 20 (large-ship version), DRBI 10 (both fore and aft of the funnel). (Giorgio Arra)

DRBI 10 is the height-finder on board the *Clemenceau*-class carriers. Like the extinct U.S. SPS-8 and -30, DRBI 10 uses a high-speed (Robinson) scanner to move its beam vertically. Work on this radar began in 1958, and each carrier was fitted with 2 sets; DRBI 10 was also installed on board 5 radar-picket destroyers, the missile cruiser *Colbert*, the training cruiser/helicopter carrier *Jeanne d'Arc*, and the missile trials ship *Ile d'Oleron*. A mobile land-based radar, Picador (TRS 2200), was developed from it (the prototype appeared in 1968). Data above are taken from the published details of Picador. Range on a fighter is said to be 100–140 nm.

◆ DRBI 23

DRBI 23 is the large L-band radome-enclosed pulse-doppler antenna on board the missile frigates *Suffren* and *Duquesne*. The antenna is a big inverse Cassegrain reflector using stacked beams (monopulse height finding). The peak power of several megawatts is generated by a carcinotron fed through 6 amplifier stages. Plots are automatically extracted. A smaller version, DRBV 13, was formerly carried on board the destroyer *Aconit*.

◆ DRBJ 11

Band: S **Scan Rate:** 15 rpm
Antenna Dimensions: diameter 3 m (dish)

The Thomson-CSF electronically scanned radar uses a circular planar antenna covered by 1000–1500 phase shifters, which steer the beam in elevation (over a 60-deg angle) and in bearing. The antenna itself is inclined at a 15-deg angle and rotates inside a radome. Surveillance range is about 100 nm.

Development began in 1982. DRBJ 11 was not delivered because of ECCM problems. *Cassard*, therefore, had to be completed without the radar. The improved version, DRBJ 11B, is now in service on board the second C70AA ship, *Jean Bart*.

The antenna of the DRBI 23 radar, shown (bottom) without its radome. The array of stacked microwave horns produces the stacked beam used for monopulse height finding. (top) shows the principle of the antenna. The horns ("sources primaires") illuminate a semireflecting parabolic mirror. The mirror reflects onto a secondary reflector that twists the polarization of the beam so that it can pass through the first reflector. This type of folded optics makes it possible to achieve considerable focusing of the radar beam in limited dimensions, i.e., within a radome. Moreover, the elaborate feed does not block the main beam of the radar, an important consideration in any stacked-beam or monopulse system. This type of operation is typical of inverse-Cassegrain antennas, although most of them are not nearly as elaborate. (Thomson-CSF)

DRBI 23 occupies the big radome of the French frigate *Suffren*. The two 100-mm guns are controlled by the DRBC 32A forward of the bridge, and the navigational radar is DRBN 32. The small radar on the foremast just above the big radome is DRBV 50. (Dr. Robert Scheina)

◆ DRBN 32

Decca RM 1226 navigational radar (see the British section, below) is being superseded by Decca 1229.

◆ DRBR 51

DRBR 51 is the Masurca missile's C-band monopulse guidance-radar, roughly equivalent to the U.S. SPG-55. The missile is built in both beam-riding and semiactive versions; each radar group consists of a pair of antennas, a large-diameter tracker (which can also measure the deviation of the missile from the line of sight) and a small-diameter command transmitter. A third antenna generates the initial gathering beam. CW power is injected into the main dish for semiactive operation. Missiles are tracked at a wavelength of 5 cm and command signals transmitted at a wavelength of 7 cm; the tracking channels are designated "blue" and "yellow."

◆ DRBV 15 (Sea Tiger: TRS 3001)

Band: S **Beam:** $1.65 \times 8 \text{ deg cos}^2$ (to 45 deg)

Peak Power: 60 kW (1 kW average) **Gain:** 29.5 dB

Pulse Width: (i) 5.5 (ii) 12 microsec (compressed to 0.5) [In a later version, this radar produces 2 types of burst, each consisting of a 0.5-microsec pulse and then a chirp, either 7.5 or 15.5 microsec long, compressed to 0.5 microsec in either case.]

PRF: (i) 2200 (ii) 1100 pps

Scan Rate: 12 or 24 rpm (also given as 15 or 30 rpm)

Antenna Dimensions: 4.54 m **Antenna Weight:** 675 kg

Sea Tiger is a combined surveillance radar for medium and larger ships, its design emphasizing a low false-alarm rate to permit automatic tracking. The radar can carry out full air surveillance out to 170 km (55-deg elevation), surface surveillance to the horizon, and surveillance against sea-skimming missiles.

The chief antijam and anticlutter measures are coherent transmission/reception (which allows doppler filtering of clutter), true frequency agility (either pulse-to-pulse on the nondoppler channel, or randomly in short bursts of 10 pulses on the doppler channel), and use of 2 pulses at 2 different frequencies. The radar uses pulse compression and detects automatically using CFAR; and DRBV 15 can provide digital data to a weapons system. Doppler processing is by 4- or 8-point FFT.

There are 2 operating modes, each using 2 pulses: 1 long pulse with compression followed by 1 short pulse for short-range sur-

DRBV 15C. (Thomson-CSF)

veillance, at a different frequency. PRF can be jittered ("wobulated").

Free-space range on a 2-m² target (Swerling 3 case) is 110 km, on a 0.1-m² nonfluctuating target (probability of detection 0.9), 40 km. Actual performance depends upon the degree of surface clutter. Clutter-rejection ratios: 45 dB vs. ground clutter, 40 dB vs. rain and sea clutter.

Sea Tiger can be used as the search radar for a Vega fire-control system. Derived from the French Army Tiger air-search radar, Sea Tiger displaced the Saturne 2 naval air-search radar.

In November 1989 DRBV 15C (Sea Tiger Mk 2) was ordered for the new nuclear carrier *Charles de Gaulle*; this was the first order for the new version, which will also equip the new *La Fayette*-class frigates and will be tested on board the experimental ship *Monge*.

DRBV 15C (Sea Tiger Mk 2) has a roll-stabilized planar-array antenna (30 dB, 1.65-deg beam) with reduced sidelobes and better gain at high elevation (to detect steep divers). Free-space range is 100 km on a fighter and 50 km on a missile. The antenna is based on earlier work on planar arrays, for such radars as Arabel, DRBJ 11, and land-based types. The short-range 2D battlefield radar, TRS 2630, uses a very similar antenna technology. The new antenna is designed so that it can be coupled to an existing Sea Tiger transmitter/receiver assembly. However, Sea Tiger Mk 2 also employs a new 2-stage (TWT and CFA) coherent transmitter/receiver. The 2 stages allow it to operate at 2 power levels, depending on whether a voltage is applied to the CFA. There are 2 channels: air (long pulse and pulse compression) and surface (short noncompressed pulse). The transmitter is frequency-agile (pulse to pulse or burst to burst). There are 4 receiving modes: normal surveillance (60 nm instrumented range, 15 rpm, FFT4), long-range surveillance (90 nm, 15 rpm, MTI sine²), antimissile surveillance (30 nm, 30 rpm, FFT4), and antimissile surveillance in bad weather (30 nm, 15 rpm, FFT8). Here FFT4 and 8 refer to the use of 4 or 8 FFT doppler filters. By rejecting signals in 5 out of 8 doppler filters, the radar can filter out moving clutter (sea returns). The receiver improvement factor is 40 dB against sea and rain clutter. Air tracks are automatically initiated (ADT); they are also automatically associated with IFF returns. The system can carry up to 128 tracks.

DRBV 15 (Sea Tiger). (Thomson-CSF)

◆ DRBV 20

This large, high-powered (1-MW) P-band radar, with a flat mattress antenna (carrying 3 rows of dipoles), is found on board the cruiser *Colbert* and, formerly, on board the 2 French carriers. Pulse widths: 8 and 4 microsec (PRF 100 and 200 pps).

DRBV 20 was the first French air-search radar. One was installed on board the battleship *Jean Bart* in June 1949. This series also included the DRBV 10 surface-search set (installed November 1948) and the DRBV 30 navigational set (installed November 1948). The slightly later DRBV 11 was conceived as a dual-purpose (air/surface) search set but proved inadequate against jet aircraft, hence the development of DRBV 22. The other radars of this generation were DRBC 10 (surface fire control for 15-in guns), DRBC 11, DRBC 30, and DRBC 31 fire-control sets.

DRBV 20C on board the cruiser *Colbert*. (Sea Power)

◆ DRBV 22/23 (Jupiter: THD 1077)

Band: L **Beam:** 2.5×50 deg (3.5×16 deg csc²)
Peak Power: 2000 kW (600 kW) **Gain:** (26 dB)
Pulse Width: 2.5 microsec (1.3 or 4 microsec)
PRF: 450 pps (600 or 200 pps)
Scan Rate: 7.5 and 15 rpm (6 or 12 rpm)
Antenna Dimensions: 24.6 × 9.9 ft (DRBV 22: 5.18 × 2.13 m)

Jupiter is the export version of DRBV 23, and its characteristics are listed above (DRBV 22 data in parentheses). DRBV 22 resembled the U.S. SPS-6B externally; DRBV 22C introduced a new elliptical stabilized antenna, which in turn was combined with a new and much more powerful transmitter in DRBV 23. Development of this set began in 1961; its maximum range is about 160 nm. DRBV 22's range is about 70 nm.

Installations: DRBV 22A—*Aconit*, *La Galissonnière*, *Duperré*, *Du Chayla*, *Cdt. Rivière* class (in French, Portuguese, and Uruguayan service); 22C—trials ship *Ile D'Oléron*; 22D—*Jeanne d'Arc*; 22E—experimental ship *Rance*; 23B—*Clemenceau* class carriers.

◆ MARS (DRBV 24)

This 2D L-band radar, for the new *Floreal*-class patrol frigates, is related to the solid-state DRBV 26C and to Astral. MARS

uses a solid-state transmitter and employs digital pulse compression. It employs a 2-module transmitter (DRBV 26C has 16 modules), with a total of 32 (rather than 256) power elements. Instrumented ranges are 110 km for the air channel and 80 km for the optional surface channel. The MTI improvement factor is 45 dB for fixed echoes. The radar cabinet is fitted for (but not necessarily with) an extraction/tracking (ADT) unit to automate its operation. The 600-kg antenna (a modified version of that of DRBV 22) has a gain of 26 dB and scans at 12 rpm. The receiver is that of DRBV 15C.

This radar was announced in the fall of 1990. Its commercial designation is TRS 3015.

◆ DRBV 26 (Jupiter II: TRS 3010)/DRBV 26C (Jupiter IIS)

Band: L (23 cm) **Beam:** 2.5×8.3 csc² (to 50 deg)
Peak Power: 2 MW (average 2 kW) **Gain:** 29 dB
Pulse Width: 2.5 microsec **PRF:** 450 pps (fixed or staggered)
Scan Rate: 7.5 or 15 rpm **Antenna Dimensions:** 7.535 × 3.05 m
Antenna Weight: 1000 kg approx (total 1450 kg)

Work on an improved Jupiter, DRBV 26, began in 1972, for the new generation of missile ships. Range is said to be 150+ nm (on a 10-m² target). Protection against false alarms and clutter includes a low-sidelobe antenna, filters for protection against signals from nearby ships (high-frequency bands as well as the same band), multiple reception channels with wide dynamic-range receivers and anticlutter circuits, MTI for air surveillance, and a CFAR antijam receiver. The main improvement over Jupiter I may have been in reliability. Resolution is 400 m and 2 deg.

Jupiter IIS (TRS 3011) has a pulse-compression transmitter (130 microsec, compressed to 0.8) and is frequency agile on a burst-to-burst or pulse-to-pulse basis. The tube transmitter of Jupiter II is replaced by a solid-state transmitter consisting of 16 modules in parallel. Claimed reliability: MTBF for each module is 6060 hr, and for the entire transmitter, excluding the modules, 2180 hr. MTTR is 15 min for the transmitter (excluding modules) and 4.5 min/module; modules can be replaced while transmitting. Thomson-CSF claims that the new transmitter makes for a service life 6 times that of any earlier radar, and better than 99% availability. Operating voltages in the transmitter are only 50 volts since no single transmitter need be particularly powerful. Transmission frequency is very stable

DRBV 26C (Jupiter IIS). (Thomson-CSF)

because of the use of a frequency synthesizer, making it possible to use more sophisticated types of signal processing, such as doppler filtering (using FFTs). Air tracks are automatically initiated and followed; surface targets are automatically tracked after manual acquisition. The radar can track up to 64 targets automatically, handing over their coordinates to the associated CDS. A 2-m² fighter can be detected at 215 km (which can be increased to 250 km by adding an additional transmitter module to the 16). Instrumented ranges: 350 km at normal power, 200 km at reduced power (backup mode, 1/10th power, at which level no cooling is required), 60 km in optional surface-channel mode. The MTI improvement factor is 45 dB for fixed echoes. In this version the antenna weighs 1630 kg.

The first DRBV 26C was installed on board the frigate *Jean Bart*.

Growth possibilities for DRBV 26 include provision of a 3-beam antenna (for "2.5D" search capability) and an increase in transmitter power by a factor of 2 or 4. As of October 1990, it was not altogether certain whether the carrier *Charles de Gaulle* would be fitted with a developed version of this radar (DRBV 26D) or with a new radar (DRBV 27, presumably the Astral radar chosen as the long-range search element of the French version of the FAMS missile system). The RFP for the ship's L-band long-range radar is to be issued in 1991.

DRBV 26 is virtually the standard French large-ship air-search radar. The commercial Jupiter, which was carried on board South African frigates, had the same antenna as DRBV 26 but a different receiver.

◆ DRBV 31

This license-built Decca X-band navigational radar survives on board the destroyer *Du Chayla*.

◆ DRBV 50

The development of this low-flier/surface-search radar began in 1961. It equipped the *Jeanne d'Arc* and *Maille Breze* classes and was planned for the *Commandant Rivière* class (which is equipped with the DRBN 32 instead). This radar survives on board Portuguese *Cdt. Rivière*-class frigates, the *Jeanne d'Arc*, the cruiser *Colbert*, the old destroyer *La Galissonnière*, the *Suffren*, and the missile-test ship *Ile D'Oléron*.

◆ DRBV 51A

Band: C (5.5–5.8 GHz) **Peak Power:** 200 kW

Pulse Width: (i) 0.6 (ii) 1.7 microsec (DRBV 51A and 51B) (iii) 0.6 microsec (DRBV 51C)

PRF: (i) 1045–1090, 1165–1190, 1215–1245, 1280–1305, 1383–1393, 1500–1600, 1808–1830, 1960–2020, 2085–2145 pps (ii) 349–360, 420–440, 500–510, 540–580, 590–615, 675–715 pps (iii) 1013 pps staggered

Scan Rate: 24 rpm (DRBV 51A and 51B); 30 rpm (DRBV 51C)

DRBV 51 (top) and DRBV 26 (below) search radars on board the destroyer *Duguay-Trouin*. (L. Van Ginderen)

DRBV 51A is a low-altitude air-search and Exocet target-designation radar, a Triton with a higher-gain slotted-waveguide antenna (for longer range). DRBV 51A, most closely comparable to Triton II (see below), is the main radar of the *d'Estienne d'Orves*-class (A69 type) aviso. DRBV 51 and DRBV 51C are secondary air-search versions with conventional antennas.

◆ DRUA-33 (Calypso)

Band: X **Beam:** 3 × 8.5 deg **Peak Power:** 70 kW

Gain: less than 29 dB **Pulse Width:** (i) 0.15 (ii) 0.5 microsec

PRF: (i) 1500–3000 (ii) 500–1000 pps

Scan Rate: 12 or 24 rpm **Antenna Dimensions:** 1 m × 48 cm

Antenna Weight: 60 kg (total weight 450 kg)

Data are for Calypso III. Calypso II had a slightly greater gain and somewhat lower power. Calypso III has anticlutter processing for better range.

The DRUA-33 submarine surface-search radar of 1964 led to the Calypso export radar. Calypso III was developed in conjunction with the German IKL design organization, for Type 209 submarines. As such, it uses a nonpenetrating mast, with the scanning mechanism at the masthead.

Operating modes are continuous transmission, sector surveillance, short-time transmission (0.1 or 1 sec only), and silent operation with a dummy load. Scan modes are full 360 deg, sector (adjustable between 10 and 180 deg), short-time scan over 10 deg, or manual scan. In 1 version of Calypso, a separate range-only antenna is mounted on the attack periscope. Calypso II could detect a 10-m² airplane at 16 nm. The improved Calypso III can detect an ASW airplane flying at 8000 ft at 18 nm.

This radar is in service in 3 navies.

Calypso IV is built around a navigational radar and is intended to simulate merchant ships' radar signals. It has the same antenna as earlier radars of the series, but a new klystron (25 kW peak power) using 1 microsec and 50 nanosec pulses for long

The corvette *d'Estienne d'Orves* shows a DRBV 51A main search radar and a DRBC 32E fire-control radar atop her superstructure. The 2 light-colored circles in the after superstructure cover 2 torpedo-firing catapults. The small slotted waveguide immediately above the bridge is DRBN 32. (U.S. Naval Institute)

and short (high-resolution) ranges. Operating options are continuous scan, sector scan, burst, and receive-only. Range on a low-flying 10-m² target (i.e., a maritime-patrol aircraft) is 20 km (10.9 nm).

Calypso II is THD 1030, Calypso III is THD 3100, and Calypso IV is THD 3110.

Danish submarines use the standard Calypso antenna with Terma-supplied electronics, and for export Terma supplies its transmitters and receivers to HDW via Thomson-CSF, which combines them with the standard Calypso antenna.

The Calypso radars are descended from a series of specialized submarine radars begun in 1956 with DRUA-30.

◆ Arabel

Arabel radar. (Direction de Constructions Navales)

Arabel is the multifunction X-band radar for ASTER missile control. The planar antenna is inclined at 30 deg inside a radome, rotating at 60 rpm. The beam is 2 deg wide and can scan up to 70 deg in elevation. The transmitter can hop frequencies over 10% of its frequency range. Thus, the radar is a much shorter-range, higher data-rate expression of much the same technology as is used in DRBJ 11. Production antennas will use a lens antenna (Radant) to steer the beam, reducing the overall number of phase shifters from several thousand to about 100, and drastically reducing both cost and energy consumption.

The first development contract was announced in April 1988, with completion of a naval prototype scheduled for the early 1990s, to meet the SAAM schedule (service entry 1999). SAAM is a short-range system, and Arabel is designed to match, with a stated range of about 50 km against 0.5-m² missiles and 100 km against larger targets. The associated computer is to be able to conduct simultaneous monopulse tracking of 50 targets, and to direct 10 simultaneous engagements. Trials were scheduled for 1988–89.

Arabel stands for *Antenne Radar à Balayage Electronique*.

◆ Astral (DRBV 27)

This new 3D radar has been chosen as the long-range acquisition radar of the French version of FAMS. Astral is derived from DRBV 26C but uses a new planar-array antenna (weight 3500 kg) and scans 1 beam electronically in elevation from 0 to 45 deg (as compared to 2 beams in DRBJ 11). Mean power will be twice that of the earlier radar (5 kW compared to 2.5 kW), and maximum range on an airplane will be about 275 km [150 nm];

Astral. (Thomson-CSF)

missiles will be detected at 50 nm. Instrumental range is 400 km [219 nm]. The ADT has a capacity of 300 tracks. Astral is a digital pulse-compression radar using doppler speed filtering (i.e., pulse compression is by phase coding rather than by frequency, and the beam is elevated by phase shifters rather than by frequency scanning). Like DRBV 26C, Astral uses a solid-state transmitter for high reliability and availability. Its software, including that used for energy management, is written in ADA.

Coverage and other characteristics are compatible with those of Arabel, so that the 2 radars can work in tandem.

The commercial designation is TRS 3505.

◆ Calypso

See DRUA-33, above.

◆ Canopus

The radar version of this director was never used. For details, see the last edition.

◆ Castor I (TRS 3200)

Band: X **Beam:** 2.3 deg **Peak Power:** 175 kW
Gain: 37 dB **Pulse Width:** 0.4 microsec
PRF: 4000–8000 pps (stepped variation) **Antenna Weight:** 80 kg

Used with Vega fire-control systems in medium-sized ships, Castor I is a stabilized monopulse-MTI tracker. Maximum acquisition and tracking range is about 30 km. A 2-m² air target can be detected (PD 0.9) at 20 km; a 0.1-m² missile can be detected (PD 0.9) at 15 km. Range accuracy is 15 m between 200 m and 15 km, and angular accuracy is 0.5 mrad. Tracking accuracy (18 km, 2-m² fluctuating target) is 15 m and 0.3 mrad.

Castor was conceived as a replacement for Pollux, to track fluctuating targets more accurately. Castor II, which entered French naval service, has a Cassegrain antenna with a multi-mode feed behind the reflector.

There is a colocated television camera.

This director replaced Pollux within the Vega II weapons system. Development began in 1969.

For later versions of Castor, see DRBC 33 above.

◆ Jupiter

See DRBV 26 above.

◆ Neptune (THD-1040)

This C-band set was the original search radar of the Israeli missile boats, and it probably survives, at least on board some of the units exported to Chile and South Africa. Israeli boats have all probably been refitted with EL/M-2207 or -2208. Neptune seems to have been an alternate name assigned to a slightly modified Triton (it shares the same THD number, and Triton and Neptune were alternate names for the same sea god); no details specific to Neptune were ever published.

◆ Pollux (THD 1280, TRS 3220)

Band: X **Beam:** 2 deg **Peak Power:** 200 kW (90 W average)
Gain: 30 dB **Pulse Width:** 0.3 microsec **PRF:** 1500 pps
Antenna Dimensions: diameter 1.1 m **Antenna Weight:** 450 kg

The Ecuadorian missile boat *Quito* has a Triton air/surface-search radar on her mast (with an ESM array above it), and a Pollux fire-control radar. The mast platform just aft of the Pollux dish carries a Decca 1229, barely visible because its antenna is end-on to the camera. (U.S. Naval Institute)

A Thomson-CSF export conical-scan fire-control radar, Pollux was capable of acquiring and tracking a small aircraft at 16 nm. Accuracy was 1 mrad in bearing and 20 m in range. Tracking accuracy was 0.5 mrad and 20 m in range at 18 km (2-m² air target). Acquisition range on a 2-m² air target was 30 km. Conscan requires several pulses to define a target's angular error, and conscan can, therefore, introduce errors if the target fluctuates. Hence the development of Castor.

Pollux was the tracker of the original Thomson-CSF Vega weapons-control system. Pollux was not accurate enough to control heavy (100-mm) guns, had limited ECCM capability, and was, therefore, replaced by Castor II (0.3-mrad tracking accuracy).

Pollux users: Ecuador (*Manta* class) and Qatar (Combattante-III class).

◆ RODEO Naval

Band: S **Beam:** 6.5 deg csc² **Peak Power:** 0.1 kW
Scan Rate: 40 rpm **Antenna:** 105 × 80 cm

This ESD lightweight pulse-doppler radar is derived from the land-mobile Rodeo 2. It tracks 6–10 targets simultaneously (TWS mode) and can distinguish fixed- from rotary-wing aircraft. It is radome-enclosed and can be stabilized. RODEO is an acronym for *Radar d'Observation et de Designation d'Objectifs*; it is designed to detect and target low fliers. A moving

target can be acquired at 12 km, and a hovering helicopter beyond 8 km (with rotor motion detected beyond 6 km). The beam can be elevated or depressed within the range +45/–5 deg. Rodeo 2 is the army's mobile version; Rodeo 2S is an extended-range fixed version.

The original land-based version appeared in 1978.

RODEO is to be used on board the carriers as a target-acquisition radar for Mistral missiles.

◆ Sea Tiger

See DRBV 15, above.

◆ Triton (TRS 3030, THD 1040)

Band: C (5.3 cm) **Beam:** 2 × 22 deg
Peak Power: 250 kW (200 kW in early units)
Gain: 38 dB **Pulse Width:** 0.2, 0.5, or 0.7 microsec
PRF: variable over a wide range **Scan Rate:** 12 or 24 rpm
Antenna Dimensions: 2.5 × 0.4 m
Antenna Weight: 170 kg (350 kg if stabilized)

A Nigerian Combattante-IIIIB-class fast attack boat shows a Triton radar at her masthead, with a Castor II director; at the right, at the foot of the mast, is a Panda optical director. (U.S. Naval Institute)

This combined air/surface-surveillance and target-indication radar, for small- and medium-sized ships, was developed as part of the Vega system. Triton can shift both frequency and PRF as a counter-countermeasure. The antenna is not stabilized. Triton can detect a 2-m² air target at 30–45 km. Accuracy in range is 30 m. Work began in 1967, and the prototype appeared in 1968.

Triton users: Ecuador (*Quito* class), Greece (Combattante-IIIIN class and Combattante-II class), Libya (Combattante-II class), Malaysia (Combattante-II 4AL class), and Peru ("Daring" class and PR-72-560 class). See also Neptune, above.

◆ Triton II MTI (TRS 3035)

Band: C (5.3) **Beam:** 2 × 22 deg
Peak Power: 250 kW (average 200 W) **Gain:** 28 dB
Pulse Width: (i) 0.5 (ii) 1.0 microsec
PRF: Non-MTI mode: adjustable PRF: (i) 1000–2000 pps (ii) 333–666 pps
MTI: 3 staggered PRFs around 1820 pps
Scan Rate: 12 or 24 rpm
Antenna Dimensions: 2.3 × 1.4 m (includes pedestal)
Antenna Weight: 180 kg

Triton II MTI is a combination air- and surface-search radar intended as the primary search and target indicator for small ships, and as the target indicator for ships equipped with a long-range air-search radar such as Jupiter (DRBV 26). Detection range on a 2-m² air target is over 30 km.

The main features are a lightweight low-sidelobe antenna; a tunable-frequency (and adjustable-PRF) transmitter; an antijam (STC, CFAR) receiver; and a linear digital MTI, useful at ranges of up to 56 km, for clutter rejection. The MTI uses a 3-memory filter with a minimum blind speed of 340 m/sec (0.5-microsec pulses). The CFAR channel uses 1.5-microsec pulses. Clutter-rejection ratio: ground, 30 dB; sea (3 m/sec), 25 dB.

DRBV 51 is the French navy's version of this radar. It was also tested on board a German fast attack boat (1980).

◆ Triton G (TRS 3050)

Band: C **Beam:** 2.1 × 22 deg **Peak Power:** 8 kW **Gain:** 27 dB
Pulse Width: 6.5/12 microsec (compressed to 0.5 microsec) (A 0.5-microsec uncompressed pulse can be included in the burst for close-range surveillance.) **Scan Rate:** 40 rpm
Antenna Dimensions: 2.3 m wide **Antenna Weight:** 180 kg total

Triton G. (Thomson-CSF)

This C- (now redesignated G-) band medium-range air- and surface-search radar has a lightweight antenna so that it can be mounted at a masthead. Triton G uses pulse compression and a frequency-agile coherent TWT transmitter (for MTI, for clutter rejection). Clutter improvement factor is 40 dB. Detection range on a 2-m² target is over 19 km. The lowest blind speed is 800 m/sec. Up to 32 air and/or surface targets can be tracked automatically. Air target tracks are automatically initiated (ATD).

The signal-processing hardware of this radar duplicates that of Sea Tiger (DRBV 15).

The prototype Triton G was installed on board a German S148-class fast attack boat in 1986, and West Germany ordered 23 of these radars in 1987 (for the S148 class) to replace their existing Tritons. One ship of the class, *Storch*, had already been fitted with Triton II and Castor II for trials (1980). The other German fast attack boats all have Dutch WM27 radars.

◆ Triton S (TRS 3033)

Band: S **Beam:** 3 × 22 deg
Peak Power: 10 kW (average 250 W) **Gain:** 25 dB
Pulse Width: 2.7 microsec (doppler channel); 0.17 microsec as pulse-compressed; compression ratio of 10
PRF: 5380 pps (doppler channel); pulse compression: fractions of 5380 pps **Scan Rate:** 24 rpm
Antenna Dimensions: 3 m wide **Antenna Weight:** 215 kg

Triton S is a pulse-doppler development of the basic Triton. Triton S uses a crystal-controlled TWT and produces 3 frequencies for air search and 6 frequencies for surface search. Air-

Triton S (above Castor, on board a fast attack boat). (Thomson-CSF)

search frequency can be shifted on a scan-to-scan basis. Surface-search frequency can be shifted on a pulse-to-pulse basis.

Triton S is a combined air/surface-search radar, effective against sea-skimmers by virtue of its very high clutter-cancellation ratio (50 dB) and its high data rate (2.5 sec). Like several other recent Thomson-CSF radars, Triton S uses a coherent transmitter for doppler processing (16-point FFT), both to get target speed and to reject clutter. Using pulse compression on the nondoppler channel, the radar is also frequency agile on a scan-to-scan basis. The lowest blind speed is Mach 1.

Performance of the pulse-doppler channel: 1-m² (Swerling III case) at 26 km; 10-m² target (Swerling III) at 44 km.

Triton S users: Nigeria (Combattante-III class) and Tunisia (Combattante-III class).

◆ MRR

Band: C
Beam: 1.75 deg (azimuth). See below.
Scan Rate: 10 or 30 rpm

The Thomson-CSF Multi-Role Radar is intended as a Triton/DRBV-51 replacement; it is the radar element of the Vega-successor small-ship combat system now under development. It can also serve as the target-designation radar (self-defense radar) of a larger ship. There are 2 operating modes, surveillance (mainly to detect medium- and low-altitude targets, primarily for peacetime) and self-defense (all elevations fully covered with a high data rate, primarily for missile defense). Each mode is further divided into fine- and bad-weather modes. In the normal surveillance mode, the instrumented range is 70 km. The maximum altitude is about 25 km [about 80,000 ft]. The vertical beamwidth, then, is probably about 20 deg. In the self-defense mode (presumably using the higher of the 2 scan rates given above), the main low beam (instrumented out to 60 km) is supplemented by 2 higher-elevation beams, instrumented out to 40 km (high) and 50 km (medium); the maximum elevation is 70 deg. The intermediate beam probably extends from about 20 deg to about 30 deg. The brochure describes the radar as monolobe, so presumably the 3 self-defense beams are generated in sequence as the main beam scans up in elevation. However, the brochure can be read to imply that at least in normal surveillance operation the radar generates a single 2D fan beam and then switches to a pencil beam once a target has been detected (like Astral and the U.S. ITAS, for example). The surface-channel instrumented range is 40 km. The air channel uses long compressed pulses, the surface channel short pulses. Pulses can be transmitted in bursts. The coherent transmitter uses a TWT. In some modes the air-channel signals are Doppler processed (on a burst-to-burst basis) for better low-altitude performance

in clutter. MRR is an ADT radar programmed in ADA. It has a capacity of 64 tracks. Signals are horizontally polarized, and the antenna is roll- and pitch-stabilized.

The RAC alert and coordination radar is a ground-based equivalent.

◆ TRS 3405/3410

Band: X **Beam:** 0.24×25 deg (inverted csc² to -25 deg)
Peak Power: 200 kW **Pulse Width:** 0.05 microsec
PRF: 1300–3000 pps

These coastal-surveillance radars are intended to sit atop cliff tops. TRS 3405 is fixed; TRS 3410, mobile. Sea clutter is reduced by frequency diversity, an adaptive detection-threshold, short pulses, and a very narrow beam. These radars can detect a wooden fishing boat (cross section 5 m^2) at 25 km.

TRS 3410 has a 5-m antenna producing a 0.5-deg beam.

OPTRONIC SYSTEMS

◆ DIBV 10 (VAMPIR)

VAMPIR was announced in 1980. It was developed by SAT to meet a NATO requirement for an IR surveillance sensor, analogous to the Canadian SAR-8. Providing all-around low- and medium-altitude surveillance, VAMPIR can provide threat warning and target acquisition to a CIC. For example, this system can be used as acquisition sensor for both chaff launchers and point-defense weapons such as Mistral. VAMPIR can also designate targets to an optronic fire-control system such as Totem, or to a radar fire-control system such as DRBC 32. The sensor head weighs 450 kg and scans at 60 rpm. VAMPIR covers both IR windows (3–5 and 8–14 micrometers) with 25-deg fields of view. An approaching missile would probably be detected at a range of about 10 km, and target designation could be accurate to within 1 mrad (bearing and elevation). The display is divided into 3 horizontal strips, 2 for the 2 IR windows and 1 for processed video. Both windows are shown because the differences between the pictures seen through them can provide valuable information. In films shown at Bourget Navale in 1980, the processed-video strip displayed a missile marker before it was apparent in either window, suggesting the degree to which

VAMPIR optronic sensor. In trials, VAMPIR reportedly detected sea-skimming missiles beyond the horizon by sensing the IR plumes rising out of the missiles' exhausts. (Société Anonyme de Télécommunications)

signal processing could enhance a target above the surrounding IR noise.

In 1980 it was reported that this sensor had detected a small helicopter at a range of 8 nm. In 1988 it was reported that VAMPIR had detected the heat plume of an Exocet before the missile came over the horizon.

VAMPIR (DIBV 10) equips the *Cassard*-class missile destroyers (C70AA type) and will equip the new nuclear carrier. DIBV 10 equips the 3 *Tourville*-class destroyers and will be installed on board other ships. VAMPIR means *Veille Air-Mer Panoramique Infra-rouge*.

In 1988 VAMPIR ML 11 was announced as a lighter and less expensive ($\frac{1}{3}$ – $\frac{1}{2}$ the price) of the existing VAMPIR. Operating in only 1 of the 2 IR windows used by VAMPIR, VAMPIR ML 11 is designed so that the operating wavelength can be changed relatively easily from range to range. The sensor is provided by SAT, the processor and turret by CSEE. Total weight is 80 kg, compared to 450 for VAMPIR, and scan rate is doubled to 120 rpm for better detection of sea-skimming antiship missiles. Elevation limits are $+60/-10$ deg, compared to a maximum elevation of 25 deg for the original VAMPIR. Target designation accuracy is 3 mrad, compared to 1 mrad for the earlier system. FoV is 6 deg. ML 11 is stabilized to within 0.4 mrad (limits: ± 30 deg roll, ± 10 deg pitch). Range in good weather should be about 15 km. The operator presets ML 11 in elevation (e.g., at 15 deg). Once it detects a target, it autotracks on each scan (TWS operation), changing elevation angle to match. As of October 1990, the prototype was in the factory, with trials expected in 1991.

In the fall of 1989 ITT Avionics agreed with SAT to apply new "multi-discriminant" algorithms developed by ITT to a new IR search-and-track device. The algorithms were tested at the U.S. Naval Surface Weapons Center, using a VAMPIR-like device.

◆ COTOL/COTROL/Totem/TRS 906

It appears that these competing lightweight optronic directors were never sold. For details, see the last edition.

◆ Lynx/PAON

CSEE's pedestal-mounted target designator is used in the Radop FCS, described below. The binocular sight (FoVs 19 or 5 deg at magnifications of 2.5 or 8) views the target via a gyro-stabilized mirror, which scans in elevation to acquire a target (limits $+65/-25$ deg). The maximum elevating speed is 1 rad/sec. Target coordinates are transmitted to the sight via the mirror gyro, and from the sight via synchros. The total weight is 120 kg.

When fitted with an image intensifier for night operations, Lynx is called PAON.

Aside from Radop applications, Lynx is installed on board the Kuwaiti TNC 45-class fast attack boats, the Omani *Nasr Al Bahr*, and the Moroccan frigate *LCol. Errhamani*.

◆ NAJA/NAJIR

The manned optronic sight is used either as a primary director for a small ship or as a backup to a radar director. NAJA can accept designations from other sensors (e.g., radar, ESM, or IR). It carries a pair of $2\times$ binoculars and a standard or low-light television. The line of sight is biaxially stabilized.

Weight is about 500 kg (260 kg for the remote-control console), and elevation limits are -25 to $+70$ deg.

In 1982 CSEE announced a private-venture version, NAJIR, which adds an IR camera to the existing optical, television, and laser channels. The IR image can be observed either through the binoculars above deck, or on a below-decks monitor. Targets can be tracked automatically, by either television or IR, and the modernized system uses a digital computer in place of the analog unit of NAJA, for easy integration with any weapons system. The improvement was too substantial to be back-fitted to existing NAJAS. NAJIR was first shown publicly in 1986.

NAJA was developed from the earlier Panda power-driven

NAJIR director, with IR camera and laser range-finder alongside. (Compagnie de Signaux et d'Entreprises Électriques)

optical director and by 1987 had replaced the latter in many Third World navies. NAJA is used in the Radop FCS and on board the Malaysian landing ship *Jerong* and the Saudi *Al Madinah*-class frigates. NAJIR is used by the French navy (*Cassard* and *Floreal* classes), by the Royal Navy (as DMAC), and by 1 other foreign navy.

◆ Panda

CSEE's optical director was the basis for the later NAJA/NAJIR. It is used in 1 version of the Radop FCS. Panda consists of a power-driven platform carrying a stabilized LOS binocular sight and an operator's seat. It can be remotely controlled to bring it into line with a target designated by some other system, such as a search radar. The platform and the sight can search in elevation (limits $+65/-25$ deg, rate 0.5 rad/sec) and in bearing (1 rad/sec). Once the target has been acquired, the operator tracks it visually, and Panda transmits target angular velocities. It incorporates an on-board ballistic/parallax computer. Presumably, Panda is basically an elaborated Lynx power-driven in bearing. Its binocular sight has 2 alternative FoVs (3 and 9 deg, corresponding to magnifications of 8 and 2.66). Total weight is less than 330 kg.

Panda is the CSEE Model 71 director; NAJA (essentially Panda plus a television camera) is Model 74. Users include Bahrain, Belgium, France, Germany, Greece, Libya, Morocco, Nigeria, Peru, Portugal, and Spain. By 1976 more than 150 sets had been ordered.

◆ Pirana

This passive 2-color tracker is typically added to a radar or director. FoV is about 17 mrad for acquisition (optical aperture 170 mm), and Pirana can detect sea-skimming missiles at about 10 km. It is used as part of optronic directors such as Totem (see below). The detector is a nitrogen-cooled focal-plane array. Total weight is 50 kg. The current version, Pirana III, is carried on board the frigates *Cassard*, *Duquesne*, *Jean Bart*, and *Suffren*.

◆ SAS 90

SAGEM's low-cost, lightweight, optronic, antiaircraft FCS and sighting system for fast attack craft was shown at Bourget Naval 1990 (October 1990). It is intended for both ground (fixed and mobile) and naval applications. The gyro it incorporates (to measure target motion) can also be used to stabilize a naval gun mount. The target range is measured passively, apparently by

comparing the target motion with the assumed target speed. SAS 90 consists of a sight-display assembly (color LCD matrix projecting a generated image overlaid on the optical image and the measuring/stabilizing gyro); an automatic tracking and range-finding CCD camera (the picture is directly digitized for easier image processing); an electronics unit (which tracks and ranges based on the CCD camera image, which generates the LCD images and conducts lead-angle computations and firing calculations; it also transmits sight data outside the system); a monocular optical sight for ground firing ($5\times$ magnification and etched reticle); and an optional FLIR. The direct-view sight has a 30×30 -deg FoV. The target direction is measured by gyro or potentiometer. The telescopic sight has a 150-mrad FoV. The CCD camera has 2 FoVs (50×40 mrad or 80×100 mrad) with a resolution of 500 pts/line. The overall fire-control accuracy is 2 mrad. An optional IR camera operates at 8–12 microns, with 2 FoVs; it has an effective detection range, in average weather, of 5000 m [5500 yds].

◆ TRS 906 (Canopus Director)

Thomson-CSF's remotely controlled optronic director was announced in 1978 as part of the Canopus system. TRS 906 can carry an LLLTV and a laser range-finder. The maximum load is 40 kg on each side. TRS 906 is controlled in azimuth by a joystick. The angular tracking accuracy of the television is 2 mrad, and the director can continue to track by memory if the target is lost briefly. Elevation range is $+85/-30$ deg, and maximum speeds in bearing and elevation are 3 and 1 rad/sec, respectively (the director can slew through 180 deg in 1.8 sec).

When carrying only a television camera, the director weighs 120 kg (0.77 m high, 0.80 m in diameter), the associated servo box weighs 80 kg, and the control console weighs 300 kg.

The projected version with an MMW radar was never sold.

◆ VISION

This CSEE periscope is currently under development. When fitted with a fire-control computer, it can function as an optical fire-control device. The head is stabilized, with a 30- or 7.5-deg field of view and with a television camera (for auto-tracking) in the optical path. Magnification is $2\times$ or $8\times$, and elevation limits are $+70/-25$ deg. The head and periscope weigh about 125 kg, and total system weight is about 300 kg.

◆ VOLCAN/Narval/VIGY 50

SAGEM's electro-optical tracker is a lighter alternative to VAMPIR. It is the sighting element of the company's SAMOS close-in weapon (as first tested in 1984) and is also offered on a stand-alone basis. VOLCAN stands for *Viseur Optronique Leger pour Conduite d'Arme Navale*. It will probably replace the relatively bulky optronic elements of directors such as NAJIR. VOLCAN is compact because its optical elements are fixed, pointing up, and because its large stabilized mirror makes for a very narrow optical path. A single 200-mm, 2-axis, gyro-stabilized mirror (stabilized to within 10–20 microrads) in the rotating head reflects the optical path onto 2 aspheric mirrors fixed in the rotating head, which in turn reflect that path down into the combination of TV and IR cameras and a laser. The rotating turret weighs 80 kg [176 lbs]; total weight is 200 kg [441 lbs]. Dimensions are 1045 mm height $\times$ 950 mm width $\times$ 660 mm depth. VOLCAN was being offered in 1990 with a 200-mm [8-in] aperture. The elevation limits are $+80/-40$ deg; the rates of train and elevation are 180 deg/sec. The line-of-sight accuracy is 0.2 mrad (stabilization is better than 20 microrad). The angular-tracking rate is 1 rad/sec (2 rad/sec for fire control). The CCD TV camera operates at 0.4–1.1 micron (FoVs 2.5–10 deg using a zoom lens); the output is 525 lines at 60 Hz (625 lines at 50 Hz is available as an option). Resolution is 0.1 mrad. The SAT CT 11 IR camera uses a SPRITE detector (Stirling cooled) operating at 8–12 microns (FoVs 2.5–10 deg using a zoom lens); output is 525 lines at 60 Hz (625 lines at 50 Hz is available as an option). The laser operates at 1.06 microns (1.54 as an option), producing a 0.3-mrad beam with a peak power of 5 MW.

The Volcan optronic director. (SAGEM)

(pulse rate 2–20 Hz); maximum range is 20 km, and range resolution is 5 m.

Narval is a CSEE/SAGEM optronic FCS using the VOLCAN tracker. The below-decks control console carries the TV and IR monitors (one above the other), the joystick for target designation, and the associated FCS computers. TV/IR FoVs are 1.5×2 to 6×8 deg. SAGEM claims that aircraft will typically be detected at 12 km and will be identifiable at 7 km. Surface ships can typically be identified at 15 km. Narval is conceived as a replacement for the much heavier (600 rather than 200 kg) CSEE NAJIR, described above.

VIGY 50 is a smaller version of VOLCAN, announced at Bourget Naval in October 1990. SAGEM's modular, stabilized, panoramic sight (optronic director) is intended for small patrol craft. It incorporates an electronic calculator (to compute lead angles for transmission to a weapons-drive system). The turret carries a CCD camera for day operation, a thermal imager, and, optionally, a laser range-finder. Elevation limits are $+60/-20$ deg. The line of sight is stabilized within 100 microrad, and line-of-sight pick-up accuracy is better than 0.3 mrad. The day camera operates at 0.5–0.9 microns, with 2 FoVs (1.7×1.25 and 6.7×5 deg). The IR camera operates at 8–12 microns (2.7×2 and 5.5×4 deg FoVs). The laser operates at 1.06 or 1.54 microns. Overall dimensions: diameter, 350 mm; height, 450 mm (sight, 50 kg; electronics, 15 kg).

FIRE-CONTROL SYSTEMS

◆ Radop

CSEE's small-ship FCSs combined an S- or X-band surface-search radar (initially Racal-Decca Series 12), a CSEE optical/optronic director, an artillery-supervision unit, and a radar display. Any version could be extended by integration with a plotting table, radio-electronic navigation system, and/or an air-

search radar. The first 2 extensions were in line with Racal's CANE series of command/control systems. Different versions of Radop were distinguished mainly by the type of CSEE optical or optronic device they incorporated:

- Radop 10, for craft under 100 tons, controlling up to 2 guns, used Lynx and, typically, an X-band radar. This was the version in the Bahreini FPB 38 boats.
- Radop 20, controlling up to 2 guns, used Panda Mk 2 and a CTC vertical console with, typically, an S-band radar. Installations: the Argentine corvette (A 69 type) *Granville*, the Congolese *Pirana*, the Libyan PS700, and the Moroccan PR72.
- Radop 30, for craft over 100 tons, used a NAJA director and a dual-frequency radar, a CTC console, a remote-control console, and a ballistics calculator. The remote control was an integral tracker and processor. Installations: Algerian Brooke-Marine-type landing ships, Argentine A69-class corvettes (other than the *Granville*), the Malaysian *Sri Indera Sakti* class, the Saudi *Durance*-class replenishment ships, the Senegalese PR72M class, the Turkish *Girne*, and the Uruguayan *Vigilance* class.
- Radop 40, for craft over 200 tons, was intended to use the Totem fully automatic director (see the last edition for details) or at least NAJIR, but the only example installed (on board the Cameroon P48S-class patrol boat) used NAJA. This version used a CANE console and could control several guns.

The Radop series was first announced at Asian Defense Expo 80, although the first example appeared on board the Turkish *Girne* in 1976. Twenty-five systems were delivered to 11 navies before production ended in 1984.

GERMANY (WEST)

◆ KAE 7600/8600

Band:	X	S
Beam:	0.9×21	1.7×20 deg
Peak Power:	25	30 kW
PRF: (both)	2000 (to 1.5 nm)/1000 (to 12 nm)/500 (above 12 nm) pps	
Scan Rate:		23 rpm
Antenna:	8 ft	14 ft

Atlas 8600 radar was selected in 1989 for the Australian/New Zealand ANZAC (MEKO 200 variant) frigate. It is the most sophisticated of a series of KAE navigational radars and uses a 61-cm (24-in) raster-scan memory-backed screen. The minimum range setting is 0.3 nm, the next is 0.75 nm, and 7 further settings double that figure, to a maximum instrumented range of 72 nm (note the variation in PRF associated with the various range scales [listed above]). This radar can manually acquire up to 20 targets, automatically tracking them with data readout including CPA and TCPA (theoretical closest point of approach). The operator can set guard zones and limitation lines for automatic acquisition and tracking of up to 40 targets. Up to 40 navigation lines can be selected, and there is storage of up to 180 video maps of 40 elements each.

Atlas 7600 AC/TM is a simpler radar, capable of plotting 10 manually acquired targets semiautomatically.

◆ TRS Series

AEG's family of C-band surveillance radars is derived from the land-based TRM series. Although a major radar supplier to the German Army, AEG is only now (1988) producing naval radars, and only the simplest of its radars has been purchased by the West German navy. Presumably, the navy considers TRS-C a test case for AEG's digital radar technology, and orders for the more elaborate 3D radars (for example, for the new Type 123 interim frigate) may well follow. It was announced in the fall of 1990 that later units of the Danish Stanflex 300 series would be fitted with a C-band Telefunken TRS-3D/16 radar in place of the AWS-6 of the initial units. The German *Thetis*-class corvettes; Type 351 minesweeping drone-control ships; and Type 331, 340, 341, and 394 mine-countermeasures craft all have

TRS-N surface-search radars, which are presumably related to other types within the TRS series.

The other major German manufacturer of land-based radars, Siemens, has not produced any naval sets, although its pulse-doppler missile-warning radar reportedly inspired the U.S. development of SPS-58/65 (see below).

The basic land-based model is TRM-S, a mobile planar-array 3D radar employing phase-coded pulse compression; this model is capable of varying its PRF. The beam is steered in elevation by phase shifting, the large version of the antenna containing 4000 elements. Phase coding can be altered on a pulse-to-pulse basis, as can transmitting frequency. The receiver has 2 identical channels, 1 for sidelobe suppression. Signal processing includes MTI and CFAR. Targets are automatically detected and correlated with targets detected by IFF, and the output is a combination of raw and processed video. AEG claims that TRM-S can detect a 1-m² target at 100 km (probability of detection is 90%). Scan rate varies from 4 to 20 rpm, and up to 4000 targets can be displayed simultaneously.

TRM-S is unusual in employing polarization agility (horizontal, vertical, and circular), and the radar can vary its vertical beamwidth by a factor of up to 8. Polarization agility is useful because circular polarization limits the effect of rain but imposes a sacrifice in target cross section. Each row of the array is fed by 2 sets of feeds, each set having its own ferrite phase shifters. Each shifter feeds a series of polarized elements, and adjustment of the phase between each pair of structures produces the desired polarization.

TRM-S was first installed in 1979.

TRM-L is a 2D version using many TRM-S components but having a much less powerful transmitter (a 1-m² target can be detected at 46 km with 80% probability). TRM-L is the standard search radar for German Roland short-range air-defense missiles. TRM-L can change its PRF and frequency on a burst-to-burst basis, using doppler filtering to reject clutter, and using separate adaptive detection thresholds for each doppler channel (to defeat ground clutter, rain clutter, chaff, and noise jammers). As in the larger TRM-S, TRM-L automatically extracts radar targets (ATD). In addition, it uses doppler velocity data to calculate target velocity, thus improving overall tracking. Again, like the larger radar, TRM-L employs pulse compression to reduce the size of its resolution cell, uses sidelobe blanking, and has a jam detector. For TRM-L, the data rate is 2 or 4 sec (15 or 30 rpm), and the maximum elevation coverage is 60 deg (csc² beam).

The naval versions are:

TRS-S, a navalized TRM-S, intended for larger vessels. The size, capability, and weight can be gauged from TRS-S's replace-

TRS-S as it would appear on board a *Bremen*-class frigate. (AEG)

TRS-3D as it would appear on board a fast attack boat. (AEG)

ment of the current DA-08 2D radar on the German *Bremen*-class frigate.

TRS-MFR is a multifunction frigate or destroyer radar, currently under development, presumably for a future German air-defense frigate (Type 124).

TRS-3D is a smaller 3D radar adapted to fast patrol boats. It is presumably comparable in size to the Raytheon MBAR and to the Hughes TAS Mk 23, both of which have been considered for installation on board German attack boats. This is the version bought by the Royal Danish Navy. At Defendory in October 1990 it was described as an agile pencil-beam radar, which may mean that it can maintain 2 simultaneous scan patterns, like EMPAR. Presumably, it competes with the new French MRR. Like the French radar, it offers MTI Doppler processing, ADT, and clutter suppression; it is intended to detect both high divers and surface-skimmers.

TRS-C is a 2D C-band radar for medium vessels, using either the S-band TWT of the others or a magnetron. TRS-C has recently (early 1989) been ordered by the German government for auxiliaries ("fleet service boats").

◆ KR-75

This AEG-Telefunken X-band coastal radar was first installed in 1977, and by mid-1982 at least 9 had been sold. Peak power is 60 kW (average power is 0.07 kW, and PRF is 4800 pps), and the beam is 0.35 deg wide, scanning at 18 rpm. A typical aircraft is detected at 13.5 nm.

◆ OFLA-M

This optronic fire-control system is optimized to detect low fliers. A television tracker and laser range-finder are mounted on a pedestal above decks, the below-decks console showing range, elevation, and azimuth data. The television tracks automatically to provide a bearing rate for the ballistic computer. OFLA-M was designed specially for simplicity, and as a result the system initially lacked an IR sensor for night or bad-weather operation. However, when the contract was amended, an IR tracker and a laser range-finder were added, with a millimeter-wave radar available as an option.

The manufacturer was AEG-Telefunken, and the name means *Optronische Feuerleitanlage-Marine*. The German navy awarded the first development contract in 1975, for delivery in 1978 for the hydrofoils then planned. The hydrofoil was canceled, and the contract amended to allow for all-weather operation.

OFLA-M was one of several optronic fire-control systems competing for the German 1985 minehunter contract, and later for the S143A fast patrol boat and the Type 122A frigate. The others included Canopus (Thomson-CSF), Totem (CSEE), LIOD (Signaal), and the Swedish 9LV100.

INDIA

Bharat Electronics manufactures several radars, details of which are not available. RAWS is a version of the Signaal DA-05. RAWL is probably a version of LW-04, but with different parameters (pulse widths 2 and 4 microsec, PRFs 500 and 250 pps, respectively, range 180 km on a 1-m² air target). Each uses a magnetron with 6 spot frequencies. RAWS has digital MTI.

According to the Indian annual Defence Ministry report for 1988/89, an indigenously developed naval surveillance radar has been installed at INS *Dronacharya*, Cochin, to detect very fast sea-skimmers. Presumably, it is the prototype for a shipboard radar, and almost certainly it is a Bharat Electronics product.

Bharat also manufactures a navigational radar, Type 1245, which is fitted to the new corvette *Khukri*.

ISRAEL

RADARS

◆ AMDR

The Automatic Missile Detection Radar by Elta is associated with the Barak defensive system. The transmitter is a TWT, and the masthead antenna produces a csc² beam. Velocity coverage is Mach 0.3–3, and maximum instrumented range is 30+ km. Elta claims 90% probability of detection of a 0.1-m² target at 15 km; estimated range against a sea-skimming missile is 16 nm.

Operating in S-band, AMDR is a coherent doppler radar using DFT (discrete Fourier transform) and doppler filtering to reject slow-moving (less than Mach 0.2) targets and to measure a target's radial velocity from a single burst of pulses (i.e., during a single antenna scan). This mode of operation makes for TWS capability. Threats are automatically evaluated and ranked, and threat data passed to the Barak weapons system, target azimuth and speed being extracted by a microprocessor. The display may be a 16-in PPI, a digital scan converter (colored TV), or an alphanumeric display (CRT). The 64-kword data processor used for correlation and tracking is programmable.

The masthead weight is 220 kg.

AMDR is presumably the successor to the earlier EL/M-2207. The first installation was probably on board the Singaporean missile boat *Victory*; this radar will also be mounted on board the experimental missile boat *Nirit* (Sa'ar 4.5) and almost certainly the new *Lahav* (Sa'ar 5). It is the target-designation radar for the Barak missile system, designating missile targets (including sea-skimmers) to the tracking and guidance radar. Besides its antimissile role, AMDR also has a role as a conventional air-search radar.

◆ Barak FCS Radar

The Elta X/Ka-band, pulse-Doppler, target-tracking and missile-guidance radar of the Barak point-defense missile system is coherent in both bands. At least as illustrated thus far, the typical ship installation employs 2 such radars for 360-deg coverage. The topside antenna weight is 700 kg, with 3 m² of deck space required internally for the radar and FCS. Missile elevation limits are +85/–25 deg. Published references to 1 radar handling 2 targets simultaneously suggest that this system time-shares its receiver/transmitter between 2 topside dishes.

◆ EL/M-2207

Band: S (3.1–3.3 GHz tunable)
Beam: 3.3 × 10 deg (csc² to 30 deg)
Peak Power: 425 kW (average 425 W)
Gain: 28 dB **Pulse Width:** (i) 1.4 (ii) 0.4 microsec
PRF: (i) 500–700 (ii) 1000–1500 pps **Scan Rate:** 12 or 24 rpm
Antenna Dimensions: 2.4 × 1 m **Antenna Weight:** 245 kg

An Israeli missile boat of the *Reshef* class, equipped with an ELTA air-search radar (either EL/M-2207 or -2208; both use the same antenna) and probably with an EL/M-2221 gunfire-control radar. The gun is an OTO-Melara 76 mm. Two single-barrel long-range chaff launchers are visible alongside the superstructure, under the bridge windows. Two box launchers (24 barrels each) for short-range chaff are visible, canted outboard, abaft and below the bridge. (U.S. Naval Institute)

Elta's air- and surface-search radar is part of the EL/M-2200 series of shore and naval radars, all of which use the same basic transceiver unit. The AT-101 antenna is stabilized, and the manufacturer, Elta Electronics, Ltd. (an IAI subsidiary), claims that its design is such as to require only 66% of the reflector area of a more conventional radar. Range is 30 nm against a 2-m² target. Resolution is better than 75 m for the short pulse, better than 230 m for the long pulse.

The AT-101 antenna is also used in the EL/M-2208 dual-band radar, and the antenna can be used in the L-band (7 × 20-deg beam) for IFF.

◆ EL/M-2208

Band:	S	X
	3.1–3.3 GHz tunable	9.345–9.405 GHz fixed
Beam:	3 × 10 deg	1 × 5 deg
Peak Power:	425 kW	25 kW
Gain:	28 dB	34 dB
Pulse Width:	(i) 1.4 microsec (ii) 0.4 microsec	0.25 microsec
PRF:	(i) 500–750 pps (ii) 1000–1500 pps	1000–1500 pps
Antenna Dimensions:	2.4 × 1 m	
Antenna Weight:	245 kg	

EL/M-2208 is Elta's air- and surface-search radar. S- and X-band transmitters (and the L-band IFF) share the same fully stabilized masthead antenna, for reduced total weight. The long pulse and digital MTI give long range and air surveillance; the short-pulse feature is useful for navigation. Estimated detection range of a jet fighter is 30+ nm, and surface targets can be detected out to the horizon. The PRF can be staggered for MTI without blind speeds.

Data above refer to the AT-101A antenna. In L-band, for IFF, this antenna produces a 7 × 20-deg beam (gain 17 dB). Scan rate is 12 or 24 rpm, and the antenna is stabilized. Antenna elevation angle can be remotely controlled. The antenna weight listed is that of the basic unit; as fitted for X-band operation it weighs 200 kg, and as fitted for S-band, 270 kg. Resolution is 1 deg in azimuth and 50 m in range.

The EL/M-2200 radar series was introduced about 1980, to replace the French Neptunes that had previously equipped Israeli warships. These radars are described as suitable for ships of over 250 tons, i.e., the *Sa'ars*. Radar volume and weight were reduced by exploiting IAI's experience with airborne radars.

This radar was conceived as a dual-purpose unit for small warships, which could not accommodate separate air- and surface-search radars. Air search requires relatively long wavelengths to achieve long range (reduced transmission loss); hence the S-band feature. On the other hand, surface search requires

a short wavelength (to reduce multipath effects), a narrow beam, and very short pulses (the last 2 to reduce clutter). IAI concluded further that the signal-to-clutter ratio is not a function of transmitted power, so the surface-search portion of the radar can operate at moderate power. The company argues that moderate power is an advantage to a ship operating in narrow waters such as estuaries (or just offshore), since under such conditions the radar may send and receive strong signals through its sidelobes, introducing ghosts and false targets. The choice, then, was S-band for air search (air alert), X-band for surface search, and L-band for the usual IFF. The same antenna is connected to 3 separate transceivers, and all data are collected in a single signal processor and then a single unified display.

The S-band beam is vertically polarized to reduce the effects of lobing, which creates holes in air coverage. On the other hand, the X-band beam is horizontally polarized to reduce the effects of sea clutter. In addition, the S-band beam can be circularly polarized to reduce weather clutter (circular polarization improves the signal-to-clutter ratio by 10 to 20 dB but reduces the target's radar cross section). The operator changes S-band polarization from vertical to circular by inserting a mechanical polarizer in front of the feeder connecting the radar transmitter to the mast waveguide.

To achieve high gain (to detect small surface targets), the designers selected a narrow pencil-beam shape. That choice in turn required stabilization, which was difficult to achieve within the 200-kg total antenna weight. The solution was to stabilize only the reflector rather than the complete antenna pedestal.

For air search, the choice was between a csc² beam-form and helical scanning. The latter was rejected because the radar would require several scans to complete an air search up to a given elevation angle and, thus, would lose data rate (a key consideration for a radar designed to detect fast attackers). The radar has 2 alternative scan rates, fast (for high data rate) and slow (for longer range).

The X-band transmitter is a frequency-agile (for ECCM as well as to reduce STA problems, to eliminate target fading, and to decorrelate sea and rain clutter) TWT, for pulse compression. For short-range detection, short noncompressed pulses are interlaced between the compressed pulses. The operator can vary both pulse width and PRF, and can synchronize PRF with the S-band transmitter (not necessarily in a 1:1 ratio). The system incorporates an adaptive (rather than manual) STC (sensitivity time control) to keep the threshold for displayed signals just above the sea clutter, taking into account the clutter's range and bearing. In at least some versions, the radar is not automatically frequency agile but instead can be tuned rapidly by hand knob, to use frequency-band diversity.

The S-band portion of the radar avoids clutter (such as chaff) by digital MTI, using a tunable magnetron capable of operating at multiple pulse widths and PRFs.

There is also a sidelobe blanker that uses a separate omnidirectional antenna and receiver.

Processing is by a combination of plot extraction and operator viewing of raw video. For example, in the surface picture a nearby land mass may appear to an automatic extractor (ATD) to be a mass of real targets (which will saturate the system's track memory), whereas the operator can ignore the land as irrelevant. Surface tracks are, therefore, manually initiated, although once they have been tagged, the system automatically tracks them (in TWS mode). On the other hand, air and sea-skimmer targets must be rapidly (hence automatically) detected and dealt with. The associated combat system, therefore, automatically detects and tracks air targets, conducts threat evaluation, and assigns weapons.

This radar equips Taiwanese Wu-Jinn II destroyers, which are armed with Hsiung Feng I missiles, similar to Gabriel.

As of 1980, well over 50 EL/M-2200 series radars were delivered or on order, many of them for export to unspecified customers.

◆ EL/M-2221

Elta's X-band fire-control radar is associated with guns and Gabriel missiles. The monopulse antenna is sometimes housed in a trainable, elevating barrel-shaped radome. There is an autonomous search mode, although targets can be designated from other sensors. Diameter is 1 m, and overall weight is 150 kg.

This radar probably originated as a reverse-engineered version of the Italian RTN-10X.

◆ EL/M-2216

Band: S (3.1–3.3 GHz, with 2.7–2.9 GHz optional)

Beam: 1.4 × 5 deg **Peak Power:** 425 kW

Pulse Width: 0.95 or 0.4 microsec (latter only in 2216)

PRF: fixed 1 of 4 or 4 staggered (900–1050 pps) plus short-pulse mode (1360 pps) in 2216 only

Scan Rate: 12.5/6 rpm

This coastal-surveillance radar is the EL/M-2215 ATC radar with a different (AT-102) antenna; data above (including antenna data) are for EL/M-2215 (AT-103 single-beam antenna). EL/M-2216 is a high-resolution dual-band (X- and S-band) system with a fast-scanning X-band component, for surface search (including small-target detection) and optional low-flier search. The 2215 radar has dual MTI, and the first blind speed is Mach 3. In addition to the single-beam antenna, -2216 has an optional dual-beam (high-low) type, AT-104. The same radar is also sold in a mobile version, EL/M-2220. It was developed from the earlier EL/M-2205.

EL/M-2216 is capable of detecting ships at a range of 20 nm.

OPTRONICS

◆ GSSS-1A1

The Gabriel Stabilized Sight System (GSSS) by Tamam (which produces the pedestals of the Elta radars) entered Israeli navy service in the early 1980s. The upper mirror of the periscope is gyro-stabilized, and the system has dual magnification (10×, 2.5×, corresponding to 5- or 20-deg field of view). A laser or IR detector can be mounted in parallel, and the system is designed for integration with an LLLTV. Tracking rate is 30 deg/sec in azimuth or elevation, and elevation limits are +60/–30 deg. Total weight is 65 kg.

◆ MKD 600

Tadiran's gyro-stabilized daylight television camera is suitable for use on board ships and helicopters. It uses a 40/400-mm focal length zoom lens (field of view 15.7 down to 1.57 deg), and can use a 60/600-mm lens. Acquisition range on a tank is 29 km, and the vehicle can be identified at 3 km. As of mid-1989, MKD 600 had been exported to 2 countries, and a publicity photograph showed it on board the hydrofoil *Shimrit*.

The earlier MKD 400 is used on board the Pioneer UAV.

◆ MSIS

El-Op's Multisensor Stabilized Integrated System carries 3 sensors (FLIR, television, and laser) in a 4-axis stabilized spherical turret. The associated command/display unit incorporates a video tracker and can control guns of up to 76-mm caliber. The laser ranger has a minimum range of 300 m. Angular coverage is +85/–15 deg, and maximum slew rate is 60 deg/sec. Line-of-sight stabilization is within 20 microrad. Fields of view are 25.7 × 9.2, 7.4 × 5.5, and 2.1 × 1.57 deg.

El-Op claims that the FLIR can detect a missile boat (4 × 6-m target, presumably head on) at 17,000 m and recognize it at 8200 m; the FLIR detects an aircraft (2.5 × 4-m target) at 16,000 m and recognizes it at 5900; and it detects a dinghy (1.5 × 1 m) at 6500 m and recognizes it at 2100 m. Corresponding figures for the daylight television camera are: missile boat, 12,000/6500 m; aircraft, 9000/5000 m; and dinghy, 6500/3500 m.

Turret diameter is 550 mm; turret height, including pedestal, is 650 mm. The turret weighs 60 kg, and total system weight is 100 kg (220 lb).

MSIS was ordered by the Israeli navy in 1988.

◆ SPIRTAS (DS-35)

DS-35 SPIRTAS (Shipboard Passive IR Target Acquisition System) sensor head. (E1-Op)

DS-35 console. (E1-Op)

MSIS turret on board a patrol boat. (E1-Op)

MSIS command and display unit. (E1-Op)

The details for this IR target-acquisition system by El-Op were first published in 1982. SPIRTAS is primarily a sea-skimmer detector, operating in the 3–5 micron band. The 120-kg mast-head sensor unit is 120 cm tall and 80 cm wide and houses a stabilized scanning head. The CRT in the CIC console can show 3 alternative displays: a low-resolution picture of the overall scene, an enlarged thermal display, and a special auxiliary display showing the intensity (i.e., heat) behavior of selected targets as well as the target data transmitted to other shipboard systems. Scanner elevation limits are $+20/-2$ deg, and a full 360-deg scan takes 8 sec (1.25 sec in the antimissile mode). The accuracy of target data is within 7 mrad. The detector is an InSb multi-element array, cooled to 77 deg Kelvin.

ITALY

RADARS

Selenia uses the prefixes RAN (*Radar Avvistamento Navale*, or naval research radar), RAT (*Radar Avvistamento Terrestre*), and RTN (*Radar Tiro Navale*, or naval fire-control radar) for its radars. The letter in the suffix generally indicates the frequency range, at least for recent radars (e.g., RAN-10S operates in S-band).

RAN-2C, -7S, -13X, and -14X, which are all listed in many reference books, were experimental sets that did not enter production.

◆ BPS-704

See 3RM Series below.

◆ SPN-703

See 3RM Series below.

◆ SPN-720

This combined carrier-landing radar was initially supplied to Argentina for the carrier *25 de Mayo*, and then to the Italian navy for the carrier *Giuseppe Garibaldi*. SPN-720 was developed by linking the SPS-702 search radar with a new tracker. This radar, developed by SMA, was announced in 1984. The radar covers the 150–270-deg sector abaft the ship, and the glide path is adjustable between 2 and 21 deg. Search range is about 15 nm; approach-control range is about 8 nm. Aircraft can be detected at altitudes up to 2000 m [about 6600 ft]. This radar is the only current Western alternative to the U.S. SPN-35, and it is shown as installed on board the Argentine carrier *25 de Mayo*.

SPN-720 carrier-controlled-approach radar. Search range is about 15 nm; approach-control range is about 8 nm. Aircraft can be detected at altitudes up to 2000 m (about 6600 ft). (SMA)

Coverage of the SPN-720 carrier-controlled-approach radar. The only current Western alternative to the U.S. SPN-35, SPN-720 is shown as installed on board the Argentine carrier *25 de Mayo*. (SMA)

◆ SPN-728

SMA's X-band surface-search radar uses a high-gain double-curvature antenna with csc² vertical cover; SPN-728 can be used for helicopter control. This medium-power X-band radar is supplied with several alternative roll- and pitch-stabilized antennas. There are 4 alternative pulse widths, and the display is raster- rather than rotating-scanned, partly so that the radar can use low-cost television-type monitors as repeaters. Targets are automatically detected.

SPN-728 antenna, for navigation and surface search. This medium-power X-band radar is supplied with several alternative roll- and pitch-stabilized antennas. There are four alternative pulse widths, and the display is a raster rather than a rotating scan, partly so that the radar can use low-cost television-type monitors as repeaters. Targets are automatically detected. (SMA)

◆ SPN-748

Gem Elettronica's X-band navigational radar for large ships uses a 10-in CRT. This radar is used on board the training ship *Amerigo Vespucci*, in 2-antenna form.

◆ SPN-749

Gem Elettronica's navigation radar for the carrier *Giuseppe Garibaldi* consists of a master antenna at the bow and a slave antenna at the stern, for 360-deg coverage that does not interfere with the flight deck. Both antennas operate in X-band (9345–9405 MHz with peak power of 20 kW), and both antennas feed a single PPI.

◆ SPN-753(V)

Gem Elettronica's raster-display ARPA navigation radar was announced in 1989. Up to 50 targets, including fast (600-kt) aircraft, are auto-tracked. They can be auto-acquired, or up to 20 can be manually acquired. Each tracked target is assigned a 2-digit tag, and data for each target can be read out: bearing and range, course and speed, CPA, theoretical CPA, latitude, and longitude. The display also shows alert and failure signals. The display can be either a ship-centered or off-centered PPI. The color display (1280 × 1024 pixels, 4 bits per pixel) can show video maps (including those drawn by the operator) and alpha-numerics as well as raw video. There is a data window (alpha-numerics) to the right of the radar image. The system can carry up to 200 target-identification symbols, as well as a selectable alert zone. The radar image can be zoomed, and it can also be frozen. Because SPN-753 interfaces with navigational systems such as GPS and Loran, own and target positions can be associated with their latitude and longitude. Both 19- and 26-in displays are available.

The commercial equivalent appears to be GEMANT 2(V)1, which uses 6-, 7.5-, and 9-ft antennas and has alternative 10-, 25-, and 50-kW transmitters.

SPN-753 can feed Gem's SSN-752 automatic tactical table.

Gem also manufactures an SPN-751 navigational radar, apparently the last of its line not to incorporate a digital scan converter (the company makes a scan converter for SPN-748 and -751).

◆ SPQ-2 (and MM/SPQ-701 and SPS-702)

Band: X **Beam:** approx 0.6 deg wide **Peak Power:** 180 kW
Pulse Width: (i) 0.15 (ii) 1.5 microsec
PRF: (i) 2500–3000 (ii) 450–550 pps
Scan Rate: fast rotation (40 rpm) available as option
Antenna Dimensions: approx 3 m wide

Data listed are for SPQ-2.

SPQ-2D operates with alternating 1.0- and 15.0-microsec pulses at a peak power of 60 kW, scanning at 15–20 rpm. This is the version on board Canadian *Iroquois*-class destroyers.

SPQ/SPS-701/702 operates in 2 modes, tactical (180 kW, 8450–9220 MHz, frequency-agile, with 0.3-, 1.0-, and 1.6-microsec pulses) and navigational (50 kW, fixed frequency between 9440 and 9500 MHz, 1.1-microsec pulses). PRFs: navigational, 1000 or 1028 pps; tactical, 593–594, 622–623, 837–839, 934–936, 1000–1004, 1036–1038, 1968–1984, 2034–2032. These radars scan at about 15 rpm.

This radar, produced by SMA, time-shares long and short pulses for both medium-range air and surface search and precise short-range navigational coverage. SPQ-2 is sometimes used for target designation. Users: Italian, Canadian (SPQ-2D in the *Iroquois*-class frigates), and Venezuelan (SPQ-2D in *Constitution* class) navies. Options include fast antenna rotation (up to 40 rpm), MTI with an L-band system using the same antenna to detect low fliers, and a transponder. Both stabilized and non-stabilized versions exist. The current variant is SPQ-2F. This radar should not be confused with the U.S. SPQ-2, an obsolete (and extinct) missile-control set for the Regulus surface-attack missile.

SPQ-701 and SPS-702 are developments of the SPQ-2. SPQ-701 is the radar of the *Sparviero*-class hydrofoil; SPS-702 is for *Maestrale*-class frigates. The SPQ-701 antenna is a parabolic reflector with a narrow vertical dimension, for surface- and air-target detection. SPS-702 uses a broader antenna with a high-elevation component above the main reflector.

SPQ-3 is an S/X-band coastal-surveillance radar, the 2 units being mounted back to back; either can vary its angle of elevation from –5 to +15 deg. Presumably, SPQ-3 uses the same transmitter as SPQ-2.

◆ SPS-768

See RAN-3L below.

◆ SPS-774

See RAN-10S below.

◆ MM/SPY-790 (EMPAR)

Band: C (5.6 cm) (frequency agile over 10% of frequency)
Beam: 2.5 deg (scan angles ±45 deg in azimuth, +95/–25 deg in elevation)
Peak Power: 120 kW (10–12% duty cycle)
Scan Rate: 7.5 rpm (data rate 8 sec)
Antenna Dimensions: 1.5 m square
Weight: 2500 kg above decks, 5000 kg below

Mock-up of the Marconi-Selenia EMPAR antenna, RNEE, 1989. (Author)

EMPAR (the European Multi-Purpose Array Radar) is to be used in the Italian variant of the Franco-Italian FAMS missile system, for target search, acquisition, and tracking. The French equivalent is Arabel. Under development by Selenia and Marconi, EMPAR employs a square array of 2200 pin diode 4-bit phase shifters, tilted back at an angle of 30 deg. The beam is steered by phase scanning in both elevation and azimuth, while the antenna itself turns; it is also electronically stabilized. The designers chose a rotating rather than a fixed array for its simplicity and relatively low cost. They rejected elevation-only scanning (as in, say, SPS-48) because that would have made for too low a data rate. By scanning in both directions, the radar can vary its effective data rate on a mode-by-mode basis, with slow scanning for longer range and faster scanning for higher data rates closer in. Scanning in 2 directions also makes it possible for the radar to track targets by monopulse techniques, since adjacent beams can rapidly be formed.

The entire array is liquid-cooled, through a water rotating joint. The transmitter is a driven TWT, for frequency agility; the radar can automatically choose optimum frequency. The radar can operate at low or medium PRF, and its signals are digitally pulse compressed. Processing includes doppler filtering (using FFT and DFT), and targets can be tracked by monopulse, using adjacent beams. Higher frequency was attractive for good target discrimination and angular accuracy, for good low-level

coverage (multipath effects can be minimized at higher frequencies), and for good ECCM (required jammer power is proportional to the square of the frequency). However, a lower frequency was attractive to avoid interference with existing X-band radars, for better weather penetration, and for better clutter rejection. Selenia considered the choice to be limited to S- or C-band and chose S. The radar was originally designed to produce a 2.5-deg beam using a 2×2 -m antenna, and the reduction in antenna size reflected in the data given above presumably means that the beam is somewhat wider.

Selenia considered both active and passive arrays. An active array, with the transmitters in the array proper, was attractive because it made for greater efficiency (no losses between antenna and transmitter), hence for reduced overall IR emissions, reduced system weight (but with more of it concentrated in the antenna), better system reliability, and lower costs (thanks to the use of standardized components). However, it would be difficult to match phases between the different modules, the modules would produce heat that would have to be carried away, and the antenna itself would weigh more. Moreover, the promised industrial production of C-band active modules, which seemed imminent in the 1970s, failed to occur.

The design emphasizes high effective data rate, to track small fast targets that suddenly pop up at short range, and also nearly simultaneous tracking of numerous widely separated targets. The phased array forms one pencil beam at a time, but it can be shifted very rapidly from position to position, on a pulse-to-pulse basis. A 1987 account of the design (which described EMPAR as a 4D radar) listed requirements as medium-altitude detection at 50–100 km, and low-altitude detection at 20 km; the radar had to scan over a 120-deg angle in elevation (and over 360 deg in azimuth).

The radar management computer is a Selenia MARA series machine, programmed in ADA. Among its functions are translation of signal data from coordinates fixed in the rotating antenna to coordinates fixed in the ship. Actual signal processing is done by a separate processor based on the Marconi transputer array processor.

Operating modes: (i) volumetric search (VOS), which can be at short or medium ranges (SRS or MRS), in each case in elevation as well as azimuth; (ii) long-range search (LRS); (iii) high-priority tracking (HPT); and (iv) low-priority tracking (LPT). VOS is conducted at a data rate of 8 sec and consists of a horizontal search (HOS) and a vertical medium- and short-range search. The horizontal search is conducted over 144 directions, the vertical over 3191 directions (spread over elevation and bearing). HPT operates at a 1-sec data rate and can maintain 36

tracks. LPT operates at a 4- or 8-sec data rate, tracking up to 264 targets, but with lower-quality information. In main (VOS) mode, on every antenna rotation (i.e., every 8 sec), the radar scans once in each MRS and SRS direction; conducts 4 scans in every horizontal direction (HOS); updates each HPT target 8 times (effective tracking data rate 1 sec), then updates each LPT target once or twice (effective data rate 8 or 4 sec); and conducts 8 up-link transmissions to the missiles it controls. Maximum operating load is 300 aircraft tracks and 24 missiles under control. Estimated tracking accuracy is 3–5 mrad. Fully loaded, the radar spends 75% of its time searching for new targets, 20% tracking ones already detected, and 5% up-linking. The 3191 beam positions cover the entire hemisphere around the radar, over a 120-deg elevation sector passing through the zenith.

The original design was a back-to-back version (for twice the data rate) but also with about half as many phase shifters (in a 2-m square face).

EMPAR is designed to detect a 0.1-m^2 target at 50 km, a 2-m^2 target at 100 km, and a large aircraft (10-m^2) at 180 km. EMPAR is to be able to handle about 300 long-range targets and to track 50 of them well enough for missile engagement.

Selenia began studies of multifunction radars as early as 1965 and conducted a feasibility study in the 1970s. The company was awarded the development contract in 1986, for prototype completion in 1990, with sea trials in 1992 aboard a *Carabinieri*-class frigate. Marconi and Thomson-CSF joined the program. The Royal Navy is reportedly interested in a shorter-range (30 km) version for its Support Defence Missile System (see entry under Surface-to-Air Missiles). EMPAR was originally the Italian radar offered for the NATO frigate and for the associated NAAWS program, and its characteristics reportedly reflect NAAWS requirements.

In FAMS, EMPAR is associated with a longer-range surveillance radar, the French Astral. This radar was chosen in 1989 instead of the Selenia RA30 (presumably an S-band equivalent to EMPAR) and SLORA (a radar using existing Ceselsa modules plus Marconi Radar components).

◆ MLA-1B

Band: L **Beam:** 3.7×45 csc² deg **Peak Power:** 600 kW
Pulse Width: (i) 1.0 (ii) 4.0 microsec **PRF:** (i) 800 (ii) 200 pps
Scan Rate: 5 or 15 rpm

Data apply to MLA-1, the original version. Resolution in this version was 170 yd.

This L-band air-search radar was the first major Italian domestic set. It appeared in 1957 and was manufactured only for export; it survives only on board Portuguese *Joao Coutinho*- and *Dealey*-class frigates. It was also widely used in the Spanish navy, and on board Italian *Almirante Clemente*-class frigates

MLA-1B air-search radar antenna on board the Portuguese frigate *Joao Coutinho*. (Embassy of Portugal)

exported to Indonesia, Portugal, and Venezuela. Peak power is 250 kW, and maximum instrumented range is about 150 nm. The antenna is about the size of that of SPS-6, but its shape is quite different.

The manufacturer, Microlambda, merged with SINDEL in 1959/60 to become Selenia. The company produced 2 other radar series, navigational sets (MLN) and fire-control sets (MLT), the latter based on U.S. Mk 26 and Mk 39 radars. The MLTs were distant forerunners of the current Orion series.

◆ RAN-3L (MM/SPS-768)

Band: L **Beam:** 2.15×9 deg plus csc² **Peak Power:** 135 kW
Gain: 30 dB **Pulse Width:** 78.4 (compressed to 1.6) microsec
Scan Rate: 6 rpm
Antenna Dimensions: 7.56 × 3.65 m [24.9 × 11.8 ft]

RAN-3L (SPS-768). (Selenia)

The Selenia large-ship search radar was developed for the Italian Defense Science Technical Committee and the Italian navy. RAN-3L is one of a range of such radars, the suffix indicating the frequency band. Rated maximum range is 150 nm (100+ nm on a fighter). Range accuracy is 70 m, and angular accuracy is 0.4 deg. The transmitter is frequency agile, and the receiver uses doppler processing for MTI. The waveform is multipulse coded, as in RAN-10S (see below). Maximum range can be increased to 160 nm by using dual-frequency diversity (to overcome the problem of STAs); range is slightly shorter with only 1 channel. The antenna is designated G12.

RAN-3L began in May 1966, following a navy proposal, as an Italian government research and development project (CTSD MM-9) for an early-warning radar with stringent anticlutter and

ECCM requirements. Selenia was chosen on the basis of its work in ground radar. A contract was signed in 1968; the defense ministry R&D organization (CTSD) paid for the breadboard version and the first prototype, and the Italian navy for 4 production prototypes, 2 of the bichannel and 2 of the mono-channel versions. The project included Selenia's development of its own pulse-coding technique and also BITE. The breadboard model was completed in 1972, and 3 years later the prototype was tested on board the test ship *Quarto*. Operational tests were completed in November 1975, in the Gulf of Gaetta, against F-104S and T-33 aircraft.

This radar in its 2 versions replaces earlier U.S. types (SPS-12 and SPS-40) on board Italian cruisers and the *Audace*-class destroyers, and RAN-3L is the 2D air-search set of the carrier *Giuseppe Garibaldi*. However, this radar was considered too heavy for small and medium ships. A new lighter radar, RAN-10S (MM/SPS-774), was, therefore, designed for the *Lupo*-class frigates, using substantially the same technology. RAN-10S is described below. Selenia also used some of the same technology in RAN-11L, which was intended for small warships and patrol craft.

◆ RAN-10S (MM/SPS-774)

Band: S **Beam:** 1.5×17 deg (coverage to 60-deg elevation)
Peak Power: 140 kW **Gain:** 28 dB
Pulse Width: 20.8 (compressed to 0.4) microsec
PRF: about 900 pps **Scan Rate:** 15 or 30 rpm
Antenna Dimensions: 4.3 × 0.7 m [14.1 × 2.3 ft]

This radar, derived from RAN-7S, was introduced in 1980 and is intended for frigates and corvettes. RAN-10S is installed on board *Lupo*-class frigates of the Italian, Peruvian, and Venezuelan navies. Maximum unambiguous range is 90 nm; effective range, about 40 nm on a fighter. Range accuracy is 20 m, and angular accuracy is 0.35 deg. The transmitter is frequency agile (sweep to sweep), and the receiver uses doppler processing for MTI. The processor includes CFAR.

RAN-10S was an early application of pulse coding, an operation in which bursts of related pulses are transmitted in place of the usual single pulses. Pulse coding was adopted to achieve a combination of sweep-to-sweep frequency agility (for antijam performance) and doppler filtering (for MTI and clutter rejection). The idea was to filter on a single-sweep basis, then shift the filter criteria for the different frequencies used on the next sweep. Matched filters tuned to different doppler frequencies can directly reject clutter on each sweep. The interval between bursts determines the maximum unambiguous range, just as the interval between pulses determines that range in a conventional pulsed radar. As with pulse compression, the use of a burst of pulses reduces peak power but maintains sufficient average power for the radar to achieve a reasonable chance of detecting a target at long range. Each pulse within the burst requires its own doppler filter, and it is, therefore, impractical to use too many pulses. However, the use of only a few pulses per burst also limits the effective pulse-compression ratio, and a high pulse-compression ratio (since it provides, in effect, shorter pulses) makes for better range accuracy and also for better clutter rejection. The solution in this case is to code each pulse within the burst, so that it is (in effect) a pulse-compression pulse.

The returning pulses are subject to Fourier analysis, to extract doppler shifts. The measured shifts cannot exceed the spacing between the different frequencies making up the pulses. For the RAN-10S, 4 filters are provided, each with the maximum bandwidth (as determined by the pulse coding), and each shifted by that bandwidth so that they cover the whole bandwidth defined by the pulse spacing within the burst; this spacing (frequency) determines the range of frequencies within the pulses.

Scan-to-scan frequency agility is accompanied by scan-to-scan shifts in coding within the bursts, and that shifting in turn reduces clutter and makes deception jamming more difficult.

Each burst cannot be more than about 10% of the interval between bursts, to avoid excessive minimum range (dead time).

RAN-10S. (Selenia)

RAN-10S. (Selenia)

RAN-10S uses 4 pulses, and the ambiguity speed is set at Mach 3 (1000 m/sec), corresponding to a pulse spacing of about 50 microsec within the burst. Since that spacing implies a burst length of about 150 microsec, the burst repetition interval is probably about 1.5 msec, corresponding to a burst repetition rate of about 670.

RAN-10S shares some of the design concepts (and parts) of RAN-3L. The roll-stabilized antenna is designated G10.

A new stabilized SMA-7104 antenna was exhibited at Genoa in June 1986 (beam 1.5×15 deg, gain 28 dB, scan rate 15/30 rpm, and weight 960 kg).

◆ RAN-11 L/X and -12 L/X

Band: L and X (combined antenna)

Beam: (L) 6.6×16 deg, (X) 1.1×6 plus csc² deg

Peak Power: (L) 0.3 kW, (X) 135 and 180 kW

Gain: (L) 22 dB, (X) 35 dB

Pulse Width: (L) 20 microsec (compressed to 2.9), (X) 1.5 and 0.15 microsec

PRF: (X) 450–550 pps **Scan Rate:** 15 or 30 rpm

Antenna Dimensions: 8 ft wide

RAN-11 L/X. (Selenia)

Selenia/SMA's small-ship (hydrofoil) search radar operates simultaneously in L- and X-bands, using the X-band transmitter of the SPQ-2 and a new pulse-doppler L-band transmitter. The latter uses pulse compression. The antenna is cut horizontally, the upper portion reflecting in L- but not in X-band. Range accuracy is 160 m in L-band and 45 m in X-band; angular accuracy is 1.5 deg in L-band and 0.2 deg in X-band.

RAN-12 L/X is the same radar as the -11 modified with a higher-power (1.1 kW) L-band transmitter. Effective X-band range against a low flier is 20+ nm. At medium altitude, range (L-band) is 12+ nm for RAN-11, and 14+ nm for RAN-12. These figures are shorter than X-band ranges because the pulse-doppler L-band transmitter necessarily operates at a higher PRF.

Development of this system began in 1969.

◆ RAN-30S

Selenia's 3D S-band radar was under development as of 1989. It has 2 operating modes: long-range, with a low data rate; and short/medium-range, with high elevation cover and a high data rate. The radar employs a planar-array antenna, roll- and pitch-stabilized, and a frequency-agile transmitter (with staggered PRF) for pulse-compressed signals (uncompressed in a supplementary short-range mode). Targets are automatically detected and tracked, and processing includes MTI. There is a single transmitting beam, with multiple receiving beams (as in SMART, or the British Type 996). Accuracy: 50 m, 0.1 deg. Range on a fighter aircraft: 50 nm in short/medium-range mode, 100 nm in long-range mode.

◆ RAN-30X

The new (ca. 1987) Selenia shipboard air/surface-search radar for small- and medium-sized ships was derived from RTN-30X. RAN-30X can use a single- or multibeam antenna. The multibeam antenna has 3 feeds that time-share power, to provide 3 stacked beams. The horn for the uppermost beam can be tilted, to vary its angle, by remote control. The transceiver is fully coherent, for MTI, and can also hop frequencies between pulses. Pulse compression is used to increase range. Range accuracy is

25 m, and angular accuracy is 0.4 deg. The planar antenna is roll- and pitch-stabilized; it has a 3-m swing circle and scans at 15 and 30 rpm. There are 2 operating modes: long-range with low scan rate and coverage of medium elevation angles, and medium/short-range with fast scan and coverage of high elevations. The manufacturer claims that a fighter can be detected beyond 20 nm.

It is possible to arrange RAN-30X and RTN-10X so that both operate from the same transmitter and receiver, with separate displays.

◆ **RTN-10X/RTN-12X/RTN-16X/RTN-20X/RTN-25X (Orion)**

Band: X **Peak Power:** 200 kW **Pulse Width:** 1.5 microsec
PRF: 450–550 pps **Antenna Dimensions:** 1.4-m diameter

RTN-10X trackers of an NA-21 fire-control system. (Selenia)

The first of the Selenia Orion fire-control radars (RTN-10X, -20X, -30X), the RTN-10X conical-scan set employs the same X-band transmitter as RAN-11 L/X. Orion was designed for one-person operation and particularly for integration into the Albatros fire-control system. Orion can scan in 3 modes: automatic blind-fire, operator-assisted blind-fire, and area. In the first mode the radar searches around a designated point, then locks on and tracks without further assistance. In the second, less accurate data are available, and the tracker searches a larger area. If the radar fails to lock onto a target, the operator can steer the radar to the target position shown on the display. Area search is a horizon or sector search at low elevation, or near a passive ESM bearing. A television camera is bore-sighted to the radar for use under heavy jamming. Targets can be acquired out to 35 km.

The Orion series was developed beginning in 1958 by SINDEL, 1 of the 2 companies that formed Selenia in 1959–60. Series production of Orion RTN-10X began in 1972. It was almost certainly derived from the 200-kW Orion 250 of the original NA-9 FCS. Versions of Orion: Orion 3A/3C for the Argentine cruiser *Belgrano* (sunk in the Falklands), 7/A for the Italian *Doria*-class cruisers and *Pietro de Cristofaro*- and *Bergamini*-class corvettes, and 10/A for the Israeli Gabriel missile boats. Orion was redesigned from 1974 on for coherent operation using TWTs and then with digital technology. Versions: 10/XF (license production in Britain from 1975 on as Type 912), 10/X7 (Italian *Audace* class and hydrofoil *Sparviero* and Peruvian ships), 10/XP (with frequency agility, for the *Lupo* class), 20/X (first monopulse version, optimized for low-altitude tracking, initially for the *Maestrale* class), and 30/X (1980, with twice the power of earlier versions). Falco (H) is a version of Orion 30/X for land-based Aspide air-defense systems.

RTN-10X is the fire-control tracker of the British Type 21 frigate (the Royal Navy designates it Type 912), and it is the tracker of the Ferranti WSA 400-series export weapons-control systems.

RTN-12X is a monopulse version using a 1.2-m-diameter inverse-Cassegrain antenna (presumably the antenna of the RTN-20X and -25X). Beamwidth is 2.2 deg (gain 37 dB), and peak power is 200 kW (0.5 microsec pulses, PRF 2000 pps) at X-Band (8850–9350 MHz). Operating modes include pulse-to-pulse frequency-agile and random-PRF. Typical tracking accuracy on a frigate is 2 min of arc and 3 m; on an airplane (2 m²), 1.5 min of arc and 3 m. In frequency-agile mode the predicted maximum acquisition range against a 1-m² target (95% probability of detection) in free space is 40 km (21.6 nm).

RTN-16X, begun in 1969, is a private-venture development of RTN-10X.

RTN-20X/25X are further derivatives of RTN-10X. Development began in 1973, and they were intended particularly for the Dardo close-in weapons system (for automatic target acquisition and for spotting rounds). RTN-20X is a digital coherent monopulse radar (TWT transmitter tube) with special ECCM features (antinodding and anticlutter). Image effects (because of reflections off the water) are reduced by comparing received signals in sequence, to select the direct-path signal. RTN-20X acquires its targets at 2–6 nm. This radar can acquire and track a target (e.g., an antiship missile) fired by the target being tracked. The antenna is a Cassegrain with twist polarization. There are 2 different (selectable) pulse widths, and the radar hops frequencies on a pulse-to-pulse or burst-to-burst basis; special signal processing is employed to avoid multipath effects when tracking low fliers.

RTN-25X is a higher-powered version of the same radar. The 2 operating modes are long pulse (coded waveform) and short pulse (single pulse). This radar is part of the NA-25 fire-control system.

RTN-25X. (Selenia)

◆ **RTN-30X**

This automatic-target-acquisition and monopulse tracker was designed as part of the Albatros Mk 2 system. Range on low-level targets (such as sea-skimming missiles) in clutter is up to 8 nm. Features include MTI, frequency agility, a coded waveform (i.e., pulse compression), and jam alarm. As in the earlier Orions, there is special antinodding (i.e., antimultipath) signal processing. RTN-30X is the most powerful tracker of the RTN series and alone incorporates CW injection for missile guidance.

RTN-30X tracking radar of the NA-30 system. (Selenia)

This radar is part of the NA-30 fire-control system (*Garibaldi*, *Maestrale* class, *Minerva*-class corvettes, etc.).

◆ 3RM Series (BPS-704, SPN-703, etc.)

Band: X

Beam: 0.8–2.0 deg × 26 deg (shaped to 40 deg) (SPN-703: 1.2 × 25 deg, BPS-704: 2.2 × 11 deg)

Peak Power: (a) 7 (b) 20 kW **Gain:** BPS-704: at least 27 dB

Pulse Width: (i) 0.05 (ii) 0.15 (iii) 0.5 (iv) 1.5 microsec

PRF: (i) 6000 (ii) 3000 (iii) 1500 (iv) 750 pps (SPN-703: 5200, 2600, 1300, 650, respectively) **Scan Rate:** 25 rpm

SMA's surface-search radars have limited air-search capability. All use slotted-waveguide antennas, beamwidths depending upon dimensions. Two transmitters are available, as noted above.

The 3RM20-H version is the U.S. SPS-63 (see below) for the *Pegasus*-class hydrofoils; the Italian navy uses the 3RM7-250 (with a second 250-kW transmitter, for air search) for its experimental hydrofoil *Sparviero*. 3RM20 is MM/BPS-704, in the *Sauro* class; her sisters all have SPQ-701. 3RM28-B is MM/SPN-703. Components of this radar are also used in the

MM/SPS-702 antenna. (Segnalamento Marittimo ed Aereo)

MM/APS-705 and -707 and in the MM/APQ-706 (see airborne radars).

In 1984 SMA announced a new radar, SPS-702, with a smaller antenna mounted back-to-back with the first and tilted at an angle of 45 deg to the vertical. This antenna would provide something like the limited 3D cover of the Soviet Head Net C.

◆ HSS-1

SMA's X-band harbor-surveillance radar employs a single narrow-beam reflector. HSS-1 employs frequency and polarization decorrelation to distinguish targets in high-density shipping lanes within highly reflective land areas, such as estuaries. The radar is semimobile.

◆ PLUTO

Selenia's coast-defense radar detects low fliers and surface craft. Its mast is self-erecting. Characteristics: S-band (TWT transmitter), peak power 135 kW (phase-coded pulses, fixed or randomly staggered PRF), beam 1.5 × 4 deg (super csc² vertical coverage), tilt between +5/–2 deg, scan rate 12 or 15 rpm. The receiver includes an adaptive clutter attenuator. Signal processing techniques include an azimuth correlator (using a moving window and pattern recognition) and a jam strobe (to provide an unambiguous bearing on a jammer; but it is not clear how or whether signals entering through a sidelobe are eliminated). MTI is digital (first blind speed is faster than Mach 3). Plots can be extracted automatically in a form suited to narrow-band data-link transmission, using a programmable message format.

IFF is integrated into the antenna (using a secondary feed in the main horn).

Pluto coastal-surveillance radar. (Selenia)

◆ RAT-10S

This is a Selenia S-band coastal radar, operating at a peak power of 450 kW (500 pps); the 0.8-deg beam scans at 6 rpm. The magnetron transmitter is tunable, and the radar incorporates an MTI canceler. A mobile version, using a smaller antenna (which made for solid coverage up to 3000 m altitude), was designated RAT-8S. Its development began in 1965.

Selenia also produced several other coastal radars, including RAT-5C and Argos 800; the RAT series is also prefixed with the name Argos.

RAT-5C was a C-band radar with a lens antenna producing stacked beams; it had 2 transmitters, to provide frequency diversity. Development began in 1965, but it seems unlikely that it entered service.

RAT-33 S/M coastal-surveillance radar. (Selenia)

◆ RAT-33S/M

RAT-33S/M is Selenia's medium-range coastal-surveillance (combined air and surface) radar. The radar operates in the S-band and has a dual-beam antenna (swing circle 5.5 m) and a scan rate of 15 rpm. Peak power is 450 kW, PRF is 1000 pps, and the 1.5-deg beam scans at 15 rpm. Accuracy is 50 m in range and 0.35 deg in angle. Polarization can be linear, circular, or elliptical. The radar samples its clutter environment in the absence of targets and automatically adapts its operation accordingly, distinguishing, for example, between clear areas and

The Medusa lightweight optronic director. (Selenia)

ground (or sea) clutter. RAT-33S/M appears to employ ATD techniques (with CFAR), and signal processing includes doppler filters and an azimuth correlator (to reject false targets behaving nonphysically). PRF is staggered to avoid STAEs. RAT-33S/M is designed for remote operation via a narrow-band data link.

◆ SPQ-3

SMA's S- and X-band transportable coastal-surveillance (air and surface) radar is related to its SPQ-2 naval radar (see above). The SPQ-3B version has a special mine-watching feature to detect the splashes of mines dropped by air into coastal waters or harbors. This radar employs 2 separate antennas: back-to-back reflectors fed by slotted waveguides in X-band for spotting and tracking, and a more conventional horn-fed parabolic reflector in S-band. Typically the 2 antennas are mounted on a single pedestal, the X-band units below the S-band. Both elements are frequency agile, and PRF is variable. Data can be transmitted in either analog or digital (ATD) form.

OPTRONIC SYSTEMS

◆ MEDUSA

This nonstabilized target-designation sight by Selenia/Elsag is used for remote control of light-caliber guns or as a building block for a more sophisticated system. MEDUSA carries either a twilight television camera or a low-light television camera, either feeding a 7-in monitor. The pedestal carries a target-designation button and an open-fire switch, and the console with the monitor carries a keyboard and a joystick, primarily to monitor the situation as viewed through the director.

◆ NA-12

The optronic backup director in the private-venture fast patrol boat *Saettia* was built by Fincantieri as a technology demonstrator.

◆ NA-16

This optronic director for the *Minerva*-class frigates, for the 76-mm gun, is used in conjunction with the Dardo E fire-control system.

◆ NA-18

NA-18 is Selenia-Elsag's optronic director. See fire-control systems, below.

NA-18 optronic fire-control console, showing a combination of synthetic video on the upper screen and a television image below. (Selenia)

◆ Galiflir

This lightweight (8 kg) FLIR is being developed by Officine Galileo. It uses an 8-element CMT Sprite detector, with serial-parallel scanning to produce a 512-line IR image, with a 4×26.7 — or 16×10.8 —deg field of view. Resolution in the narrow field is 0.15 mrad.

◆ OG 30

The Officine Galileo optronic director, for *Maestrale*-class frigates, was introduced in 1980. The current version, OG 30A, is the electro-optical component of the NA-30 fire-control system but can also be combined with other systems or used alone. OG 30A carries a laser range-finder, an IR imaging camera, and a television camera on a stabilized pedestal. The system includes a video converter, TV tracker (i.e., signal processor: it is designated P4700), and displays. With the tracker, the daylight and IR cameras can operate in either a surveillance or a tracking mode. The standard devices are: P4651 daylight television camera (1.8×2.4 —deg field of view, 700 lines to CCIR standard), a Galileo IR television camera (8–14-micron wavelength, 3×6 —deg field of view, 200 lines per frame, at a frame rate of 25 per sec), and a P0700 laser range-finder (1.06-micron wavelength, peak power 20–25 MW, 15 bursts/sec, range 400 m to 15 km). The entire system can elevate at 2.2 rad/sec (about 126 deg/sec) within limits of $-25/+85$ deg, and it slews at up to

1.5 rad/sec (about 86 deg/sec). It can turn continuously for surveillance or automatically track an air or surface target. Typically, the range on an air target is 16 km, and on a sea-skimmer, 6 km. OG 30B is a simpler (thermal imager only) version, feeding directly into an NA-30 director.

◆ OG.R7

The Officine Galileo manned optical director is essentially a telescope and is open sight linked to a computer. Targets are tracked and guns (e.g., 76-mm) controlled by means of a joystick. About 250 had been manufactured as of late 1988, buyers including Greece, Peru, and West Germany (the last for secondary control in Type 143 fast attack craft). OG.R7/2 is a tracking system using a binocular telescope and an open sight, coupled to a fire-control computer, with joystick control and a stabilized line of sight. Magnifications are $2.3 \times$ and $7 \times$ (corresponding to 30- and 10-deg fields of view). Maximum rates of train (elevation) are 100 (60) deg/sec; maximum lead angle (in train) is 25 deg; maximum lead angle (in elevation) is 20 deg. Crossing range limits are 100–2000 m, and target speed limits are 60–350 m/sec. OG.R7/2A is a more elaborate pedestal sight with an optical head, external image intensifier, 2-axis stabilization, and a digital computer for lead-angle computation. The sight is moved electro-hydraulically in azimuth, and in elevation by a servo. OG 20 (OG.R7 Sea Cat) was a special version for Sea Cat missile control, employing additional telescopes for missile guidance and gun direction. A typical total weight (for OG.R7/2A) is 550 kg, and the current version is OG.R7/3.

◆ PEGASO

This optronic director by Selenia/Elsag, similar to NA-18, carries several sensors (e.g., IR camera, TV camera, laser range-finder), with a single-operator below-decks console and a digital computer. Pegaso is used in the NA-16 system (*Minerva*-class corvettes).

PEGASO optronic fire-control system director, showing television and infrared cameras. (Selenia)

◆ SIR-3

The Selenia thermal imaging surveillance system was announced in 1984. Unlike most IR sensors, SIR-3 consists of a pair of boxed sensors carried on the 2 sides of a central pedestal. The 2 detectors elevate to track air targets, and the pedestal scans in azimuth. Each box contains a linear-array detector (presumably, each side detects in a different IR band), cooled to 77°K. Selenia claims that SIR-3 provides particularly accurate elevation data. The output is compatible with a television monitor, the usual display being a 60-deg-wide strip.

The SIR-3 IR surveillance system. (Selenia)

◆ VTG 120/N

Officine Galileo announced this new naval thermal imager, based on the army's VTG 120, at Mostra Navale 1989. VTG 120/N is a pedestal-mounted lookout and target-designation sight, which can transmit target elevation and bearing in digital form. The detector is a 60-element, parallel-scanning, linear-array detector using cooled cadmium-mercury-telluride (CMT) elements (8–14-micron band); the detector is cooled by air bottles (for 2 or 4 hr) or by a Stirling closed-cycle refrigerator. The operator views the scene through a miniature CRT in the eyepiece, and the same original can also be passed to a remote monitor. There are 2 alternative magnifications, 4× and 12× (corresponding fields of view are 60 × 120 and 20 × 40 mrad).

◆ VTG 240/N

This thermal imager was announced at Mostra Navale 1989. It is intended as part of an optronic or radar/optronic fire-control system. Like the smaller VTG 120/N, it uses a 60-element parallel-scanned CMT array detector; the output is a 240-line IR image that can be fed into a tracker or converted to 625-line television format for display. Resolution is 0.16 mrad; the IR telescope has a 2-position lens (fields of view 2.3 × 1.15 or 6.9 × 3.45 deg). Total weight, including control console, is 28 kg.

FIRE-CONTROL SYSTEMS

◆ Albatros

Selenia-Elsag's medium-range surface-to-air missile system uses the semiactive Aspide missile. Albatros is designed to be added to an existing gunfire-control system so that no additional tracker/illuminators are required. Instead, Albatros uses 1 or 2 slaved illuminators (presumably CW injection in existing tracking radars).

The original Albatros Mk 1 fired the Sea Sparrow (RIM-7H) missile. Tested in 1973, Mk 1 never entered production. Mk 2 fires the Aspide. Mod 2 and Mod 5 employ Elsag (Elettronica San Giorgio) fire controls. Mod 8 uses the Ferranti WSA 400; Mod 9 uses a Signaal radar. Both the Elsag and the Ferranti versions use the Selenia Orion RTN-10X radar for fire control. Illumination is provided by a Selenia RTN-12X Sirio radar that uses the same antenna as the Orion. Total reaction time, from target designation to missile launch, is 8 sec.

In some installations 2 radar channels are provided. The tracking radar can receive CW illumination reflected from the target and track that radiation, or the tracking radar can track conventionally. Both channels share the same antenna.

The system exists with both 4- and 8-cell launchers, the latter duplicating the existing NATO Sea Sparrow launcher; however, in Albatros the 8-cell launcher can be combined with an automatic reload magazine carrying up to 16 missiles; the missiles are carried in 4-round trays, each of which duplicates 1 layer of the missile launcher. The magazine pivots up to mate with the rear of the launcher for reloading, and each missile is rammed into its launcher cell by a loading arm.

◆ Dardo

Selenia-Elsag's close-in weapons-control system was designed to deal with sea-skimming missiles. Dardo uses an Orion RTN-20X and a television camera to control a twin 40-mm/70 gun mount. The radar was developed specifically for the CIWS role, the television being used to monitor the engagement and also to control the gun in a jamming environment. Targets are detected by a separate search radar, and any target within a preset range can be engaged automatically. The system will shift automatically to deal with a sequence of targets.

Dardo is designed to engage targets between 900 and 3000 m. Its effectiveness derives from its very low dispersion, 2.5 mrad for the system as a whole (based on about 1 mrad for the 40-mm gun).

This system was first used on board *Lupo*-class frigates (the first of which was delivered in 1976). In July 1980 the frigate *Sagittario* used Dardo and the associated twin 40-mm to engage a series of 6 Rushton aerial targets (19-cm diameter, 2.8 m long) towed at high speed to simulate sea-skimmers. Four were shot down by the initial bursts, and 2 more were considered sufficiently damaged to count as kills at a range greater than 1000 m.

An extended Dardo E system was announced in 1984. It consists of the 2 separate systems of the carrier *Garibaldi*, a Dardo for close-in defense, and the line-of-sight NA-30 Mod B. The weapons might be a twin 40-mm gun, a 5-in/54, and an Aspide launcher, controlled by a search radar and a tracker.

◆ NA-9

This fire-control system by Nuova San Giorgio is based on the Orion 250 X-band radar and is derived from the earlier Italian navy Argo system. The first of 23 ordered by the Italian and other navies entered service in 1964. Claimed performance: for a target approaching at up to 600 m/sec (angular velocity 6 deg/sec), average miss distance at 1000–4500 m is 8 m.

NA-9C simultaneously controls 40-mm and 5-in guns.

NA-9D simultaneously controls guns and short-range anti-aircraft missiles (two 5-in and 2 launchers against 1 or 2 targets).

The system occupies a fixed cabin, with the radar dish on top and 2 periscopes flanking a cab in front. Each periscope operator has a director control panel.

Current applications: *Vittorio Veneto*- and *Andrea Doria*-class cruisers and *Audace*- and *Impavido*-class destroyers.

◆ NA-10

These fire-control systems use the Orion 10X and 20X con-scan radars. Mod 2 is intended for frigates and larger ships, Mod 3 for fast attack craft. Orion 10X was designed specifically for the Albatros system, so that NA-10 may be equated with the fire-control part of Albatros (see above). NA-10 is similar to NA-9 but incorporates further miniaturization and a closed-circuit television.

Users: Iraq (*Lupo* class), Italy (*Lupo*, *Alpino*, *Cassiopea*, *Sparviero* classes), Libya (Mod 2 in *Dat Assawari*, Mod 3 in *Assad al Bihar* class), Peru (*Lupo* class), Venezuela (*Lupo*, *Alm. Clemente*, and *Constitucion* classes).

◆ NA-18

Selenia-Elsag's optronic fire-control system is used to control guns up to 3-in caliber. The system consists of an optronic director (twilight TV camera, laser range-finder, IR camera) and an operating console (raster displays for the images; a joystick for target acquisition and manual tracking; and processing, interface, and television automatic-tracker units). The console carries a 15-in high-resolution monitor for synthetic video and a 9.5-in monitor for television and IR images. As an option, the 15-in monitor can carry the ship's search radar video. The system can then be used for navigation and command/control, becoming the SEN-100 small ships' combat system.

If the radar option is adopted, the 15-in monitor can be arranged in either PPI (rastered) or B-scan (range × bearing rec-

NA-18 optronic director. (Selenia)

NA-18's display-and-control console, for one-person operation. (Selenia)

tangular format: $7.2 \text{ km} \times 60 \text{ deg}$) form. The B-scan is particularly useful for splash spotting in a surface engagement. Radar targets are manually initialized, the system then performing rate-aided tracking on up to 9 of them. They can be designated for fire control either with the trackball or by track number.

Targets can also be designated to the system from CIC or from shipboard ESM. To overcome difficulties in tracking fast targets by TV or IR, the 15-in monitor uses a special display of 4 con-

tiguous images corresponding to 4 adjacent director positions (either in elevation or in azimuth), all frozen, corresponding to a vertical or horizontal swath. This frame freezing eliminates blurring due to director motion and makes for easier acquisition by the operator. Laser echoes are presented as bars with range-gate limits superimposed.

The 9.5-in monitor shows the cross hairs and the tracking window, the system status and warning messages, target data (coordinates, radial speed, angle of attack), main weapons status, and alarm messages. The 9.5-in monitor is located under the large monitor, flanked by 2 keypads for quick inputs, with a trackball and joystick in front.

The NA-18 computer incorporates several alternative tracking models (algorithms), automatically selecting the 1 it supposes is appropriate to the target at hand. Targets are tracked in 3 dimensions (in range by the laser), and the computer filters these tracking data in all 3 dimensions. In the event the laser fails, the system can track in angle at a prefixed firing range (corresponding to a barrage-firing mode). The operator can always shift from automatic to manual (joystick) tracking and can aim using the cross hairs of the TV monitor.

The system can digitally control up to 2 guns of different caliber, and it can carry 2 independent sets of ballistics (for different ammunition) for each gun in the computer's memory. Control takes account of parallax and ship's motion, and guns are automatically triggered when the target comes within their precomputed effective range. In surface firing, spotting corrections are manually entered through quick-input devices at the console. In the antiaircraft mode, observed spotting errors are compensated for by joystick.

The standard TV camera uses a zoom lens (focal length 30–360 mm), with a $2.54\text{--}30.5\text{-deg}$ field of view; the camera operates at CCIR 625/50 scan standard. The IR camera operates in the 8–12-micron band, using a closed-cycle cooling system, with a $4 \times 2.6\text{-deg}$ field of view. An alternative IR camera has 2 fields of view (6.9×3.45 and $2.3 \times 1.15 \text{ deg}$). The laser range-finder operates at 1.06 microns (neodymium YAG3), with a 15-Hz PRF and a peak power of 18 MW; the range-finder can provide ranges between 400 m and 15 km. The associated computer is a 24-bit machine with a 250-nanosec memory-access time (clock rate 4 MHz) with a combination of ROM, semiconductor memory, and tape memory.

The tracking platform servo's operating limits are as follows: elevation limits $+84/-22 \text{ deg}$, training speed 126 deg/sec, elevating speed 86 deg/sec.

Elsag described NA-18 as the simplest of a series of modular weapons-control systems using common consoles and a data bus. NA-18 uses the simplest computer (which is also used by the SCLAR rocket launcher) and very nearly the simplest console. The more elaborate versions of the same system are NA-21 and NA-30.

User: Thailand (PSMM Mk 5 class).

◆ NA-21

Selenia-Elsag's radar gunfire-control system was announced in 1980. A digital version of the earlier NA-10, NA-21 is designed to control 3 guns of 2 different calibers plus a surface-to-air missile (typically Albatros), and can also designate targets to a surface-to-surface missile. The associated fire-control radar is the Orion RTN-10X, with a television camera for visual control.

Like NA-18, NA-21 is a modular combat system using standard consoles, computers, and data busing. Users: Ecuador (*Esmeralda* class) and probably Iraq (modified *Wadi M'ragh* class).

◆ NA-25

This modular Selenia-Elsag radar and optronic fire-control system controls 2 guns of different calibers, using an Orion RTN-25X. An IR sensor and a neodymium YAG laser can be mounted on the radar director to provide an alternative range sensor, and a television camera is an alternative tracker. NA-25 can perform command/control as well as fire-control functions, using a

multiprocessor (MARA 286) and a special console (MAGICS) incorporating 2 high-resolution color monitors. The system can be set for programmed autonomous search (360 deg or by sectors) or can be fed by video from the ship's search radar. NA-25 automatically evaluates the threat presented by various targets and engages them.

◆ NA-30

Selenia-Elsag's radar/optronic weapons-control system controls up to 3 guns of 2 different calibers, as well as anti-aircraft missiles. The associated tracking radar is the Orion RTN-30X, combined with an electro-optical ranger (IR/laser) and a television tracker (as in NA-25). NA-30 is a modular combat system using a data bus and 1 or 2 control consoles.

NA-30 is designed to operate automatically (with operator veto) against a target designated by a search radar, by the system's own fire-control radar (in search mode), or by some other sensor, such as ESM. NA-30 is designed to control several weapons against a single target in coordinated firing mode: typically, an Aspide missile and up to 3 guns (with parallax corrections and 2 independent sets of ballistics with 1 fuze-setting computation). Automatic operation is intended to counter fast targets such as antiship missiles; there is also a manual mode for use against surface ships or slow air targets.

The main (supervising) console carries 2 monitors: a 19-in raster-scan CRT to show radar PPI (search radar or fire-control radar, the operator choosing between them) or a B-scan (azimuth/range) track presentation with track labels and other graphics; and a 15-in raster-scan CRT for TV or IR images with superimposed alphanumeric (e.g., CIC orders, FCS and weapons status, and alarm messages). The operator interacts with the system mainly by means of a variable-function keyboard, a numeric keypad, a trackball, a joystick, and a range handwheel. There are also pedals for gunfire control and for "voluntary" tracking initialization.

The radar/optronic director has elevation limits of $+84/-22$ deg; and the maximum training speed is 2.7 rad/sec (elevating 1.5 rad/sec), corresponding to 155 deg/sec (86 deg/sec). Like NA-18, NA-30 employs a 24-bit computer.

NA-30 was announced in 1982 and entered service in 1985. It is installed on board Italian *Maestrale*-class frigates and the carrier *Giuseppe Garibaldi*. When combined with the RAN-30X search radar, ESM, and CIC equipment, NA-30 forms the SEN 300 combat system for low- and medium-tonnage ships. In Italian naval service this system is called Dardo-E.

NA-30 was carried by 2 Italian ships operating in the Persian Gulf for 18 months; it reportedly experienced only 1 significant fault, which was corrected on board. In a test, controlling a 76-mm gun, this system hit 8 out of 8 Rushton targets, flying at less than 24 ft altitude, and at 2-3 km range.

◆ OG 3

This Officine Galileo GFCs for small ships, broadly comparable to the U.S. Mk 56, survives on board the *Pietro De Cristofaro*-class corvettes. It was formerly also on board the *Bergamini*-class frigates. The associated radar is RTN-7A. OG 2 (now extinct) was a simpler FCS, comparable to the U.S. Mk 57.

JAPAN

RADARS

◆ OPS-1

Designed about 1955, OPS-1 was a Japanese-produced version of the U.S. SPS-12. The structure of the antenna is more like that of SPS-6B/C (which was electronically much like SPS-12). Physically, the OPS-1 antenna showed features of both SPS-6B/C and SPS-12.

◆ OPS-2

Reportedly OPS-2 was a Japanese-produced version of the U.S. SPS-6C. Peak power was given as 400 kW.

◆ OPS-4

This surface-search radar, with a solid antenna, still equips the former submarine-rescue ship *Chihaya* and once was common on board both combatants and auxiliaries. OPS-4 may be a Raytheon 1404 commercial set.

◆ OPS-9

This surface-search radar, with a very long slotted-waveguide antenna, operates in X- (I/J) band. OPS-9 equips the mine-countermeasures craft and some of the miscellaneous auxiliaries.

◆ OPS-10/13/19/22/29

These surface-search radars for small ships have slotted-waveguide antennas. OPS-13 is the search radar of the PT 11 class. OPS-29 equips the small patrol boats (PB type).

The Japanese torpedo boat PT 13 is equipped with an OPS-13 surface-search radar. (*Ships of the World*)

◆ OPS-11

OPS-11 is the first Japanese-designed air-search radar. The antenna is an 8×4 array of yagi antennas. Previous Japanese

OPS-11 air-search radars at the mastheads of 3 *Iakatsuki*-class destroyers. (Jake Yamada)

OPS-11 on board a *Takatsuki*-class destroyer, with OPS-17 surface-search radar above, and GFCS-1 atop the bridge. The big radomes are part of a jamming system called OLT-3; the small ones are probably DF radomes (NOLR-6). (Author)

dependence on U.S. radar technology suggests that OPS-11 may be related to SPS-40, with a radically different antenna. Reports that OPS-11 is a UHF long-range pulse-compression radar would corroborate that relationship.

OPS-11B reportedly operates at about 300 MHz, its low frequency having been chosen for long range and for fewer fades. The antenna is an array of 24 yagis.

◆ OPS-12

This planar-array air-search radar is probably similar in operation to SPS-52. Unlike SPS-52, OPS-12 lacks a serpentine feed running up 1 edge. However, an extension visible on the right side of the main antenna may contain the feed. This arrangement might make for a more symmetric array, easier to stabi-

OPS-12 3D air-search radar on board the destroyer *Shirane*, with OPS-28 above it. The 2 gun directors above the bridge are GFCS-1A. (Japanese Maritime Self-Defense Force)

lize. OPS-12 equips only the *Kurama*-class helicopter-carrying destroyers.

NEC produces a land-based air-search radar, NPG-880, whose antenna is similar in appearance to that of OPS-12. NPG-880 is a frequency-scanning (serpentine feed) radar employing ferrite phase shifters between the serpentine feed and the radiating elements themselves. That arrangement makes it possible to use chirped (pulse-compressed) pulses at fixed elevation angles, the ferrites canceling out the effect of frequency change within each chirp. The U.S. SPS-48E employs similar techniques. NPG-880 employs a TWT/CFA transmitter.

◆ OPS-14

OPS-14 is an L-band radar with a somewhat larger (higher gain) antenna than that of OPS-1/2. This radar is manufactured by Mitsubishi Electric. The first was fitted to the destroyers *Akizuki* and *Teruzuki*, and the radar is on board all destroyers and frigates after the *Murasame* and *Yudachi*. FY67 ships and later have OPS-14. FY73 and later have OPS-14B, with MTI. However, large warships are also being fitted with OPS-11. The peak power of OPS-14B is 400 kW (500 kW in OPS-14), and the beam dimensions are $5 \text{ deg} \times 30 \text{ deg csc}^2$. The improved OPS-14C version will be on board Improved *Hayatsuki*-class destroyers.

◆ OPS-15/16/17/18/35/36/37

Band: C (5450–5825 MHz) **Beam:** $2 \times 20 \text{ deg}$
Peak Power: 150–200 kW **Pulse Width:** 0.3 or 1.4 microsec
PRF: 604–667 pps **Scan Rate:** 15 rpm

Data apply to OPS-18, built by Nihon Musen.

These surface-search radars superficially resemble the U.S. SPS-5/10, with their openwork antennas. OPS-37, a Japanese version of the U.S. SPS-5B, has an antenna that is noticeably smaller than those of the others. OPS-16, -17, -35, and -36 operate at somewhat higher frequency, closer to X-band. OPS-15 equips the training ship *Katori* and some of the ex-destroyers (now serving as auxiliaries). OPS-16 is the surface-search radar on board some older frigates. OPS-17 was the standard destroyer surface-search radar; it is now being replaced by OPS-28. OPS-18 equips the new *Towada*-class underway-replenishment ships.

◆ OPS-19

A slotted-waveguide navigational radar, OPS-19 is sometimes used in combination with the much larger OPS-28 (e.g., in the destroyer *Kurama*, on the foremast, and in the *Yubari*-class frigates).

◆ OPS-24

This new planar-array (probably phase-phase) radar replaces OPS-14 on board the *Hamagiri* and later *Asagiri*-class destroyers.

OPS-24 air-search radar on board the new Japanese destroyer *Hamagiri*, 1990. The flat-plate antenna is tilted back, so this photograph, taken from below, somewhat reduces its apparent height. (Sea Power)

◆ OPS-28

OPS-28 is a large slotted-waveguide surface-search and short-range air-search radar. The current version, OPS-28C, is the functional successor to OPS-17, replacing it in the *Tachikaze*-class destroyer *Sawakaze*. OPS-28 is also replacing OPS-18.

OPS-28 is a specialized sea-skimmer detector, broadly comparable to the U.S. TAS Mk 23.

◆ ZPS-4

This search radar, installed in the *Uzushio*-class submarines, uses a fully enclosed antenna in a cylindrical radome.

The Japanese submarine *Makishio* shows a ZPS-4 radar. (*Ships of the World*)

◆ ZPS-6

ZPS-6 is a submarine search radar in the current *Yushio* class.

◆ Furuno Radars

These commercial navigational radars are used primarily by the U.S. Navy; they do not appear to be used by the Japanese Maritime Self-Defense Force. For details, see the U.S. entries below.

FIRE-CONTROL SYSTEMS

◆ GFCS Model 1 (GFCS-1)

Model 1A controls 5-in guns; Model 1B controls 3-in guns. This system is mounted from the *Natsugumo* and *Nagatsuki* on. Made by Mitsubishi Electric, GFCS-1 is also designated Type 72. An earlier Type 68 system is on board the *Harusame*. This

The new Japanese destroyer *Asagiri* shows both the OPS-14C air-search radar (forward) and the new FCS-2-12E missile (Sea Sparrow) fire-control radar (aft, under the big radome). The small surface-search radar on the platform atop the foremast is OPS-28, and the radomes on the main mast are part of an EW suite consisting of an OLR-9C passive system, an OLR-6C, and an OLT-3 jammer, plus SRBOC launchers. The gun director atop the bridge is FCS-2-21A. (*Sea Power*)

radar-equipped director, similar to the U.S. Mk 56, is for 5-in guns. In some ships it replaced a U.S. Mk 63.

◆ GFCS Model 2 (GFCS-2)

This Type 79 fire-control system exists in 2 versions. Model 2-12, enclosed in a radome, controls guns and Sea Sparrow missiles from the *Ishikara* on. Model 2-21, on an open pedestal, controls guns only. Both are manufactured by Mitsubishi Electric.

Type 79 is a digital system replacing the earlier analog Type 72. Type 79 employs an unmanned director whose Cassegrain monopulse tracking antenna can be seen mounted on a pedestal. This arrangement is an improvement over the conscan tracker of Type 72, in which the on-mount operator is exposed to the elements. Reportedly, the search antenna in the 2-12 system shares the same transmitter as the tracker, as in the Signaal "eggs."

◆ FCS 3

The current research-and-development plan includes a phased-array fire-control system, FCS 3.

FCS-2-21A. (*Sea Power*)

NETHERLANDS

RADARS

◆ DA-01/02/04

Band: S (2.9–3.1 GHz) Beam: $1.5 \times \text{csc}^2$ (DA-02 1.7 deg)
 Peak Power: 400 kW Gain: 32 dB
 Pulse Width: (i) 1.3 (ii) 0.5 microsec
 PRF: (i) 500 (ii) 1000 pps Scan Rate: 6–60 rpm
 Antenna Dimensions: 15.3 ft wide Antenna Weight: 4400 lb

DA-01 was the first postwar Dutch target-designation (DA) radar, introduced in 1954 on board Dutch destroyers. The commercial (Signaal) designation was SGR-105. Claimed performance included detection of a 2-m² target at 50 nm and at 35,000 ft. DA-02 used a broader-beam (1.7-deg) antenna but greater power (500 kW, 40 nm at 30,000 ft) and was first exported to Argentina for the former U.S. light cruiser *Nueve de Julio*. There was no DA-03. DA-04 was the last of the series, a simplified version of DA-01 using an unstabilized antenna (1200 lb).

DA-01. (Signaal)

◆ DA-05

DA-series antenna on board a Dutch frigate, 1978. The British UA-8/9 ESM antenna is on the pole mast above. For DA-05, see the photograph of the Indonesian *Malahayati* under the entry for the Bofors 4.7-in/46 gun. (U.S. Naval Institute)

Band: S (6 preset frequencies between 2900 and 3100 MHz)
 Beam: 1.5×8 deg (csc^2 cover up to 40 deg)
 Peak Power: 1200 kW Gain: 32.2 dB
 Pulse Width: (i) 1.3 (ii) 2.6 microsec
 PRF: (i) 1000 (ii) 500 pps Scan Rate: 10 or 20 rpm
 Antenna Dimensions: 4.87 × 2.75 m [about 16 × 9 ft]
 Antenna Weight: 725 kg

DA-05 was the first of a new series of DA radars, analogous to LW-04, using elliptical antennas and more powerful magnetrons. Like LW-04, DA-05 has digital MTI. Claimed performance includes detection of a 2-m² target at 72–84 nm and about 60,000 ft; minimum range is 1000 m. This radar can discriminate targets 1.5 deg apart in azimuth and 200–400 m apart in range. DA-05 is the primary air-search radar of the Belgian *Wielingen* class and is also used by the Dutch and Spanish navies. DA-05/M is a land-based mobile version, and both DA-06 and -07 are land-based.

DA-05/4 on board the Irish *Eithne*, 1986, with IFF interrogator above. (Author)

DA-05. (Signaal)

◆ DA-08

Band: S Beam: $1.5 \times \text{csc}^2$ to 40 deg
 Peak Power: 145 kW (5.1 kW average) Gain: 33 dB
 Pulse Width: (i) 35 (ii) 69 microsec PRF: (i) 1000 (ii) 500 pps
 Scan Rate: 10 or 20 rpm (selectable)
 Antenna Dimensions: 4.4 × 3.9 m; depth 6.5 m
 Antenna Weight: 2500 kg

DA-08 on board a Turkish frigate. (Stefan Terzibaschitsch)

This coherent pulse-compression radar is derived from, and is analogous with, the larger LW-08. Claimed range on a 2-m^2 target is 78–92 nm. Minimum range is 0.8 nm. The antenna is stabilized. Each pulse consists of a 1-microsec non-modulated pulse and a 34- or 68-microsec frequency-swept (pulse-compression) pulse. Compressed pulse length is 0.6 microsec. There are 6 fixed crystal-set frequencies plus a jumping frequency. Resolution: 1.5 deg in azimuth, 120 m in range. A modified version of this radar scans at 15 rpm and has a PRF of 2400 pps; instead of the digital MTI of the basic radar, it uses an FFT for MTI.

DA-08 is the primary air-search radar of German *Bremen*-class frigates and *Hamburg*-class destroyers.

DA-08. (Signaal)

◆ LW-02/03

Band: L (1220–1350 MHz) **Beam:** $2.2 \times \text{csc}^2$ (ratio 1:10) deg
Peak Power: 500 kW **Gain:** 31 dB
Pulse Width: (i) 2 (ii) 5 microsec **PRF:** (i) 500 (ii) 250 pps
Scan Rate: 1–10 rpm (in some, 3/6 rpm)
Antenna Dimensions: 7.8×4.25 m [25.6×13.9 ft]
Antenna Weight: 2100 lb

LW-02 was the first postwar Dutch destroyer radar, and it was exported to Australia, Colombia, Sweden, and West Germany under the commercial designation SGR-114/12. Claimed performance included detection of aircraft at 100 nm and 59,000 ft.

LW-03 was a similar radar with a scan rate of 5 or 10 rpm.

There is also LW-01, a much larger radar (antenna 11×4.88 m [36.1×16 ft], 3200 lb, with a beam $1.8 \text{ deg} \times \text{csc}^2$ [ratio 1:12], gain 33 dB, scan rate 3 or 6 rpm or 1–6 rpm) using the same transmitter, for cruisers and aircraft carriers. The commercial designation was SGR-114/06, and the sole survivor is on board the Argentine aircraft carrier *25 de Mayo*.

◆ LW-04

Band: L (6 preset frequencies between 1250 and 1350 MHz)
Beam: $2.2 \times 10 \text{ deg}$ **Peak Power:** 1100 kW (LW-04/2 version)
Gain: 30 dB **Pulse Width:** (i) 1.3 (ii) 2.6 microsec
PRF: (i) 1000 (ii) 500 pps (staggered) **Scan Rate:** 7.5 or 15 rpm
Antenna Dimensions: 7.35×4.8 m **Antenna Weight:** 1400 kg

LW-04 introduced the elliptical antenna characteristic of current Dutch air-search radars. No commercial (SGR) designation has been announced, but LW-04 first appeared on board the German destroyer *Hessen*. These radars have digital MTI and can operate on any 1 of 6 preset frequencies. Claimed range on a 2-m^2 target is 120 nm at 55,000 ft. Resolution is 2.2 deg in azimuth, 200 or 400 m in range.

No LW-05 has been announced; LW-06 and -07 are land systems.

LW-04. (Signaal)

◆ LW-08

Band: L (6 preset frequencies between 1250 and 1350 MHz)
Beam: $2.2 \times \text{csc}^2$ to 40 deg
Peak Power: 150 kW pulse compressed; average power 5.2 kW
Gain: 30 dB **Pulse Width:** (i) 35 (ii) 69 microsec
PRF: (i) 1000 (ii) 500 pps **Scan Rate:** 7.5 or 15 rpm
Antenna Dimensions: 8.8×7.525 m
Antenna Weight: total 5000 kg (antenna 1500 kg)

The pulse-compression waveform includes a 1-microsec pulse for short-range resolution, and then a long "chirp" for long-range performance. The high average power (5.2 kW) corresponds to 5100 kW applied to 1-microsec pulses; that power gives some idea of range performance (a range of 145 nm at 85,000 ft is claimed for a 2-m^2 target). The short initial pulse is

LW-08 on board a *van Heemskerck*-class missile frigate. This version has a double feed; there is also a single-feed version. (Signaal)

used for surface warning. Any of 6 preselected frequencies can be used, and there is provision for pulse-to-pulse frequency jumping through the entire band. Resolution is 2.2 deg in azimuth, 300 ft in range. Pulse-compressed pulses are equivalent to 0.6-microsec pulses. LW-08 can handle target speeds up to Mach 5 (which must be the first blind speed), and up to 64 tracks. The MTI improvement factor is 35 dB. Minimum range is 2 km. The antenna is stabilized.

The British Type 1022 marries an LW-08 transmitter to a Marconi narrow-beam (squintless) antenna.

LW-08 was first used on board the Dutch "standard" frigate *Kortenaer*.

◆ SPS-01

Band: S

Beam: [search] 1.5×2 to 30 deg; [track] 1.5×1.5 deg (approx, depends on elevation)

Peak Power: 750 kW **Gain:** about 39 dB

Pulse Width: 40 microsec **PRF:** 460 and 540 pps, staggered

Scan Rate: 20 rpm

SPS-01 is the big multifunction radar of the Dutch missile-destroyers *Tromp* and *de Ruyter*. It combines a broad-beam search radar with a high-data-rate radar for tracking multiple targets. Five antennas are mounted to rotate together: 2 back-to-back paraboloids (with feed horns moving to generate any of 5 alternative beams, plus a sixth, fixed, low-angle beam); 2 back-to-back frequency-scanned arrays at right angles to the paraboloids; and an IFF mounted below 1 of the 2 paraboloids. The low-angle search beam operates continuously to provide short-range warning (40 scans/minute using the back-to-back anten-

SPS-01 occupies the large radome of the Dutch destroyer *Tromp*. The small radome forward of the bridge is for a Signaal WM-25, and 2 SPG-51s aft control the Standard Missile. The 2 slotted-waveguide surface-search radars are Decca 1226s. (U.S. Naval Institute)

SPS-01 array. The serpentine waveguide feeding the diagonal slotted waveguides is visible between the 2 arrays. (Signaal)

nas). The other 5 search beams are used in sequence (1 by 1 during subsequent rotations), so that for each the effective data rate is 8 scans/min. This scheme is used, not for height finding, but rather to give solid vertical coverage. The search beam's dimensions vary with elevation, the vertical beamwidth being 2 deg at an elevation of 2.5 deg, but 30 deg at an elevation of 21 deg. Targets are automatically detected, and their 2D (range and bearing) positions fed into the central computer, which instructs the 2 frequency-scanned radars to find the contacts in 3 dimensions for tracking. Each of the 2 frequency-scanned arrays is slanted to the vertical, the combination of the 2 oppositely slanted arrays making for full 3D operation. The net data rate is 40 scans/min, because of the back-to-back operation.

The entire radar is fed by a single time-shared power source.

Discussions with the Royal Netherlands Navy began in 1958, and a first working model was completed in February 1964. The 2 operational radars were completed in 1969. SPS-01 was originally known as MTTR, the Multi-Target Tracking Radar, and for a time was a joint project with the Royal Navy.

◆ VI-01 (SGR-109)

Band: S **Beam:** 3.5×1.2 deg **Peak Power:** 500 kW

Gain: 39 dB **Pulse Width:** (i) 1.5 (ii) 0.5 microsec

PRF: (i) 500 (ii) 1000 pps

Scan Rate: (elevation) 50 scans/min (+8/-2 deg) or 20 scans/min (+50/-2 deg); the sector scanned varies automatically with range. Scan in terms of bearing: 51 deg/sec

VI-01 is the nodding height-finder on board the Argentine carrier *25 de Mayo*. The transmitter is the same as that of the contemporary DA-01 series. Claimed performance for the very similar land-based radar is a range of 150 nm, coverage to 120,000 ft. Up to 6 randomly spread targets (over 360 deg) can be handled per minute.

◆ ZW Series

ZW-04 no longer survives; no sales of ZW-08 or -09 have been reported. See the last edition for details.

◆ ZW-01/3 (SGR-103)

Band: X (8.5–9.6 GHz) **Beam:** 1.0×3.5 deg
Peak Power: 180 kW
Gain: 39 dB **Pulse Width:** (i) 0.1 (ii) 0.3 microsec
PRF: (i) 2000 (ii) 1000 pps **Scan Rate:** 7.5 or 15 rpm
Antenna Dimensions: width 2.56 m **Antenna Weight:** 300 kg

ZW-01 appeared in 1954 and was widely used in the Dutch and German navies. ZW-03 is an improved version, also widely used. These radars are described as surface and low-altitude air-search sets. The search antenna is stabilized on the horizon.

Typical performance: a jet fighter ($1\text{--}3\text{ m}^2$) can be detected at up to 30 nm, and a bomber ($10\text{--}40\text{ m}^2$) at up to 48 nm. Small vessels can be detected at about 18 nm, and periscopes at 4.5 nm. Minimum range is 50 m.

◆ ZW-06/07

Band: X (9.325–9.475 GHz) **Beam:** 0.9×19 deg
Peak Power: 60 kW **Gain:** 32 dB
Pulse Width: (i) 0.06 (ii) 0.6 microsec
PRF: (i) 4000 (ii) 2000 pps **Scan Rate:** 24 rpm
Antenna Dimensions: 2.9×1.2 m [about 9.5×3.9 ft]
Antenna Weight: 130 kg [287 lb]

For ZW-06, range on a 10 m^2 target is about 14 nm, and an airplane at 20,000 ft can be detected at that range. The very short pulse was adopted for high resolution. The air coverage is necessary for helicopter control in ASW. The transmitter is coherent, for clutter and jamming rejection.

Applications include the Dutch *Kortenaar* class, the Brazilian *Niteroi*, the Spanish *Descubierta*, and the Indian *Leanders*.

ZW-07 is a submarine version of ZW-06, with a peak power of 50 or 60 kW (pulse width 1 microsec, PRF 1200 pps). There are also a short-pulse mode (0.1 microsec, 35 kW, 2400 pps) and a single-pulse mode (0.22 microsec, 100 kW, can be 2500 pps). Gain is 28 dB; dimensions of the half-cheese antenna are 1.0×0.250 m. The beam is 2.4×16 deg. Resolution is 2.4 deg in azimuth. Performance: range on a 10 m^2 target is about 16 nm (at 25,000 ft). In the single-pulse mode a ship (50 m^2) can be detected at 13.5 km, and a 10 m^2 target at 9 km.

ZW-06 surface-search radar. (Signaal)

ZW-07 surface-search radar for submarines. (Signaal)

◆ ZW-12

Band: X **Beam:** (i) 0.9×19 deg (ii) 1.5×10 deg
Peak Power: 50 kW (100 W average)
Gain: (i) 31.2 dB (ii) 32.2 dB **Pulse Width:** 0.55 microsec
PRF: 4000 pps **Scan Rate:** (i) 24 rpm (ii) 60 rpm
Antenna Dimensions: (i) $2.65 \times 1.2 \times 1.78$ m (ii) $1.5 \times 1.2 \times 0.85$ m **Antenna Weight:** (i) 130 kg (ii) 175 kg

In the data above, (i) is the conventional parabolic antenna and (ii) the stabilized slotted waveguide (version 12S).

Despite the radar's surface-search designation, Signaal describes ZW-12 as a helicopter-control (using a special VESTA transponder) and limited air-warning radar. There are 2 antennas, a conventional mesh reflector and a stabilized cylindrical (slotted-waveguide) antenna (ZW-12S). There is provision for an optional TWS unit, capable of tracking 2 surface targets simultaneously. ZW-12/1 has an unstabilized antenna, and ZW-12/2 is stabilized.

The control console has a 12-in PPI and a 15-in television for light-pen control.

◆ LIROD-8 GFCS4

See LIOD under optronic systems below.

◆ MR-05

Band: L (1200–1400 MHz) **Beam:** 3.5×18 deg
Peak Power: 5 kW **Gain:** 26.5 dB
Pulse Width: 50 (compressed to 0.6) and 1 microsec
PRF: 700/1400 pps **Scan Rate:** 15 rpm
Antenna Dimensions: $4.8 \times 2.54 \times 3.34$ m
Antenna Weight: 600 kg

Signaal announced this new air-search radar, to replace DA-05, in 1990. It combines solid-state transmitter technology (4 solid-state amplifier modules, each providing part of the RF power) with a stealthy, i.e., low-peak-power (pulse compression) waveform. The alternative short-pulse mode is used to achieve a short minimum range. The antenna is a double-pillbox (an enclosed radome) with very low sidelobes (45 dB down from main lobe). Operating modes: normal surveillance (360 deg), sector scan, and silent operation. The radar operates in PRF stagger, fixed frequency, and in frequency-agile (FA) mode, hopping pseudorandomly among 8 frequencies. FA modes are either MTI (frequency maintained over several sweeps) or jumping (frequency jumps from sweep to sweep). The video processor supplies air video as MTI and LIN video; the MTI channel uses a 3-point moving-target indicator. All targets are displayed in the LIN (linear) mode. The video processor supplies surface video in linear or log form. In both channels, interference from other radars and multiple-trace (STA) echoes are suppressed by an interference-suppression unit (ISU) and a correlator. Maximum range is $100 + \text{km}$ [55 + nm].

MR-05 is fitted for, but not with, IFF. The number of alternative frequencies can be increased from 8 to 56. Other options are a stabilized antenna and a tracking processor (for ADT operation).

Signaal describes MR-05 as suitable for vessels displacing 1000 tons and up. The antenna outwardly resembles that of MW-08, albeit without the latter's striplines.

◆ SMART/MW 08

Band: S
Beam: 2 deg horizontal; each beam is about 9 deg wide
Peak Power: 150 kW **Gain:** 23-dB transmitter; 31.5-dB receiver
Pulse Width: 0.6 microsec compressed **PRF:** 3800 pps
Scan Rate: 27 rpm **Antenna Dimensions:** $4.8 \text{ m} \times 2.05 \text{ m}$
Antenna Weight: 1200 kg (plus 385-kg drive)

SMART is the Signaal 3D radar designed particularly to deal with antiship missiles, with radar cross sections as small as 0.1 m^2 , and with speeds as high as Mach 3. SMART covers all threats from sea-skimmers up to divers approaching at a 60-deg angle. SMART can automatically detect and track (ADT) up to 160 air and 40 surface targets at medium and long range. Signaal chose S-band as the best balance between range, clutter rejection,

SMART. (Signaal)

tion, and overall dimensions (for frigate installation). An X-band version was also designed.

Inside the antenna are a single horn transmitting antenna and a linear array of 16 strip-line receiving antennas. Received signals are preprocessed within the antenna itself: the output of the 16 receivers is fed into a digital beam-former producing 12 independent elevation beams. The antenna rotates in bearing. In effect this operation is monopulse height finding by a novel form of stacked beams. The 12 beams cover the entire hemisphere (from 0 to 90 deg of elevation). The combination of narrow beams (in bearing and elevation) and a high data rate makes it possible to designate targets directly to directors. Sidelobes are very small.

The transmitter is a TWT for pulse-to-pulse coherence and, therefore, MTI. MTI analysis (by FFT) is applied only to areas affected by weather or sea clutter, to reduce the overall processing load. PRF is optimized to avoid second-time-around problems. The radar is arranged to react automatically to jamming by changing PRF, and the radar can vary PRF or frequency by burst. Target range and speed are compared on a burst-to-burst and scan-to-scan basis to avoid false targets (which can be discerned by their unnatural behavior).

Transmission modes are fixed frequency, frequency agility over scan, and burst-to-burst frequency jump.

The antenna is stabilized against roll and pitch.

SMART is to replace DA-08 in both *van Heemskerck*-class missile frigates and in all 8 *Karel Doorman*-class frigates

MW 08. (Signaal)

(formerly the M class); the order was placed on 24 December 1986. SMART was an unsuccessful contender for the British Type-996 requirement.

SMART has been adopted for the German Type 123 frigate (in preference to the French Arabel, the British Type 996, and the U.S. Target Acquisition System). As a result, the German frigate will have much the same air-defense-radar system as the new Dutch M class; SMART will also equip the 2 Dutch L-class area-defense missile ships. This radar is being adapted for land-based use under the designation Vanguard.

MW 08 is a SMART development in G- (formerly C-) band for short- and medium-range cover, up to 70 deg elevation. MW 08 can automatically detect and track up to 20 air and 10 surface targets, and it can control gunfire against 2 surface targets. The array is reduced to 8 strip-lines (hence the reduced elevation coverage). Each of 6 pencil beams is 2×12 deg, and peak power is 50 kW (pulses are compressed to 0.6 microsec). The antenna is 2.488×1.160 m (weight 430 kg plus 90-kg drive). Maximum free-space range (single scan, 80% probability of detection) on a 0.1-m^2 target is 17 km (45 km for SMART); on a 1-m^2 target, 27 km (65 km). The radar can handle target speeds of up to Mach 4 (Mach 5 for SMART).

MW 08 has been ordered for the 3 Portuguese MEKO frigates.

◆ SCOUT

SCOUT is the Signaal equivalent of the Swedish BEAB PILOT; Signaal and BEAB are no longer associated companies, so each must have its own version. SCOUT was first shown at Bourget Naval in October 1990 (Signaal is now associated with Thomson-CSF). The X-band SCOUT has an output (equivalent to the average power of a conventional radar) of 1 W. It scans at 24 rpm, and its antenna is 1.84 m wide and weighs 75 kg (the associated processor weighs 21 kg). It is expected to detect a corvette at the horizon and a 15-ft wooden or GRP boat at 8 nm. The ESM counterdetection range (free-space, using a -60-dBm receiver) is estimated as 1.5 km, i.e., well within its own detection range. Range scales are 0.75, 1.5, 3, 6, 12, and 24 nm. Signaal claims that SCOUT is equivalent to a conventional 20-kW radar.

◆ STIR

Band: X and K **Beam:** 1.4 deg (0.3 deg K-band)

Peak Power: 220 kW (20 kW K-band)

Pulse Width: 0.29 (0.14) microsec **PRF:** 1800 or 3600 (7200) pps

Antenna Dimensions: diameter 1.8 m

Antenna Weight: total weight 1700 kg

This Signaal Tracking-and-Illuminating Radar is the lineal successor of the postwar M 40 series dishes. Essentially the tracking radar of the WM 20 series, STIR is removed from the egg and weather-proofed. The original version used a magnetron transmitter. Then the TWT transmitter developed for Goal-keeper was combined with a larger antenna, primarily for missile fire control in the Dutch *van Heemskerck*-class frigates. The Canadian TRUMPs will use the TWT transmitter with the earlier 1.8-m antenna, as the larger antenna would add too much top weight.

STIR uses a Cassegrain monopulse antenna. There are 2 basic versions, STIR 180 (1.8-m antenna and magnetron transmitter) and STIR 240 (2.4-m antenna and TWT transmitter). STIR 180 can also be supplied with the TWT transmitter. The data above are for the STIR 180 magnetron. Instrumented range is 60 km, and total weight is 1800 kg. The TWT version uses pulse compression (0.3-microsec pulses, PRF 3200 to 6400 pps). Average power is 5 kW (peak power 100 kW), compared to 230 W (40 W in K-band) in the magnetron-driven version. Instrumented range is 180 km. STIR 240 (TWT) provides a 1-deg beam and a target-acquisition range (not instrumented range) of $140+$ km for a 1-m^2 target.

A version with a 1.2-m antenna is under development.

By the end of 1986, over 50 STIRs were operational, with over 30 more on order. The 100th STIR was ordered in 1988.

STIR (1.8-m version). (Signaal)

Both versions of STIR with ZW-06 (below) and DA-08 (above) on board the missile frigate *Jacob van Heemskerck*. (Signaal)

A version of STIR, VM40, was proposed (but rejected) as the British lightweight Sea Wolf director.

In 1987 Signaal announced STING, a modified STIR intended to control vertically launched Sea Wolf. The result is small enough (710 kg) to fit on board a fast patrol boat. A single unit time-shares the processing of all 3 signals produced by the radar: X- and Ka-band tracking, and a missile gathering beam (receiving a signal from the missile itself). Signaal credits the combination of X- and Ka-bands with image-free tracking virtually

down to the sea surface. MTI (achieved through the use of an FFT) is used for clutter rejection.

◆ Signaal Coastal Radar

This slotted-waveguide radar is in service in the Netherlands, Belgium, France, West Germany, and Saudi Arabia. Characteristics: X-band (8850–9150 MHz); beam 0.25, 0.4, or 0.5 deg $\times$ inverted csc²; pulse width 0.050 or 0.200 microsec; PRF, respectively, maximum of 4000 and 2000 pps; peak power 40 kW.

◆ Reporter

Signaal's TWS coast-defense radar was announced in 1980. It can track up to 8 targets automatically or 4 manually. The prototype was completed in 1979, using parts from the existing Flycatcher (Goalkeeper) radar.

OPTRONIC SYSTEMS

◆ LIOD/LIROD-8

LIOD is an unmanned optronic director carrying a television camera or IR sensor and a laser range-finder. LIOD can operate either autonomously or in conjunction with a larger fire-control system. Range on fast aerial targets is about 11,000 yd in good weather. By 1980 LIOD had already been sold to Indonesia, Morocco, Nigeria, and South Korea. LIOD is designed for simultaneous control of 2 dual-purpose guns (with identical ballistics).

LIROD is a smaller version in which a Ka-band or X-band tracking radar replaces the IR sensor. In LIROD-8, the radar is the Ka-band (35 GHz, beam 1 deg) set used in Goalkeeper. Peak power is 20 kW (pulse width 0.14 microsec, PRF 14,400 pps); the antenna is 0.6 m in diameter. The director does carry a television camera, and LIROD-8 can be used as a tracking channel for a WM20-series fire-control system.

Estimated reaction time from target designation to open-fire was 5.5 sec. The director could slew at 120 deg/sec and could elevate at 80 deg/sec (limits -25 to $+85$ deg). The director proper weighed 300 kg and had a width of 1.5 m.

LIOD is the basis of the Signaal/Bofors RBS 70-based small-ship defense systems; see the Swedish RBS 70 missile and the Signaal OPTICAT below. Users: LIOD—Indonesia (PB 57-class ASW version), Ireland (*Eithne*), Korea (HDC 1150-class frigates), Malaysia (FS 1500-class frigates), and Turkey (FPB 57 class). LIROD—Argentina (MEKO 360 and 140 frigates), Australia (River-class frigates), Greece (Osprey 55 type), Korea (*Ulsan* and

LIROD (foreground) and a WM20-series "egg." (Signaal)

Donghae classes), Indonesia (*Fatahillah* and former Dutch *van Speijk* classes), Kenya ("Province"-class missile boats), and Mexico (*Cormoran* class). LIROD-8—Thailand (*Ratanakosin*-class and *Chonburi*-class fast attack craft).

◆ IRSCAN

Signaal's infrared scanner, usable both as a stand-alone system and as part of Goalkeeper, is to be evaluated with the latter in mid-1991. It employs a rotating stabilized turret, scanning in 3 alternative elevation patterns (low, medium, and high [to 40 deg]) and carrying 3 sensors (3–5-, 8–12-micron bands). Output is displayed on a 15-in television monitor, and processing is TWS.

FIRE-CONTROL SYSTEMS

Signaal does not distinguish between fire-control radars and the associated fire-control systems.

The Dutch M1 and M2 FCSs are now extinct, having been superseded in surviving ex-Dutch cruisers and destroyers (in Peruvian service) by WM25 and M45. For details, see the last edition.

◆ M4

Band: X Pulse Width: 0.5 microsec PRF: 1600 pps

M4 (SGR-108) can be distinguished from earlier Dutch fire-control radars by its cut-parabola antenna with a central feed supported by heavy pylons. Versions of the M4 fire-control system include M4/1 for 40-mm guns (1957), M4/2 for 40-mm guns (1961), and M4/3 for 40-mm guns and Sea Cat missiles (West Germany, 1961). M4 users: Germany (*Rhein*-class tenders) and Turkey (former *Koln*-class frigates and former *Rhein*-class tenders). Formerly on board Colombian modified *Holland*-class destroyers (no longer in service).

◆ M40 Series

Band: X Peak Power: 180 kW

These radar directors succeeded the M1 through M4; they use roll- and pitch-stabilized enclosed-dish antennas with conical scan for air-target tracking and elliptical scan for surface targets. Because the stabilizer is in the director, no axis conversion is needed (as it would be from a below-decks stable element), and overall weight is reduced. These directors can be fed by a target-indicating radar, which provides an initial bearing and range. The radar then automatically locks on and tracks. There is no optical range-finder, the director operator acquiring and following the target using a pair of binoculars on an aiming bar. Total director weight is 1250 kg; working circle diameter is 2.8 m.

The radar transmitter is almost certainly the same one originally used in the M20/WM20 series described below, and computing limits match those of the other system (maximum target air speed 900 yd/sec, maximum surface target speed 34 yd/sec, maximum target range 32,000 yd). The 2 main versions are M44 (Sea Cat missile control) and M45 (medium- and light-caliber guns). Each has an associated optical sight, but fields of view differ depending on application: 12 deg (magnification 4×) for M44, 8 deg (magnification 6×) for M45. Displays are A- and B-scopes. The associated solid-state digital computer of M45 is hard-wired for particular ballistics (for 2 or 3 different weapons, depending on how extensive the range tables are, i.e., on how much memory they consume). Computer functions: tracking of an air target, tracking of a surface target, antiaircraft fire, surface fire, and shore bombardment, in the last 2 cases with starshell fire. In the case of M44, the gunfire functions are replaced by firing bracket computation and launcher control.

M44 gathers the Sea Cat missile by means of a flight controller on the aiming bar. Guidance is generally visual, but the director can guide the missile by radar, using a second range gate and an F-scope.

Users: M44—India (*Leander*-class frigates), Indonesia (former *van Speijk*-class frigates), and Turkey (former German *Koln*-class frigates). Formerly on board Swedish destroyers. M45—

The Signaal IRSCANIRST turret. (Signaal)

An M45 director on board the German training ship *Deutschland*, now discarded. A similar radar, without a manned cab, was mounted above the ship's bridge. (R. Cheung)

Australia (River-class frigates), Germany (*Hamburg*-class destroyers and *Rhein*-class tenders), India (*Leander*-class frigates), Indonesia (former *van Speijk*-class frigates), Peru (former Dutch *Friesland*-class destroyers), and Turkey (former *Koln*-class frigates and former *Rhein*-class tenders). Formerly on board Swedish destroyers.

◆ WM20/M20 Series

Band: X

Beam: 1.5 × 7.0 deg (search antenna)
1.5 × 4.7 deg (later search antenna)
2.4 deg (track antenna)

Peak Power: 180–200 kW **Gain:** 33.5 dB (small search antenna)

Pulse Width: (i) 0.22 (ii) 0.45 microsec

PRF: (i) 3600 (ii) 1800 pps **Scan Rate:** 60 rpm

Radar data are for the system as originally developed. The early "eggs" were nearly spherical and had small search antennas (e.g., for Norway and Australia). The U.S. Mk 87 was derived from 1 such version (M22). About 1970 Signaal developed a larger search antenna (for greater gain, to achieve about 20 km greater range) with a larger vertical dimension (hence a narrower beam in the vertical). To accommodate it, the standard egg-shaped radome was enlarged, the portion below the joint being given a short straight section so that the entire egg seemed elliptical rather than spherical. The new search antenna entered service in 1973 and is exemplified by the U.S. Mk 92 system. In each case, the search antenna can scan either horizontally or helically, rising by 1 vertical beamwidth every second (i.e., every 360-deg scan) to reach its maximum height in 4.5 sec. That maximum is 25.5 deg in the case of the 7-deg antenna, and 21.1 deg for the 4.7-deg antenna. During the early 1970s a new 1-MW crossed-field amplifier was introduced. The transmitter was presumably that used in the earlier M44/45, with an added short-pulse mode intended primarily for navigation.

These multichannel WCs can generally be recognized by their egg-shaped radomes. The weatherproof egg saves weight by eliminating the requirement to weatherproof antennas separately; dry air is pumped directly inside. Colocation of the search and track antennas eliminates parallax corrections. Because both antennas use the same transmitter, there is no need to shift range scales between them. The result is very rapid reaction. Similar colocation is used in Goalkeeper (though without a common radome), in the U.S. Phalanx, and in the Soviet Pop Group and Cross Sword fire-control systems. The chief disadvantages of colocation are a relatively low location for the search antenna and possible blind spots in a ship with several fire-control radars. The air tracker is monopulse; surface targets are tracked by TWS operation of the search antenna (scan rate 60 rpm).

The WM-series replaces an earlier M-series (M20, M24, M26, M27, M29) that used the same radars but had much more prim-

The original version of the Signaal "egg," in this case for WM22 on board the Canadian destroyer *Iroquois*, 1986. (Author)

The later, more elongated, version of the Signaal "egg," in this case for WM25, is shown on board the Dutch frigate *Abraham Crijnssen*, 1986. The hemispherical top, housing the tracking antenna, matches that of the earlier version. (U.S. Navy)

itive computers. The latter were digital, but their programs were hard-wired into them, so that they could carry only a very limited set of ballistics. The first Signaal "eggs" appeared on board Norwegian *Storm*-class gunboats (M26), Swedish *Visby*-class frigates (probably M24) and *Spica*-class missile boats (M22), and German *Zobel*-class torpedo boats (M20) in the mid-1960s. The

U.S. Navy tested M22 (as Mk 87) on fast gunboats, and later adopted the WM system as Mk 92.

All examples of the WM-series share a standard weapons-control console and a standard radar (tracker) cabinet; target-designation sights and a lightweight optronic director (LIOD) can be added as required. The weapons-control console contains an SMR-S1 computer, and it in turn can be connected to a horizontal tactical display console. In that case the system becomes a "Mini Combat System," a miniature version of SEWACO. Signaal designated its mini-combat-system versions of the WM20-series by the fire-control number, as in WM25/41. WM26/41 was unique in lacking any separate tactical display console, the command function being exerted from the weapons-control console. Signaal defined a "Compact Combat System" as a WM-series weapons-control system and 2 or 3 tactical data consoles.

Type numbers indicate system capability:

- WM20 is designed to control torpedo and gunfire on board small attack boats. WM20 has 1 air and 1 (with an option for another) surface gun-control channel and 2 torpedo fire-control channels. The system can control 2 light or medium guns against 1 air and 1 surface target, or 2 torpedoes against 2 surface targets. WM20 can track 1 air and 3 surface targets simultaneously.
- WM22 is a simpler system for larger surface ships (such as frigates), tracking 1 air target. This system is intended for use with a long-range air-search radar and can control 2 guns against 1 air and 1 surface target simultaneously. A third gun channel can be added as an option. As an application, the WM22/41 mini combat system controls 2 gun channels. Performance, as of about 1980: air-search radar detection of a 1-m² target at up to 30.5 kyd (height, by helical scan, of up to 25,000 ft); surface surveillance up to the radar horizon; tracking of a 1-m² target at up to 29,000 yd, accommodating a target speed of up to 720 yd/sec. Maximum surface tracking speed was 100 kt in horizontal scan, or 60 kt in helical scan. System reaction time, from detection to firing, was about 6 sec. These performance figures are typical of all dual-antenna (egg radome) systems as they were delivered about 1975.
- WM24 has 1 air and 1 surface gun-control channel (with an option for a third) plus an ASW-control channel; it is the only system in the series with an ASW capability.
- WM25 can control a semiactive surface-to-air missile (providing CWI for target illumination); this system also has 2 gun channels. It can simultaneously track 1 air, 1 surface, and 1 shore target; or 1 air and 2 surface targets. Air targets are tracked by the pulse doppler dish and surface targets by the search antenna in TWS mode.
- WM26 is a simplified system for fire control and navigation, limited to 2 single-purpose guns. WM26 is the only version of the basic system that does not employ the double-antenna radome.
- WM27 has 1 antiaircraft gun channel, 1 surface gun channel, 1 surface-to-surface missile-control channel, and 2 torpedo-control channels. Besides WM20, WM27 is the only system in the series with torpedo-control capability.
- WM28 can track 1 air and 1 surface target simultaneously, plus 1 surface-to-air missile and 2 light or medium guns. This system is license-built (in modified form) in the United States as Mark 92. In its original form, WM28 has 2 gun channels and 1 surface-to-air channel.
- WM29 controls 1 command-guided surface-to-air missile (such as Sea Cat) and 2 gun channels (1 surface only). WM29 is designed to include a Signaal lightweight optronic director (LIOD), which can be used as a secondary tracking channel.

In each case, 1 of the surface gunfire-control channels can be used for shore bombardment.

The series is modular; Signaal, the manufacturer, integrates it into a full combat information system, using a combination of vertical and horizontal displays, weapons-control consoles,

target-designation sights, and optronic directors, plus the characteristic egg-shaped radome.

The egg-shaped radome (diameter 2.39 m, height 3.26 m, weight 780 kg) encloses a pair of antennas fed by a common radar transmitter and stabilized on a common platform. Generally there is a tracking dish above and a cut paraboloid search antenna below. In one case, M26, only the search antenna is used, and it is mounted above the platform. During search, all power is fed to the lower antenna, but once a target has been detected, some power is fed into the tracker. Signaal points out that mounting both antennas on a single platform eliminates errors in transferring a target from search to track. A small ship may, moreover, have only a single position suitable for antenna mounting. The search antenna can also be used to designate to a separate tracking antenna (STIR).

Radar features include digital MTI, circular polarization (CP) for search, and pulse doppler tracking (PDT) for tracking air targets in clutter. The main search radar scans either in fixed elevation or helically. The associated optical sight can be used to track surface targets, or air targets up to an elevation of 5 deg. The optical sight has an 8-deg FOV, and a magnification of 8×. Some versions also had a television tracker.

In its original form the system could detect a 2-m² air target at up to 30.5 kyd and at an altitude of up to 24,000 ft (in helical-scan mode). A similar target could be tracked at 29 kyd. Maximum tracking speed for an air target was originally 900 yd/sec (later reduced to 720 yd/sec, probably reflecting the somewhat slower speed of programmable digital computers compared to their hard-wired cousins), and surface targets can be tracked at up to 100 kt (horizontal scan; 60 kt during helical scan). Maximum allowable projectile time of flight was 64 sec (depending on ballistic tables), a figure that was probably determined by the cycle of ballistic calculation and correction. Signaal claimed that system reaction time was 6 sec from moment of detection to opening of fire.

The weapons-control console carries a 16-in PPI, as well as A- and B-scopes and an alphanumeric display. The PPI is an analog type, showing raw radar video plus synthetic data. The associated alphanumeric display shows 16 lines of data (32 characters each).

In 1973 it was claimed that the effect of cumulative improvements, including an enlarged search antenna, had been to double the effective range: 20% from the enlarged antenna, 20% from the use of a tunnel diode amplifier, and 50% from the power increase to 1000 kW by using a cross-field amplifier. At that time the claimed search range was about 25 nm on a 1-m² target.

As of 1979, Signaal was offering a fully coherent traveling-wave transmitter as an option in WM20-series radars, for clutter rejection and ECM resistance. Signaal also offered alternative frequencies for search and tracking, and doppler MTI for clutter rejection (FFT analysis of returning signals to extract their frequency shifts). Fitted with this transmitter, the radar was expected to detect a 1-m² target at 60 km (search mode) or to track it at 50 km. Pulse compression was used for search, so the peak power may seem low. Transmitter characteristics were: peak power 150 kW; search pulse width 12.4 microsec (compressed to 0.2) with PRF of 2000 pps, or 6.2 microsec (compressed to 0.2) with PRF 4000 pps, or 0.2 microsec with PRF 2000/4000 pps; tracking pulse width 0.6 microsec with PRF 12,000 pps for pulse-doppler performance.

Signaal is currently (1989–90) offering an upgrade to existing WM20-series radars, based on 1 applied to German WM27s on board Type 143 fast attack craft. The original Philips spin-tuned magnetron transmitter, which was replaced by a Varian coaxial magnetron in later WM20-series radars, is replaced by a solid-state coaxial magnetron. The original spin-tuned unit had the virtue of providing great frequency diversity, but it was not very stable at any 1 frequency, and its lifetime was relatively short. Moreover, as it degraded, it did so gracefully, and operators could not always be sure that their radars were losing performance. The new magnetron is very stable (for good MTI) and

The back-to-back squintless search antenna added to a West German WM27. (Signaal)

very reliable, and when it does fail, it does so catastrophically so that the operator knows when it has to be replaced. It is tuned by a piston, among 6 crystal-controlled frequencies, for limited frequency diversity.

At the same time, a slotted-waveguide (squintless array) antenna, with a vertical beamwidth of 30 deg that is tilted up at 15 deg, is being added back to the existing 4.7-deg antenna. The existing antenna scans up to 21 deg in 4.5 sec. The new antenna provides much greater instantaneous elevation coverage, and the operator can feed radiation either to it or to the existing antenna. This antenna can be fed either by the 230-kW driver or by the 1-MW cross-field amplifier. The 4.7-deg antenna retains its helical-scan mode. The new antenna has a low gain, and the modification was practical only because the ships were equipped with cross-field amplifiers, which produced sufficient radar power. New software greatly reduces the multipath problem at low angles of elevation. The new software also improves ballistics and prediction calculations.

Signaal offers sidelobe suppression: the combined antenna mounting ring is replaced by 1 carrying a pair of horns (facing outward) as well as a sidelobe-suppressing switching box. The preamplifiers, MTI plus linear amplifiers, cross correlator, test generator, and filter are all replaced. The horns are used for an auxiliary receiving channel.

Signaal also offers multipath/STAE clutter suppression by optimized PRFs and also by installing adaptive threshold circuitry in the MTI canceler. The existing pseudorandom PRF-stagger program is replaced by a PRF-step-stagger program, which divides the PRF range (3200–4000 pps) into 10/11 steps, causing

the STAE pulses to appear in different range bins and so to be rejected by the video correlator (ATD program).

For future upgrades, Signaal is offering to replace the existing magnetron transmitter with a 1-kW TWT (for pulse compression and coherent operation). The resulting digital radar employs FFTs (in place of the earlier analog MTI) to detect moving targets by their doppler shifts. Up to 20 targets can be automatically detected and tracked. Presumably, the TWT involved is the same as that now being introduced in production versions of the STIR fire-control radar for the new Dutch and West German frigates (the Canadian TRUMP project employs the earlier magnetron version).

Signal M20 and WM20 Series Applications:

- M20: Germany (*Zobel*-class torpedo boats, then transferred to Type 343 mine-countermeasures ships)
- M22: Finland (*Turunmaa* class), Indonesia (PB 57-class patrol boats), Malaysia (FS 1500 frigates and the frigate *Rahmat*), Nigeria (formerly on board Vosper Mk 3 frigates), Norway (*Oslo*-class frigates, now removed), Spain (*Lazaga*-class fast attack boats), and Sweden (*Halland*-class destroyers and *Spica*-class fast attack boats, now discarded; survives on board *Alvsborg*-class minelayers)
- WM22: Argentina (Lurssen TNC 45-class FACs), Australia (River-class frigates), Canada (Tribal-class frigates), and Thailand (frigate *Makut Rajakumarn*; WM22/61 in *Chonburi*-class patrol boats)
- WM24: Nigeria (*Erin'mi*-class frigates)
- WM25: Argentina (MEKO 360H2-class frigates), Belgium (*Wielingen*-class frigates), Germany (*Bremen*-class frigates), Greece (ex-Dutch *Kortenaer*-class and Osprey 55-class missile corvettes), South Korea (*Ulsan*-class frigates), Morocco (41 version in frigate *LCol. Errhamani*, FCS version in *Lazaga*-class attack boats), Netherlands (*Tromp*-class destroyers and *Kortenaer*-class frigates), Nigeria (MEKO 360H frigate), Peru (cruisers), Spain (*Descubierta*-class frigates; some may have WM22/41), Thailand (PFMM Mk 16 corvettes, *Ratcharit*-class missile boats), and Turkey (MEKO 200-class frigates)
- WM26: Norway (*Storm*-class fast attack boats), Singapore (110-ft Type B fast attack boats)
- WM27: Germany (S143/143A/143B-class fast attack boats)
- WM28: Argentina (MEKO 140 A16-class corvettes), Bangladesh (*Megna*-class fishery-protection patrol boats), Indonesia (*Hajar Dewantara* training frigate, *Fatahilah*-class frigates, and PSK Mk 5-class patrol boats), Iran (Combattante II-class attack boats), South Korea (*Donghae*-, HDC 800-, and HDC 1150-class frigates), Nigeria (WM28/41 in FPB 57-class fast attack boats), Singapore (FPB 45-class fast attack boats), Thailand (*Prabrarapak*-class patrol boats), and Turkey (WM28/41 in *Dogan*-class fast attack boats).

◆ Sea Sparrow Radar Upgrades

There are 2 new Signaal radar concepts to increase the capability of existing Sea Sparrow missile systems. SIR, a Slaved Illumination Radar, would be controlled by a 3D radar such as SMART; it is similar in concept to the SPG-62 slave illuminator used in the U.S. Aegis system. SIR would be a STIR without its radar components, retaining only its CW illuminator. No prototype has been made.

The alternative is MEMPHIS (Multiple-Engagement Phased-Array Illumination System). A single director can track 4 targets within a 90-deg sector, and the director can rotate to cover the full 360 deg. MEMPHIS uses an X-band reflector composed of numerous small pistons, tightly packed, each driven by what amounts to a loudspeaker motor. Each has 8 alternative positions. The reflector as a whole, then, shows a series of alternative stepped surfaces. It might be termed a Fresnel reflector, in analogy to a Fresnel lens consisting of a series of alternating steps. The direction in which the reflector stares is changed by moving the pistons, and they can move continuously in a ripple.

This motion can also be used to distort the beam produced by the reflector. Although the resulting motion is not as fast as that of an electronically driven phased array, MEMPHIS is much simpler and much less expensive. A proof-of-concept reflector has been built, but as yet there is no full prototype. An operational MEMPHIS would be radome-enclosed.

SPAIN

◆ Dorna

This is a new secondary fire-control system proposed by Inisel, combining a TV and IR tracker with a laser rangefinder/designator and with a tracking radar. Work has been proceeding since 1986, but the Spanish navy has yet to choose a radar type, which may be single- or dual-band (Ka/X). The TV/IR tracker will be based on a TV/IR tracker Inisel uses for a land-based system, Felis. Inisel hopes that Dorna will be adopted for the modernization of Spanish frigates and corvettes.

SWEDEN

The primary electronics manufacturers are Ericsson and Bofors (BEAB). BEAB was formerly PEAB (Philips), formed in 1975 by combining 3 companies of the large Philips industrial electronics group. Philips also owned Signaal and MEL, and Signaal and PEAB had a noncompetition agreement. However, in 1989 Philips decided to sell off its defense arms. It sold PEAB to Bofors (hence the renaming, to BEAB), and it sold majority control of Signaal to Thomson-CSF, ending the noncompetition agreement. MEL was sold to Thorn-EMI.

Most of the Philips (now BEAB) radars are based on a tunable (i.e., frequency-agile) magnetron developed in 1955. This device was intended primarily to solve the problem of echo fluctuation (due to small phase differences from different parts of the target, so that reflections from different parts of the target interfere with each other) and glint (apparent movement of the target echo center, even beyond the physical area of the target). Both phenomena vary with signal frequency and, thus, can be avoided if the radar rapidly changes frequency. The PEAB (BEAB) magnetrons change resonant frequency by spinning a tuner coupled magnetically to an external motor. These magnetrons entered production in the mid-1960s; Ferranti uses a license-built version in the Seaspray helicopter radar.

RADARS

◆ BEAB C/X-Band Radar

Band: C and X

Beam: csc^2 in C-band, linear in X-band

Scan Rate: 30/60 rpm

Antenna Dimensions: 2.4×1.0 m

Antenna Weight: 100 kg [220 lb] (plus 350-kg platform)

This is the primary radar of the 9LV Mk 3 systems. The BEAB X-band radar and the Ericsson C-band Giraffe share a single new antenna to solve the masthead space problem. Both use BEAB displays. The BEAB element is probably the standard 9LV magnetron search set. Signals from both radars are vertically polarized. Because the radar is not sold separately from the 9LV Mk 3 system, it has no separate designation. This is the main radar of the Swedish *Göteborg* class, and it is the target-indication radar of the Australian-New Zealand ANZAC frigate (these ships have SPS-49 for long-range air search). In the Finnish *Hel-sinki-II* class, this antenna (stabilized) serves the Sea Giraffe C-band radar and an X-band navigational radar.

◆ Eagle

PEAB's K-band (35 GHz) narrow-beam (0.8 deg wide) coherent pulse-doppler tracker, intended to work with the Trinity 40-mm gun, was announced in 1988. This radar employs pulse compression to reduce counterdetectability, and there is a special operating MTI mode allowing pulse-to-pulse frequency agility. Two nearby targets can be tracked simultaneously, and

PEAB claims that the inherent multipath error at 10 km is less than 0.4 mrad. PEAB claims that antenna gain is so great (and sidelobes so small) as virtually to preclude any attempt at escort jamming. Peak power is 75 W, and PRF is 30–40 kHz. The radar head weighs 80 kg, and PEAB claims that a sea-skimming missile at an altitude of 5 m can be tracked at 5 km.

◆ Sea Giraffe 50/50HC/100/150/150HC (PS-75)

Band: C (5.4–5.9 GHz)

Beam: 2.1 deg (50), 1.8 deg in larger versions

Peak Power: 15 kW (50, 50HC, and 100); 60 kW (150, 150HC)

Gain: 29 dB (50); 30 dB (50HC and 150HC); 36 dB (100 and 150)

Pulse Width: 3.2 and 6.4 microsec, compressed to 0.3 microsec in surface-search mode. There is also a short pulse (0.2 microsec) for fire control.

PRF: 1000–7000 (depends on mode) **Scan Rate:** 30 or 60 rpm

Antenna Dimensions: 2.3×0.7 m (50); 2.4×0.8 m (50HC and 150HC); 2.4×1.8 m (100, 150HC)

Antenna Weight: 250 kg (50); 700 kg (100, 150HC)

Sea Giraffe, announced by Ericsson in 1982, is a family of 5 multipurpose (air- and surface-search, fire-control) naval radars, using 3 different fully stabilized antennas (1 for Sea Giraffe 50, 1 for 50HC and 150HC, and 1 for 100 and 150) and 2 transmitters (1 for Sea Giraffe 50, 50HC, and 100, and 1 for Sea Giraffe 150 and 150HC). Both transmitters operate in C-band and are fully coherent so that MTI can be used for clutter rejection

The Sea Giraffe 150HC 4-beam antenna chosen for the Canadian "City"-class frigates. (Ericsson)

Sea Giraffe 150HC coverage. (Ericsson)

(50–55 dB ratio). In the designations, HC denotes an optional high-elevation antenna to detect missiles diving at angles of 60–80 deg.

Sea Giraffe 50 and 50LW (lightweight) use antennas with single beams; 50LW uses a slotted waveguide. Sea Giraffe 150HC has 4 beams to provide high cover against steep divers. Sea Giraffe 50 and 150HC are stabilized. Sea Giraffe 150HC covers 0–70 deg in elevation. Instrumented ranges are 25, 50, and 100 km.

At least in the case of the Canadian-frigate 150HC, air targets are automatically detected and tracked; surface targets are manually detected and then auto-tracked. Presumably, the surface targets of interest are mixed with large numbers that are irrelevant (e.g., fixed points ashore), and a radar attempting to track all of the targets it can see would be overloaded.

These radars are all derived from the Ericsson Giraffe (PS-70R) land air-defense radar, so named because it is carried at the upper end of a tall tower. The main difference from Giraffe is the greatly improved range resolution (through pulse compression), so that the radar can distinguish small targets close together.

Waveform, PRF, and pulse width can all be varied to combine short- and long-range performance, e.g., for search out to 100 km or for high-accuracy search at 20–25 km. All versions are frequency agile both in MTI and in non-MTI modes, the frequency changing about 4–10 times while the beam is on a target. Antennas have very low sidelobes to reject standoff jamming; all are of csc^2 form, and all have integrated IFF via their antenna feeds. There are separate air- and surface-search modes. For air search, pulses are transmitted and received uncompressed, their nearly pure frequencies making for effective digital MTI performance. For surface search, the signal is modulated at the TWT by a linear FM signal (a chirp) produced in a surface acoustic wave (SAW) delay line.

Radar frequency was chosen partly on the basis of the requirement for clutter rejection through MTI. MTI performance varies with both the radar frequency and the character of clutter. Sea clutter has a typical velocity of 10 m/sec; and rain and chaff speeds depend on wind velocity: 25–30 m/sec are not unusual. The longer the wavelength (the lower the frequency), the higher the clutter velocity at which MTI begins to lose its efficacy. For X-band that velocity is about 10 m/sec, for C-band about 20 m/sec, for S-band about 35–40 m/sec, and for L-band about 70 m/sec. This characteristic limits selection to C-band and lower frequencies, Ericsson preferring the highest possible frequency to limit antenna dimensions and weight. On the other hand, the higher the frequency, the better the radar's resistance to jamming, and higher frequency produces less lobing loss against low-flying targets.

Ericsson chose a TWT rather than the more usual magnetron transmitter for its better MTI improvement factor (typically

50–55 dB rather than 25–30 dB in an incoherent magnetron, i.e., successful detection in clutter 100 times as strong); for its ability to suppress STA echoes (which become a serious problem for a radar operating at short instrumented range; the coherent radar remembers the phase of the transmitted pulse and so can reject any returning STA pulse because it will have the wrong phase); for its ability to combine MTI with frequency agility (the radar sends a burst of pulses with 1 frequency, then shifts to another); and for its flexibility in waveform (the TWT merely amplifies the incoming signal, whereas the magnetron both creates the signal and amplifies it). Sea Giraffe exploits this last quality of the magnetron by using both long uncompressed pulses (for air search) and compressed pulses of the same length (for surface search).

For air search, the signal processor uses MTI to eliminate clutter. The operator can avoid blind speeds by shifting or staggering PRF. MTI reduces sea clutter by 40 dB by using shifted PRF, or by 50 dB by using staggered PRF. The MTI can compensate for own-ship speeds of up to 45 kt. For surface search, the radar moves among 4 frequencies to avoid spot jamming. This mode employs pulse compression and instantaneous gain control (IAGC). The operator can select a combined mode, in which every 2 air-search scans are followed by a surface-search scan, and would choose to watch either air- or surface-search video. Finally, there is a fire-control mode employing a narrow pulse, in which the radar scans a narrow area around the target. The operator designates targets, and shell splashes can be spotted with an accuracy of 0.1 deg and 20 m.

Sea Giraffe 50 and 50HC were indeed for fast attack craft. Maximum range against a 0.1-m² target (single scan, 50% probability of detection) is about 18–19 km; a 4-m² target at low altitude can be detected at about 40 km by version 50 (45 km by 50HC). Accuracy is 0.3 deg in azimuth and 25 m in range; resolution is 1.7 deg in azimuth and 45 m in range.

Sea Giraffe 100 and 150 were intended for offshore-patrol vessels and fishery-patrol vessels. Sea Giraffe 150HC was intended for larger attack craft, corvettes, and frigates. Maximum range against a 0.1-m² sea-skimmer is about 27 km; against a 4-m² airplane, about 63 km. The HC suffix means high (angle) coverage.

Sea Giraffe 50, 50HC, and 100 are designed for minimum equipment below decks, all the radar units being mounted in a single cabinet.

The Swedish Navy ordered Sea Giraffe for its modernization of the Spica-II-class fast patrol boats, and the first boat completed her trials in September 1982. Sea Giraffe 150HC was ordered for the Canadian "City"-class frigates.

A modified system, embodying a new openwork antenna and a second (3-cm) transmitter, is to equip the new Swedish Göteborg-class corvettes. Philips supplies the 3-cm transmitter and the antenna; the rest of the system is the existing Sea Giraffe 5.5-cm transmitter. No designation has been released.

Coastal Giraffe 75F is a new version, with an instrumented range of 75 km. The radar should be able to detect a 3-m² target, flying at about 2000 m, at a range of about 100 km; a 0.1-m² target flying at about 1000 m should be detectable at about 43 km.

◆ 9GR600

Band: X (8700–9500 MHz, with 400–450 MHz bandwidth)
Beam: 1.1×7 (1×3) deg **Peak Power:** 200 kW
Gain: 35.5 (38) dB **Pulse Width:** (i) 1 microsec (ii) 0.25 microsec
PRF: (i) 1000 (ii) 3000 pps **Scan Rate:** up to 60 rpm
Antenna Dimensions: 2.1×0.3 m (2.7×0.7 m)
Antenna Weight: 260 kg including turntable

Data refer to the radar with the 9GA209 antenna used in the 9LV200 fire-control system. This antenna is stabilized, and it can scan helically, elevating its beam to cover up to 40 deg vertically (20 deg vertically as used in the 9LV200 Mk 2 system). Elevation and scan are independent, so the operator can trade off coverage against data rate. Data in parentheses refer to the 9GA218 antenna. This latter can also be used at L-band

Sea Giraffe on board a Spica-II-class attack boat, at the masthead. The gun is a Bofors 57-mm/70 Mk 2. The box launchers aft carry RBS 15 missiles. (Ericsson)

(1010–1110 MHz and 1250–1350 MHz), with a 6×20 - or 8×25 -deg beam (gain 20 or 17 dB, respectively).

The transmitter is a tunable magnetron, with a tuning rate of 1000 cycles/sec.

The same radar is used with a stabilized 9GA202 antenna in the TORCI torpedo fire-control system, with the 9GA205 in the Mareld coastal radar, and with the 9GA300 antenna in the Subfar submarine set. Characteristics of these antennas are:

	9GA202	9GA205	9GA300
Dimensions	2100 × 560 mm	4500 × 625 mm	1000 × 140 mm
Weight	135 kg	225 kg	85 kg
Beam	1.1×4 deg	0.6×4.5 deg	2.4×16 deg
Gain	37 dB	40 dB	26 dB
Scan	to 60 rpm	to 40 rpm	to 24 rpm

9GA202 can spiral-scan, up to 20 deg elevation (this optional feature adds 25 kg to the antenna's weight).

◆ 9LV200 Tracker

Band: Ku (bandwidth 670 MHz) **Beam:** 1.3 deg

Peak Power: 65 kW **Gain:** 40 dB

Pulse Width: 0.2 microsec **PRF:** about 2000 pps

Antenna Dimensions: diameter 1 m

The antenna is a stabilized monopulse Cassegrain, and television or IR trackers (including a laser range-finder) can be mounted alongside. Processing is MTI, and frequency can be shifted randomly on a pulse-to-pulse basis. The hydraulic drive can slew at 85 deg/sec.

9LV200 search (top) and tracking (bottom) radars. (PEAB)

The transmitter is a tunable magnetron, with a tuning rate of 1000 cycles/sec.

9LV200 Mk3 employs a new coherent Ku-band (15.9–17.1 GHz) tracker, using a new TWT transmitter. This tracker operates over a bandwidth of more than 10% of its base frequency, among more than 100 frequencies. It uses multiple PRFs and pulse widths, but in all cases pulses are compressed in its receiver to 0.2 microsec. The new Cassegrain antenna has a multi-mode feed to achieve low sidelobes in both its sum and difference channels. Operating modes are pulse doppler, MTI, frequency agile, and fixed frequency.

With the radar are mounted a television (FOV 42×31 mrad), an IR camera (8–12-micron band, FOV 52×35 or 157×105 mrad, with closed-cycle Stirling cooling), and a laser range-finder (Nd-Yag, 1.06-micron wavelength, peak power 4 MW, PRF 10 Hz). The associated TV/IR tracker can follow either a centroid or an edge, with an accuracy of better than 0.15 mrad. The radar of the 9LV200 Mk 3 system is designated 9GR400.

◆ ELSA

ELSA is a lightweight 3D radar, under development by Ericsson and Marconi, for fast attack craft and frigates. This radar scans only in elevation (it rotates to scan in bearing), by phase shifting (by about 30 ferrites) rather than by the frequency scanning of current U.S. radars. Like Sea Giraffe, ELSA will operate at a wavelength of 5.5 cm and presumably will use a Sea Giraffe transmitter. Marconi is responsible for the antenna and beam-steering computer. The carbon-fiber antenna is electronically stabilized so that it weighs about one-third as much as a conventional 2D stabilized antenna.

This approach is interesting because it suggests that the addition of a special antenna and a small beam-steering computer can convert an existing 2D radar to 3D operation.

A sketch released by Marconi in 1989 shows 10 beams, providing solid coverage out to 60-km range and up to a height of 20 km, the lower beams reaching greater ranges (i.e., provided

ELSA, the new Ericsson-Marconi 3D radar, as sketched by Marconi, 1989.

with more energetic pulses). The drawing suggested a maximum elevation angle of about 85 deg, each beam being about 6 deg wide. Marconi suggested that the new radar could replace current search radars in small warships, and that it could support longer-range search radars in larger ones, functioning as a target-indication radar to cue a fire-control tracker onto a target. For example, it could replace Sea Giraffe in the Canadian "City" class. This radar will scan at 30 rpm, and it will operate in C-band (5 cm). Approximate antenna dimensions are 2×1 m.

◆ PILOT

Band: X (9345–9405 MHz) **Beam:** 1.2×20 deg
Average Power: 1 W **Gain:** 30 dB
Frequency Sweep: 50, 25, 12.5, 6.25, 3.125, 1.5625 MHz
PRF: 1000 pps **Scan Rate:** 24/48 or 20/40 rpm
Antenna: single or dual 5-ft slotted-waveguide
Antenna Weight: 55 kg single antenna; 90 kg for dual antenna [121/198 lb]

PILOT is a naval low-probability-of-intercept ("quiet") radar that uses frequency-modulated continuous-wave (FMCW) technology. Radar range is a function of average radar power, not of peak power. However, radar intercept receivers are triggered by the presence of a powerful peak signal; they do not sense the build-up of radar energy over time. The greater the pulse repetition rate, the closer the average power comes to peak power; conversely, the lower the peak power must be to provide useful amounts of average power. Ultimately, then, the least detectable way of providing sufficient average power would be a continuous radar transmission (CW). If continuous transmission occurred at a pure frequency, no information would be gained. In PILOT, the transmission frequency varies so that information can be recovered. This scheme seems analogous to the operation of an FM radio (as contrasted with normal radar, which is like an AM radio). It seems possible that FM transmissions are also easier to receive than standard AM transmissions (as most radio listeners have discovered), so that the average power level can be reduced, compared to that required by a conventional radar. PILOT uses 512 range-resolution cells; and at short range, resolution is typically about 3 m.

CW radars typically require separate transmitting and receiving antennas. However, a reflected-power canceler (RPC) makes it possible to use a single antenna. The RPC subtracts a sample of the transmitted signal from the received signal. In the data above, both antennas transmit and receive; the dual antenna adds about 25% more range.

PILOT. (Signaal)

PILOT is a joint venture of Signaal, Philips Electronics of Sweden, and the Philips Research Laboratories in the United Kingdom. PILOT was announced (in April 1988) at the British laboratory. The name means Philips Indetectable Low-Output Transceiver, and the radar is to be marketed jointly by Signaal and Philips of Sweden. It was announced in the fall of 1988 that PILOT would equip the new Swedish Göteborg-class corvettes, presumably as a stealthy navigational radar.

It was announced in December 1989 that PILOT had been tested as the navigational radar of the Dutch frigate *Jacob van Heemskerck* and also on board the German trials ship *Walther von Ledebur*. In one case a PILOT-equipped ship was able to turn on her radar during a radar-silence exercise without being detected by ships operating in company with her. PILOT also ran trials in the Baltic on board a Swedish *Spica*-class gunboat.

As of mid-1989, Philips and Signaal were considering several new versions for airborne and submarine installation. Signaal was in contact with submarine radar mast manufacturers in Germany (IKL), Italy (Riva Calzoni), and Britain (Barr & Stroud). PILOT can also use an existing navigational radar antenna, the operator switching between it and the conventional set.

COAST DEFENSE

◆ 9KA100

PEAB's electro-optical coastal-artillery fire-control system consists of a sighting unit (Kobra) and a ballistic computer. Kobra incorporates a laser range-finder, and the pedestal can carry an LLLTV or an infrared imager. This device is used to supplement the heavier 9KA400 and 9KA500 and also, as a stand-alone unit, to modernize older fixed or mobile coastal-defense batteries. At least 20 have been ordered, for use in Sweden and abroad.

◆ 9KA400 (Mareld/Kastell)

9KA400 are the current Swedish fixed coastal fire-control systems. The original Mareld entered service in 1965, and a digital version became operational in late 1976. A Mk 2 version is now in production. Sweden and at least 4 other countries, including Norway and Spain, ordered at least 70 Kastells, and Inisel produces the 9KA410 version under license. See 9KR400 for details of the radar. The digital computer is the same type as used in the 9LV200 Mk 2 naval fire-control system. 9KA400 is made by PEAB.

◆ 9KA500 (Kardinal)

PEAB's mobile coastal-artillery fire-control system is derived from the fixed 9KA400. There are 2 alternative versions, using 2 antennas: GA250/K (K-band, 15.9–17.1 GHz) and GA250/X (X-band, 8.5–9.6 GHz). Each is 2.3×0.55 m, the different frequencies making for different beams (respectively, 0.7×2.2 and 1.2×4 deg, gains 42 and 36 dB). Both are horn-fed reflectors, scanning in 2 alternative speeds (ratio 1:2, in the 6–60 rpm range). The K-band version gives the same precision as 9KR400 in a lightweight mobile form but has lower peak power (65 kW rather than the 200 kW of the X-band version). On the other hand, the K-band version suffers less from multipath.

In fixed form, 9KA500 is designated 9KA400 Mk 3 Kastell; it has been sold to Norway. 9KA500 is designated ARTE 727 in Swedish service. Each m/80 coastal battery has 2.

◆ 9KR400

Band: X (8700–9500 MHz) **Beam:** 0.6×4 deg
Peak Power: 200 kW **Gain:** 40 dB
Pulse Width: 1 or 0.25 microsec
PRF: 1000 or 3000 pps, respectively **Scan Rate:** up to 40 rpm
Antenna Dimensions: 4.5×0.625 m
Antenna Weight: 260 kg (including turntable)

The standard Swedish coastal-artillery radar, 9KR400 employs a 9GR600 X-band frequency-agile transmitter and a 9GA205 antenna. 9KR400 is the main sensor of the 9KA400 Mareld coastal-artillery fire-control system, which is also used by Spain, and of the 9CSI600 STINA naval command system. This radar is used by Spain and Yugoslavia, in the latter case

integrated with 9LV200 fire-control systems on board fast attack craft.

OPTRONIC SYSTEMS

♦ TVT-300

The simple SAAB optronic director consists of a television camera on a gyro-stabilized platform, tracking electronics, and a display console. Targets are acquired either manually or from a search radar. The operator moves an electronic gate over the displayed target to initiate autotracking. The camera tracks the contrast between the target and its background (i.e., presumably the edge of the contrast rather than the centroid of the target).

Users: Norway (*Sleipner*, *Hauk*, and *Storm* classes) and possibly Singapore (110-foot Type B class).

TVT-300, a television sight. (Saab)

♦ EOS-400

SAAB's optronic director, announced in 1979, incorporates an automatic television tracker and a laser range-finder. The target is designated using coarse data from an associated radar, and a below-decks operator locks on the television tracker for auto-tracking. The operator can also manually track by joystick. The system can continue to project the position of a target by memory when visibility is poor or when the target is temporarily obscured, e.g., behind trees. The tracker locks onto the target again when it reappears. The tracker also has an optional surface-target search mode.

One or two weapons can be slaved to the director, ballistics being computed by an associated microcomputer. Elevation limits are $+85/-30$ deg. Reaction time: operator time to lock on is 1–2 sec, and gun data calculation time for a target approaching at low altitude is 3 sec; maximum platform transient time (180-deg slew) is 3 sec. Slewing speed is 150 deg/sec in both train and elevation.

The television camera is a 40×30 -mrad FOV, and a 300-mm focal length; the laser range-finder is an Nd-YAG type pulsing at 10 Hz, with a maximum effective range of about 20 km. Range accuracy is 4 m for ranges less than 5 km, and 5 m for greater ranges. An optional thermal imager has a 52×35 -mrad FOV. The television tracker is digital and uses correlation tracking; it can deal with contrasts as poor as 5%. Calculated maximum tracking range, for a target occupying 1% of the full picture frame, and with a contrast of 60%, in a situation where visibility is 23 km, is 14 km. Angular tracking accuracy is 0.4 mrad. The entire platform is roll- and pitch-stabilized.

The director proper weighs 220 kg, and its swing circle is 1.006 m in diameter. Below-decks equipment adds another 405 kg.

EOS-400 was conceived as intermediate between TVT-300 and EOS-500. It is on board the Finnish *Turunmaa* class.

EOS-400. (Saab)

♦ EOS-500

EOS-500 is a more sophisticated equivalent of EOS-400, usable either autonomously or as part of a larger fire-control system. On designation of a target the system is automatically turned onto the appropriate bearing, the operator scanning the sensor head vertically by joystick. The operator then manually tracks until the target is within a gate, when the switch to autotrack can be made. Like EOS-400, EOS-500 can memory-track in bad or obscured visibility.

The first example was built for the Swedish coast-defense artillery.

FIRE-CONTROL SYSTEMS

♦ 9LV100 Series

This lightweight optronic fire-control system for small patrol boats (75–100 tons) is manufactured by PEAB. The director car-

The 9LV100 optronic director, carrying an IR camera and gyro on the left, a laser range-finder on the upper right, and a television camera on the lower right. The most basic version of the director lacks the infrared camera. (PEAB)

ries a SAAB television camera and an LM Ericsson laser ranger (wavelength 1.06 microns, PRF 10 kHz) and is comparable to the Signaal LIOD. A Philips USFA thermal camera (8–13-micron range) is available as an optional extra. The optronic director is based on KALLE, a ground antiaircraft system (using the 40-mm/70 Bofors gun) in service with the Swedish Army. The associated surface-search radar is an unstabilized standard navigational type, operating in S-band for maximum aircraft detection range (15–20 km). The radar has both long and short pulses, for, respectively, search and navigation. In KALLE land tests, which should approximate the 9LV100's performance, a 40-mm/70 was able to place 80% of 300 rnds within lethal radius (5.5 m) of a target at 2000–3000 m, and average reaction time was about 5 sec.

This system was announced in 1977 and thus was developed after 9LV200. The first was for the Finnish minelayer *Pohjanmaa*, and others were sold to Bahrain and to Malaysia.

LV indicates antiair warfare (luftvarn).

◆ 9LV200 Series

The 9LV200 is a fast-patrol-boat fire-control system, designed initially for the Swedish *Spica* class, to replace the Dutch Signaal M22 of the *Spica-I* class. The requirement, issued in 1968, emphasized defense against antiship missiles, using a new Bofors 57-mm/70 gun with special ammunition. The system also had to be very compact, given the small platform for which it was intended. PEAB (now BEAB) won the competition in 1969, using its own broad-band pulse-to-pulse frequency-agile radar transmitter (a spin-tuned magnetron) as well as a new type of motor and bearing promising very high tracking accuracy. Both were needed to detect, track, and engage small targets at relatively low altitude in a very cluttered environment. The pulse-to-pulse agility (frequency diversity) would seem to eliminate the STA problem for longer-range targets.

This system is normally integrated with Ericsson EPLO command/control consoles, so that a typical missile boat will have an EPLO horizontal 3-operator console, plus 1-operator 9LV200

consoles (with 12-in CRTs) for gunfire control (separate units for AAW and antisurface) and, if required, also for torpedo control. The associated mainframe computer, which conducts the actual fire-control calculations, is a Philips P800. The Mk 1 version of 9LV200 employs a hard-wired version of the computer; Mk 2 introduced the programmable digital version. Mk 2.5 introduced a new high-level RTL 2 software language. In Mk 3 distributed computers located in the consoles, and connected by a data bus (LAN), replace the single mainframe. Some versions of Mk 3 also include the command/control element formerly supplied by the separate (albeit integrated) EPLO consoles and their associated computers. In other cases, such as the Danish Standard Flex 300, the command/control consoles are still separately supplied.

The Royal Swedish Navy designates the Mk 1 computer as ARTE (*Artillerieldledning*) 722 (*Norrkopping* class). The equivalent Royal Danish Navy designation, applied to the *Willemoes* class, is Rakel 203 Mk 1 (Rakel means *Radar Kanoneldledning*). The Royal Swedish Navy designates Mk 2 as ARTE 726 (*Hugin* class; 726E in the *Stockholm* class). The PEAB designation for the *Stockholm*-class system is 9LV300 (see below). The associated torpedo fire-control system is TORCI, which is described separately in the ASW section.

Mk 1 is fitted to the Swedish *Spica-II*-class missile boats, to the experimental *Jaegaran* (prototype of the *Hugin* class), to the Danish *Willemoes* class, and to the Yugoslav *Rade Koncar* (as 9LV202). The Malaysian *Handalan* class (*Spica-M*) is equipped with a 9LV212 system.

Mk 2 was introduced in 1977 for the Swedish *Hugin* class. Export versions include 9LV223 (Bahreini *Ahmad al Fateh* class), 9LV225 (Finnish *Helsinki* class), and 9LV228 (Kuwaiti *Istiqlal* and *Al Boom* classes). Other export versions equip the Iraqi training frigate *Ibn Khaldun* and the UAE *Baniyas* class, and later units of the Yugoslav *Rade Koncar* class have Mk 2 systems, but precise designations are unknown.

Mk 2.5 versions include 9LV230 (Malaysian *Musytari*).

Mk 3 has been adopted for the Swedish *Göteborg*, for the Danish Standard Flex 300, and for the later units of the Finnish *Helsinki-II* class. Development began late in 1980 and was completed in 1985, the first production contract (for the *Göteborg* class) following in December 1985.

Mk 1 was conceived as a family of systems to control 1 or more dual-purpose guns (40–120-mm) simultaneously against 1 or more targets, for 80 tons and up. Its main sensors were a stabilized 200-kW X-band target-indication radar (which would also be the main search radar for systems installed on board small warships) and a 65-kW Ku-band monopulse target tracker (with Cassegrain antenna) mounted coaxially with a television tracker (such as the TVT-300 optronic director, described above). The search radar also functions as the surface-target tracker (TWS operation at 60-rpm scan rate, as in the *Seafire* system described below). It scans helically, its feed rising as it rotates to tilt its beam upward.

For a larger ship, 9LV200 was designed to work with a longer-range L-band pulse-doppler air-search set, an Ericsson Sea Giraffe that replaced the 9LV200 search set (e.g., in the Swedish corvettes and on board the training ship *Carlskrona*). The design also allowed for pulse-doppler operation of the tracker, to improve its performance against low fliers.

The main displays are a 16-in true-motion (TM) PPI for surface targets, plus a 12-in PPI in the main control space and a display unit with a north-stabilized relative motion display. There is also an operator television display, taking the output from the camera mounted with the tracking radar. The system operator designates air targets from the 12-in PPI, and the separate tracker automatically tracks them. Surface targets are designated from the PPI to a B-scope (for rate-aided manual tracking) or to the main search radar's TWS memory, as in *Seafire*. The system can, therefore, track and engage 2 targets (1 surface and 1 air) simultaneously. As in *Seafire*, the fall of shot can be observed on the B-scope; in this case it can also be observed by television using the tracker A-scope to detect misses in range.

The 9LV200 Mk 3 director, with television, laser, and infrared camera on the left. (PEAB)

Thus, although the system was designed for very quick reaction, it appears to have been conceived too early to benefit from the automatic radar detection and tracking techniques embodied in, say, Phalanx or Goalkeeper.

Mk 1 uses a hard-wired computer with limited memory for either ballistics or targets. Mk 2 can maintain up to 16 tracks in TWS mode. The manufacturer estimates that a target can be detected at 9 km (with some margin), designated at about 7.5 km (5 sec after initial detection), with loss of tracking quality because of multipath occurring at about 6 km (9 sec). At that point the system shifts to IR tracking, the target symbol being positioned on the IR display at about 4.8 km (12 sec) with IR lock-on achieved at about 4.3 km (14 sec). Fire begins at a range of about 3.7 km (15–16 sec) and becomes effective at about 2.8 km (i.e., after about 19 sec). These figures are for a 0.1-m² sea-skimmer (altitude 2–3 m, speed 333 m/sec, or about 650 kt).

The current Mk 3 uses different radars and also emphasizes standardization of consoles, computers, programming language (ADA), data bus (Ethernet), and interfaces. The basic system consists of a C-band TWT (pulse compression) search radar, a fire-control channel (including a new pulse-compression monopulse tracker), a gun-control (surface-fire) channel, an interface unit, a video distribution unit, a C3 processor (with data base), and control consoles. ECM and an X-band radar can be added. The system has sufficient capacity to add more tracker channels, a CIWS-control channel, SAM and SSM control, ASW functions, helicopter control, and additional EW capacities. Several of these options have been realized in the Australian frigate system described below under the 9LV400 series.

In the *Göteborg* class, the search radar is a dual-band (C/X) unit, with a separate high-beam C-band antenna, made of "air porous" material to reduce wind loading. The X-band channel may be used with a stealthy PILOT radar (see above) or with a conventional slotted-waveguide set.

The standard console is a 3-CRT (one 20-in for color or random scan, two 12-in to display video or tables) work station. There are 2 touch-input boards on which variable menus can be displayed (equivalent to variable action buttons), a standard keyboard, and 1 or 2 "joy-balls" (a mix between joysticks and trackballs). The associated single-board CPU is based on a Motorola 68020 processor; it carries 4 Mbytes of RAM (random access, i.e., working, memory) and 256 kbytes of EPROM holding permanent programs. There are 3 serial channel interfaces. Typically a ship will have a tactical console, a weapons console, and (optionally) an EW console. The consoles are tied together by a dual Ethernet bus, each of whose elements has a capacity of 10 Mbits/sec. The bus can accommodate up to 100 nodes per segment, far beyond the requirements of 9LV200.

The 9LV systems are descended from a series of Philips torpedo fire-control systems of the 1950s (see the Antisubmarine Warfare section). A late 1950s system, RATSI, was the first in the series to use radar to track and localize the target. Evaluated in a destroyer, RATSI showed that it could display the fall of

shot. In the mid-1950s a gunfire control system, PROSIT, displayed target and hit data, but had no ballistic computer. The next system, SLAC, introduced a ballistic computer. Philips introduced a corresponding ASW FCS for Swedish destroyers in 1958. All of these systems became extinct when the Swedish destroyers were stricken (the only foreign application was a pair of Colombian destroyers, now also stricken).

◆ 9LV300 Series

This WCS for 250–400 ton vessels is manufactured by PEAB. 9LV300 consists of 9LV200 plus 9LV100. This system is on board Swedish *Spica*-III (*Stockholm*)-class fast attack boats. This system can handle 2 air targets simultaneously; its search radar operates in TWS mode to control antiship missiles. The Royal Swedish Navy designation for the system, as installed on board the *Stockholm* class, is ARTE 726E. The Omani *Dhofar* class is equipped with 9LV307 (but *Dhofar* herself is equipped with a Plessey AWS-4 radar in place of the usual 9LV-series search set). There is also a 9LV331 (Bahreini 62-m Lurssen boats) version.

◆ 9LV400 Series

This WCS for frigates and corvettes up to 1450 tons, by PEAB, was announced in 1978. 9LV450 incorporates ASW as well as antiaircraft and antiship fire controls and is suited to a flotilla leader carrying an ASW helicopter. The 450 designation indicates a system with ASW capability added (" + 50"); similarly, 9LV250 would be 9LV200 plus ASW.

9LV400 is installed on board the Swedish training ship *Carlskrona*. Its EPOs (see the Surveillance and Control section) employ 23-in PPIs, and it has a high-capacity TDMA data link. The Royal Swedish Navy designation is *Stridssock Eldlednings System for Marinen* (SESYM). As a training ship, *Carlskrona* has 2 CICs, 1 duplicating that of a *Hugin* and the other that of a *Stockholm*.

9LV450 will equip the new Swedish corvettes of the *Göteborg* class. It will incorporate ARTE-726E (i.e., 9LV300) for gun fire control, as well as RCI-400 (missile fire control), TORPE (torpedo fire control), 9AU300 (ASW fire control), and 9CM300 (ECM control).

9LV453 has been selected as the combat system of the Australian-New Zealand version of the MEKO 200 frigate. It is described (in the Surveillance and Control section) under tactical data systems.

◆ Seafire

Seafire was an integrated PEAB WCS for fast attack boats, developed from the TORCI torpedo fire-control system of the Norwegian *Snogg* class. It competed with the Signaal WM-26 system of the Norwegian *Storm* class (armed with one 75-mm and one 40-mm gun, 4–6 Penguin missiles, and a 57-mm flare launcher) and was presumably a forerunner of the 9LV200-series system in the Swedish *Hugin* class. Seafire retained the special-purpose analog computer of the earlier TORCI, which used electromagnetic components. It incorporated 3 separate sets of 75-mm ballistics, among which it could switch rapidly. No 40-mm ballistics were incorporated, on the theory that the gun's range hardly merited such sophistication.

The search radar was the standard PEAB stabilized X-band 9LV spiral-scan search set described above, for continuous surface and limited air search. It could be provided with 2 magnetrons for improved ECM resistance. There were 2 displays, a PPI and a B-scope for target tracking and spotting. The system could also maintain indirect fire against a short target. Seafire included a 3-axis stabilized periscope as a backup for target indication and optical tracking of surface targets. Alternatively, the system could incorporate a television sight.

The radar scanned at 60 rpm and tracked surface targets by TWS. Targets were designated to the tracking memory by trackball on the radar console. One such target could be displayed on the B-scope, which also showed the fall of shot. The radar generally used regenerative rate-aided tracking, monitored by

The Danish missile boat *Bille* is equipped with a 9LV200 fire-control system, including the 9GA208 search antenna (on the masthead platform). The slotted-waveguide is designated NWS-2 in the Danish Navy. (L. Van Ginderen)

The Denezy tracker radar, tilted for stabilization. (Contraves)

the operator, and corrected by trackball. An electronic symbol on the main display showed the area covered by the B-scope. The system could engage the target shown on the B-scope, then quickly shift to a second target stored in its memory (and rate-aided tracked). Targets could also be acquired manually.

SWITZERLAND

◆ Denezy/M-46/CGS-1

The 4 Danish *Falster*-class minelayers and the 2 *Peder Skram*-class frigates, all completed in the 1960s, use this Contraves FCS to control their guns (3-in/50 for the minelayers, 5-in/38 and 40-mm for the frigates). A seventh system was installed at the Danish naval training base. This project, the first full Contraves naval system, was code-named Denezy within Contraves, and the designations M-46 and CGS-1 have been published; they are presumably Royal Danish Navy designations. The system consists of X-band conscan trackers, with unique 6-axis stabilization, and a below-decks analog predictor, using the Contraves computing capacitor. The trackers are probably those used later in Sea Hunter. This system competed with the contemporary Signaal M40 series. Previous Contraves naval work, from the early 1950s on, had been at the subsystem level for the French, German, Japanese, and U.S. navies.

◆ Sea Hunter 4

This system was developed by Contraves and Contraves Italiana; it entered service in 1967 on board the modernized Iranian destroyer *Damavand* and was later installed on board 4 Iranian frigates (delivered 1961–72; 3 survive) and on board the Libyan frigate *Dat Assawari* (1973). The Libyan system was replaced by a Selenia FCS when the ship was modernized in Italy in 1979–83. It employed only a single tracker; the surviving systems each have dual trackers and are sometimes described (incorrectly) as double systems.

Sea Hunter was designed to control guns, surface-to-surface missiles (Standard SSM in the destroyer, Sea Killer in the Iranian frigates), and the Sea Cat anti-aircraft missile (only in the Libyan case did the system not control an antiship missile). The X-band tracker is probably that originally developed for the Denezy system, described above, but has a simpler 4-axis (roll, pitch, bearing, and elevation—hence the suffix “4”) mounting. The same mounting can also carry a search-radar antenna, which rotates about the base of the tracker and shares the same radar transmitter, as well as an LLLTV and (in the case of Sea Killer) a small dish transmitting the beam-riding guidance signal. In the Iranian ships, only the upper of the 2 trackers carries the search antenna.

Sea Hunter 4: the upper forward stabilized mount shows the search antenna, track antenna, and Sea Killer Ku-band command antenna below the television camera. The search antenna could also be mounted separately. (Contraves)

Sea Hunter 4 on board an Iranian Vosper-Thornycroft frigate, with a separate search antenna. Both tracker mounts carry Sea Killer command antennas. (Contraves)

Operations room (CIC) of an Iranian Vosper-Thornycroft frigate, showing the target-designation console, with its pantograph, in the foreground. (Contraves)

The radars use an X-band magnetron (peak power 180 kW, randomly variable PRF of about 2000, adjustable frequency). The search radar operates at a pulse width of 0.27 or 0.5 microsec, the tracker only at 0.27 microsec. The tracker is a 100-cm paraboloid generating a 2.2-deg beam (4.4-deg when off-axis dur-

ing conical scanning), using linear or circular polarization. The search antenna is a 2-m slotted waveguide feeding a cylindrical hog-trough reflector to form a 1×30 -deg csc² beam. It scans at 20–50 rpm (continuously variable). Detection range on a 3-m² target (Swering Case I) is 45 km [49,000 yd]; the same target can be tracked at about 40 km [44,000 yd]. Reports that the tracker is the Selenia RTN-10X are incorrect; the tracker is a Contraves design.

The combination of search and tracking radars on the same stabilized base (and connected by a large U-shaped waveguide, hence presumably sharing the same radar transmitter) recalls the slightly earlier Signaal "egg." The system can accept external target designation, or it can acquire targets using its own fan-beam radar or the tracker (scanning in a helical pattern). The fan-beam search radar operates against surface targets in TWS mode.

Sea Hunter 4 was probably the first application of television guidance to a missile (in this case, Sea Cat); it used a Marconi Aerospace television.

Below decks are two 1-operator consoles (surface engagement and system control). The radars and the external target designation sight feed into the system-control console, whose PPI carries a pantagraph for target designation (the position of the pantagraph, positioned over raw radar video, reads target coordinates into the system). A small TV monitor is located above the main console, which carries the weapons-assignment panel and a B-scope (for splash spotting). Typically, the main console is used to engage the primary target, using the main tracker; the surface console can engage a separate surface target, using the search radar in TWS mode. Both consoles connect to the single system fire-control computer, which automatically computes a solution for the assigned target. The analog computer uses the Contraves computing capacitor, as in the land-based Super Fledermaus.

The basic system can control self-guiding surface-to-surface missiles (Standard), but it requires an additional tracker and an additional console to control the command-guided Sea Killer. This console selects missiles for launch, selects guidance mode, and monitors the system and the missiles. The console contains a television monitor and a joystick for optical command guidance. This version also includes a Sea Cat blind-fire control console (note, however, that the Sea Cat missile launcher was replaced by a twin 23-mm gun during the Iran-Iraq war; it is unlikely that the gun is controlled by the Sea Hunter system).

The Iranian ships also have a stabilized optical sight (the operator sits on a stabilized platform) as an emergency alternative channel for 35-mm-gun control.

Sea Hunter was originally the FCS of the Sea Indigo beam-riding surface-to-air missile, an abortive adapted land weapon. Sea Indigo in turn was adapted to the antiship role as Sea Killer Mk 1, controlled by Sea Hunter 2 on board the defunct Italian fast attack boat *Saetta*. Sea Hunter 4 was carried only on board the 4 Iranian Mk 5 frigates (1 of which was sunk during the Iran-Iraq war, and 1 of which was severely damaged). The Sea Killer Mk 2 missile carried by these ships is also used by the Italian navy as an air-to-surface weapon (Marte), and a version using the helicopter radar was proposed as Mariner.

Sea Hunter competed with the Signaal M20 and WM20 series; it appeared just as digital FCSs were replacing analog types. After losing the competition for a large contract, Contraves dropped Sea Hunter and began to rethink naval gunfire-control requirements, a process that ultimately led to the design of Sea-guard.

◆ Seaguard

Contraves's modular combat system is usually associated with a standard quadruple 25-mm gun (Sea Zenith 25). Seaguard includes a dedicated high-data-rate dual-beam C-band radar (the Plessey Dolphin/AWS-6) to detect both sea-skimmers and high divers (70-deg coverage, to 14 km altitude, and to 35 km range), and a 3-axis tracker (Ku-band radar, FLIR, and laser). The Siemens-Albis Ku-band radar (0.9-deg beam) incorporates a pat-

ented means of suppressing mirror (multipath) effects, encountered in tracking very low flying targets, that result from reflections off the sea surface. Missiles flying at up to Mach 3 can be engaged.

The Ku-band tracking radar operates at 15.7–17.5 GHz, with a peak power of 85 kW, and 80 nanosec (0.08 microsec) pulses; beam width is 19 mrad. This radar acquires missiles at 0.25–10 km and aircraft at 0.25–16 km. Weights: above-decks 1350 kg, below-decks 1350 kg. The radar antenna's diameter is 1.23 m. The alternative X-band tracker (for SAM control, if desired) operates at 8.6–9.5 GHz (peak power 2 or 4 kW, with 0.4–4 microsec pulses and a 31-mrad beam). Tracking range is 0.3–45/70 km. Weights: above-decks 1200 kg, below-decks 1300 kg. CW illumination can be provided through this tracker. This radar's antenna diameter is 1.315 m.

The associated FLIR has an FOV of 3×2 deg (operating at 8–11.5-micron wavelength). It incorporates a centroid tracker. The laser operates at a wavelength of 1.06 microns, with a 25-Hz data rate, and a 13-nanosec pulse length. The television sensor has an 11×8 -deg FOV.

The Ku-band module is designated TMK. It tracks with an angular speed of 3 rad/sec (172 deg/sec) in all 3 axes and weighs 1350 kg [2975 lb]. The 3 axes are alpha (train), beta (the offset radar turns around an axis at an angle to the horizon), and lambda (the radar antenna elevates through $+120/-30$ deg relative to the canted beta axis). The alternative separate X-band module is designated TMX-CW.

An alternative X/Ka-band tracking and illumination module (TMX/Ka-CW) employs a TWT transmitter and pulse compression; the module carries optional electro-optical sensors (TV or FLIR). The Ka-band radar operates at 34–34.45 GHz with a peak power of 75 W (pulse length 0.13/3.7 microsec: compressed/uncompressed lengths). Beamwidth is 8 mrad (0.5 deg), and tracking range is 0.3–20 km. The associated X-band radar, which shares the same antenna, has a peak power of 25 kW (pulse width 0.3/1.65 microsec) and a beamwidth of 30 mrad (1.7 deg). Tracking range is 0.3–70 km. Total above-decks weight is 1440 kg [3174 lb]; below-decks weight is 1390 kg [3064 lb]. Angular speed in all 3 axes is 3 rad/sec (172 deg/sec), and the radar dish's diameter is 1.4 m [55 in].

X-band is used to achieve long enough range (70 km) for the system to engage air targets with a surface-to-air missile. The tracker can avoid multipath problems by using all of its sensors, and it can track targets all the way to the zenith, elevating up to 120 deg. CWI can be injected into the X-band tracker waveguide. Contraves offers configurations controlling both conventionally mounted surface-to-air missiles and vertically launched missiles.

The main external elements of the Seaguard system, on display at RNEE 1989: the Dolphin acquisition radar, the radar director, and the 4-barrel 25-mm gun, capable of pointing up to the zenith and very agile. (Author)

The Seaguard gun mount demonstrates the agility it gains from its canted roller path. The device in the foreground is the Plessey Shield chaff-rockets launcher. (Author)

There is also an alternative electro-optical tracking module, TMEO, a pedestal carrying a FLIR or television on 1 side and a laser on the other; alternatively the pedestal can carry a light-weight W-band radar. The module is biaxially stabilized; the above-decks equipment weighs 230 kg, and the below-decks equipment weighs 490 kg. Elevation limits are $+80/-20$ deg, and train and elevation rates are both 1.3 rad/sec (74.5 deg/sec). The FLIR operates in the 7.5–11-micron band, with 2 alternative FOVs, 20×15 and 2.7×2.0 deg; resolution is 0.11 mrad. The alternative television camera has 31×23 - and 3.1×2.3 -deg FOVs. The laser range-finder, which is eye safe, operates at 1.57 microns and emits 1–3 pps.

For data concerning the associated Dolphin C-band search radar, see the description of the British AWS-6 radar.

The gun consists of 4 independent Oerlikon KBB 25-mm cannon, with a combined rate of fire of 3400 rnds/min. The axis of the mount is canted to allow for very high angle engagement of diving targets even from a heavily rolling or pitching ship. Ammunition capacity in the standard system is 1600 rnds, sufficient for about 18 engagements without reloading (one 80-rnd burst per target), and the manufacturer claims that tests of the high energy AMDS (Antimissile Discarding Sabot) ammunition show that it can kill with a single hit. Contraves claims that the special 25-mm AMDS round is equivalent to a standard 30-mm round.

The original deck-penetrating module was designated GM25. Elevation limits are $+127/-14$ deg, and angular speed (both for elevation and for train) is 2.5 rad/sec (143 deg/sec). Ammunition is carried in four 300-rnd drums, the hoists making up the rest of the total of 1660 rnds. The ammunition itself incorporates a 156-gram penetrator (total weight is 288 grams), and time of flight to 1000 m is 0.78 sec (muzzle velocity is 1355 m/sec, or 4444 ft/sec). Total weight above decks is 4400 kg (2690 kg below decks), and swept radius is 2.591 m.

In 1989 Contraves announced a second gun module, Sea Shield (GM25-SS), to supplement the earlier Sea Zenith (GM25-SZ). Sea Shield is mounted entirely above decks (without any magazine below decks), and omits the very high elevation firing feature of the heavier Sea Zenith. Ammunition supply is limited to 1000 rnds in four 250-rnd magazines (11 engagements), and elevation limits are $+80/-20$ deg. Train rate is 2.0 rad/sec; elevation is at 2.5 rad/sec. Total weight above decks rises to 5450 kg, but below-decks weight is only 1590 kg. Swept radius is 2.6 m. Sea Shield cannot be reloaded while it fires; however, Contraves argues that there is enough ammunition on the mount to deal with a concentrated multiple missile and aircraft attack.

In both modules, burst length (and the number of cannons fired) can be controlled, e.g., when the gun is used in limited surface actions (e.g., in the naval policing role).

The manufacturer claims a reaction time from acquisition to open fire of 4 sec, compared to a reported 6 sec for Phalanx. The manufacturer also estimates that 2–4 scans by the search radar (i.e., 2–4 sec) are required before the tracker can begin its own target search in azimuth. Seaguard is designed to shift targets every 5 sec or so, depending on the change of angle involved. Contraves claims that the last round will generally reach the target at about 300 m, where it must burst the target to avoid damage to the firing ship; the company claims a 95% net probability of hitting by that time.

The system is designed to permit expansion to control all ship's weapons, using additional trackers and a NAUTIS multiconsole combat system. All versions are linked together by data bus, the individual modules (tracker and gun) having their own microprocessors. The manufacturer claims that this architecture (as opposed to 1 incorporating a single central computer) makes for quicker reactions. Modules are: gun (CIWS-GM), tracker (CIWS-TM), general-purpose tracker (GPTM), electro-optical tracker (EOTM), electronic warfare (EWM), and command/control (CCM). GPTM can be used to control medium-caliber guns and surface-to-air missiles, using a Contraves

X-band pulse-doppler radar. The CCM is a horizontal 2-operator console that can be used both for command/control and for threat evaluation/weapons assignment, incorporating a 24-in PPI screen.

Seaguard was adopted by the Turkish Navy for its *Yavuz*-class MEKO frigates. In these ships the system consists of 1 search module (SRM), 2 trackers (TMK), and 3 guns (GM25), each of the last provided with sufficient ammunition for 15 engagements. A land-based version has been purchased for the Chinese Army (PLA).

Seaguard is a private-venture system; development began late in 1977. Contraves-Oerlikon collaborated with Plessey, with Siemens (both the German firm and its Swiss subsidiary), and with Elettronica of Italy. The project was announced at the beginning of 1980. By mid-1982 prototypes of all the modules had been tested, and the Italian Navy had priority for deliveries for trials. However, Italy did not adopt Seaguard.

A variant of the Seaguard FCS is being used to control an Emerlec twin 30-mm gun on board the Saudi minehunters being built in Britain. This is a combination of Contraves Pittsburgh and Contraves Zurich equipment (presumably, the EO element is from Pittsburgh). In addition, Contraves is supplying the tracker for a customer (unnamed) with its own SAM under development.

◆ Sea Hawk Mk II

Sea Hawk is a Contraves electro-optical fire-control system for small warships and auxiliaries; it can also work within a large-ship command/control system. Announced in the United States early in 1990, it was an unsuccessful competitor for the *Arleigh Burke* (DDG 51)-class electro-optical system, as a replacement for the abortive Seafire (Mk 121). A 2-axis gyro-stabilized platform carries a laser range-finder, a FLIR, and a television camera. Contraves claims that superior stabilization is achieved by placing the rate gyro module directly on the elevation axis of the pedestal, rather than using a takeoff and a servo. The pedestal is designed to operate in sea-state 3 and to survive in sea-state 5.

The below-decks elements are a pedestal electronics cabinet (PEC) containing the central system controller (a 16- or 32-bit microcomputer), the read-out unit for pedestal pointing angles, the servo unit, and the sensor power unit; the operator control console, with two 9-in monochrome monitors (FLIR and TV, simultaneously), a keyboard, and a joystick; and a weapons-control module (WCM) containing its own 32-bit processor. The WCM processes target and gun stabilization data and calculates gun ballistics; it can accommodate several different sets of ballistics simultaneously. Motion analysis techniques are chosen based on the type of target (fast, slow, or shore). For air targets, the system can do intermittent tracking (e.g., when a target is obscured), projecting ahead target motion. For surface targets, it can fire either to hit or to make a near miss (for policing). The shore-target mode includes offsets from beacons or other prominent points. The WCM also holds fire when a gun is pointing into the ship.

The television has a zoom lens (32–320-mm focal length) and uses CCIR format. The FLIR operates at 8–12 microns and has 2 FOVs (12×8 and 3.16×2.1 deg); its output is in CCIR format. The Nd-YAG laser has a 1-mrad beam (PRF 10/pps); range limits are 280–20,500 m [300–22,400 yd].

Targets can be designated by the host command/control system, from bridge target indicators, or by the FLIR or television. When targets are designated by radar, the director acquired them by scanning in elevation. Targets designated from the bridge are brought directly into the camera's FOV, and they are acquired by joystick and tracking window. If 2 targets are visible, then the system can change from 1 to the other by joystick; targets can also be designated via the keyboard, or by automatic horizon or sector scans. Once a target is acquired, it can be automatically tracked in 2 or 3 dimensions (in the latter case, using the laser).

The pedestal weighs 310 kg and requires 1.5 m of swing clearance; the PEC weighs another 320 kg, the OCC another 230, and the WCM another 130 kg [for a total of 2182 lb].

TAIWAN (GOC)

Taiwan currently manufactures a fire-control radar, designated SPG-24, which is used on board fast patrol boats armed with Hsiung Feng I missiles. Reportedly, the U.S. contractor for the SPG-24 program was ABA. The main developmental problem was conversion of the radar from analog to digital processing.

Taiwan also manufactures a navigational radar using a small X-band slotted-waveguide antenna, designated UPS-60. The initial batch, to equip missile-firing boats, was 57 radars, and more have been ordered. UPS-600 is a larger (and presumably lower-frequency) surface-search set, possibly derived from the U.S. SPS-64. At least 15 SPS-64s have been bought for coastal surveillance.

UPS-60(X)C is employed with mobile coastal-defense units. CS/SPG-24 has replaced HR-76 in some coastal-defense units.

In July 1988 a model of a phased-array radar, externally similar to the U.S. SPY-1D of the *Arleigh Burke* class, was exhibited in Taiwan. This is 1 of 2 alternative radars for the second series of *Perry*-class frigates; it is a modified version of the FARS radar that RCA (now the RCA Division of GE) proposed for the German navy and then for NAAWS. It is now designated ADAR-2N. The alternative, which was proposed in competition with FARS for the German contract, is the Raytheon CMAR, a fixed-array radar operating in C- rather than X-band, and employing some SPG-51 technology. Compared to ADAR-2N, CMAR should be larger and heavier, but it should have superior anti-clutter performance. As of early 1990, Taiwan was expected to choose the second-series combat system, including both the radar and the tactical data system, about mid-1990.

The RCA radar also exists in a larger land-based version, designated Chang Bai (Long White). It is a joint development project with the Taiwanese CSIST (Chang Shun Institute of Technology), which is responsible for advanced Taiwanese systems. A land-mobile version, controlling Sky Bow 1 missiles (similar in outline to the U.S. Patriot), is now operational. Each land-based system consists of a main radar with 4 illuminators, linked to 3 or 4 launchers each. Each launcher contains 4 missiles. The expected range of the phased array is 500 km.

At least initially, the frigates will be armed with SM-1 missiles, fired from vertical launchers. However, it seems likely that ultimately a navalized version of Sky Bow, controlled by the chosen phased-array radar, will appear.

The SPG-24 radar on board a Taiwanese (GRC) *Hai Ou*-class missile boat. The slotted waveguide above is UPS-60. There is a periscope in the foreground. (Fu S. Mei)

USSR

The *Sverdlov*-class cruisers and "Kotlin"- and *Skory*-class destroyers are now being discarded. As a result, the following radars have been omitted from this edition (details can be found in the previous edition of this book): Cross Bird, Egg Cup, Half Bow, Knife Rest, Long Bow, Post Lamp, Top Bow, and Top Trough. The following fire-control systems have been deleted: Fire Iron, Four Eyes, and Round Top.

SEARCH RADARS

Of all these radars, High Sieve survives on board the patrol icebreaker *Purga*. Ball End survives on board T-43-class fleet minesweepers.

◆ Band Stand

This radome is associated with the SS-N-9 missile on board *Nanuchka*-class missile corvettes and also with the SS-N-22 missile on board *Sovremennyy*-class destroyers and some *Tarantul*-class missile corvettes. Because these missiles have OTH range, Band Stand probably accommodates a targeting data link. However, *Tarantuls* also have a masthead antenna, Light Bulb, described as a probable missile data link. The combination of Band Stand and Light Bulb might be comparable to the combination used to target SS-N-3/12 missiles, the missile sending back its own radar picture for comparison with that provided by a targeting aircraft. Alternatively, Light Bulb may be the shipboard antenna for a Soviet equivalent of Link 11, as in the German AGIS system (in which missile boats are tied directly into a shore-based command/control system). *Tarantul-II* (the first production version) has Band Stand even though the ships are armed with SS-N-2C; in this case whatever is inside the radome replaces Square Tie/Plank Shave (as in *Nanuchkas* built for export: see Square Tie below). These ships have Light Bulb, which thus far has not appeared on board any other Soviet warships.

In export *Nanuchkas*, Band Stand covers a Square Tie antenna, apparently for cosmetic reasons.

◆ Big Net

Band: L (about 850 MHz) **Beam:** 5 deg
Pulse Width: 3.5 or 2.0 microsec **PRF:** 250 or 550 pps
Scan Rate: 6.7–8.6 rpm **Antenna Dimensions:** 25 ft wide

The large air-search radar, on *Kresta-I*- and some *Sverdlov*-class cruisers, and on some *Kashins*, Big Net can probably detect a large airplane at altitude at ranges of 100+ nm. Big Net is probably the cruiser/destroyer air-search radar developed in 1948–55 under the designation Fut-N, tested in the Baltic in 1955. The radar detected aircraft at a range of up to 150 km.

A Big Net air-search radar on board the *Kashin*-class destroyer *Strogii* at Massawa, 1972. (Royal Navy)

This radar entered service about 1957 and is contemporary with Top Trough.

Big Net was the last major Soviet 2D long-range air-search radar. Its Soviet name is Echo. About a decade after its introduction it was succeeded, in effect, by Top Sail.

◆ Don Series

Band: X (9375 MHz) **Beam:** 1.1×20 deg
Peak Power: 80 kW **Pulse Width:** (i) 1 (ii) 0.5 microsec
PRF: (i) 800 (ii) 1600 pps **Scan Rate:** 12 or 15 rpm

This series includes Don-2 and Don Kay. There was also a Donets-2, with a slotted waveguide (68.7×4.8 in, 1.4×20 -deg beam, seen in 1960 on board a trawler). The data here are for Don itself.

A Koni-class corvette shows a Don-2 radar just above her yardarm. The air-search radar above is Strut Curve; the fire-control radar forward of the mast is Hawk Screech, and Drum Tilt is partly obscured aft. (U.S. Naval Institute)

Don Kay surface-search radar is visible below and forward of the Head Lights C missile-guidance director on board the "Kresta II"-class cruiser Vasily Chapaev. The small radomes visible just abaft the missile director (1 pointed up, 1 down) are the Bell Slam and Bell Tap associated with the Side Globes ECM system. The larger radome on the centerline is Bell Clout. (Sea Power)

◆ Flat Screen

This previously unknown planar-array UHF air-search radar replaced Top Sail on board the Kara-class missile cruiser *Kerch*. This radar seems to have been fitted during a refit begun in April 1988 and completed about February 1989. The antenna consists of a series of slotted waveguides, the gaps between the arrays being quite visible. The serpentine feed characteristic of frequency scanning is quite visible on the right-hand side of the array, and the antenna is crowned by an IFF interrogator. This new long-range 3D air-search radar probably operates at a much higher frequency than Top Sail, most likely S-band. The antenna is about 6 m wide and 7 m high; it is tilted back at a 5-deg angle.

Flat Screen on board the Soviet cruiser *Kerch*, early 1989. The radar in the foreground is the Head Lights set used to control the ship's SA-N-3 missiles. The small flat array projected out from the uptakes is an IFF interrogator (Square Head). Although the ship retains her original series of ESM/ECM radomes, Rum Tub has been added (array visible just behind Square Head). (Eric Grove)

◆ Half Plate

The modified Top Plate, as its name implies, operates in S-band. Half Plate A is on board the missile transport *Aleksandr Brykin*. Half Plate B is on recent Grisha-Vs, superseding Strut Pair.

◆ Head Net A/B/C

This S-band small-ship radar is roughly contemporary with Slim Net. Range on a large high-altitude airplane is about 60–70 nm. Head Net A is a single antenna, about 22.5×5 ft. That size implies a fan beam somewhat less than 1 deg wide.

Head Net B had 2 antennas arranged back to back, providing a higher data rate. B is now extinct, having been installed only in *Desna*-class missile range ships (removed 1980, replaced by Head Net C). The back-to-back arrangement is widely used in Soviet naval radars (see Strut Curve, Strut Pair, Top Pair, Top Steer); presumably, both antennas typically share a common waveguide feed running up the mast between them. This arrangement reduces structural interference with radar emissions and increases the net data rate of the radar. In the case of a 2D/3D combination, the back-to-back arrangement probably greatly simplifies designation of a target from radar to radar, since there is no parallax error, and also economizes on the mechanical stabilizers the Soviets seem to favor.

Head Net C, which is the height-finder used with the SA-N-1 missile (and is the secondary 3D radar in *Kresta II*- and *Kara*-class cruisers), has 1 of its 2 back-to-back antennas canted at 30 deg to the horizontal. The 2 fan beams are, therefore, canted, and the relative apparent positions of the same target in the 2 beams measure its height (vee-beam height-finding). The operator finds the target with the conventional antenna, marks it, and sets range gates on the second beam to measure altitude. This vee-beam system was invented during World War

Head Net C air-search radar on board the Kashin-class destroyer *Strogii* at Massawa, 1972. The object at the base of the radar pedestal is a Watch Dog ESM antenna. (Royal Navy)

II, and a U.S. vee-beam set, CPS-6, provided to the Soviets under Lend-Lease, was copied postwar. The system is simple, but it is not as satisfactory as a true 3D radar. Head Net C entered service in 1963.

The Soviet designation for Head Net C is MR 310 (at least in the export version used by the Indian Navy). The Soviet name is Angora.

It now appears that Head Net C has been superseded by Top Plate.

◆ Kivach 3

Kivach 3 is a current small-combatant (e.g., mincraft) navigational radar.

◆ Mius

X-band surface-search radar.

◆ Mad Hack

This is the large flat object, which some have described as a phased-array radar, on board the intelligence-collection ships SSV-33 and SSV-501. Each flat plane has 12 sides. Although these objects are generally described as radar arrays, 1 of the flat planes on SSV-33 faces aft directly into extensive superstructure, which seems odd for a radar. One of the planes on board SSV-33 faces directly up. Close-ups of the amidships structure of the ship suggest that each plane may be a cover for some other sensor, hinged on 1 side.

◆ Neptune

Band: X (9430 MHz) **Beam:** 1.6×20 deg
Peak Power: 42 kW **Pulse Width:** (i) 0.25 (ii) 1.0 microsec
PRF: (i) 2700 (ii) 675 pps **Scan Rate:** 14 rpm

Neptune is a navigational radar of the 1950s. Production ended in 1960, but this radar remains in service.

◆ Nyada

X-band surface-search radar.

◆ Palm Frond

This surface-search radar is the current standard, replacing Don 2 and Don Kay from the Krivak class on. In accord with previous Soviet policy on surface-search radars, the usual complement is 3 sets (Krivaks have only 1, plus a Don Kay in Krivak-II; all Krivaks have 2 navigational radars).

A Palm Frond antenna is visible in front of the Strut Pair air-search radar on board the *Udaloy*-class destroyer *Admiral Vinogradov*. The back side of another Palm Frond is visible at left, and Kite Screech is in the foreground, right. (S. Zaloga)

◆ Peel Cone

This air/surface-search radar on Pauk and Stenka classes supersedes Pot Drum.

◆ Peel Pair

X-band surface-search radar of the late 1960s. It looks like a pair of Don-2 antennas mounted back to back.

Peel Pair (forward of the Band Stand missile-control antenna) on board a Nanuchka-class missile corvette. The smaller radomes are Fish Bowls (data links). (Ships of the World)

◆ Plank Shave

This search/missile-targeting antenna on Tarantul-class missile corvettes is the successor to Square Tie. The Indian navy calls this radar Harpoon; the name may be a translation of the Soviet name. This antenna is about the size of that of Don-2 and is marked by its large stabilizing vane and its overhead feed.

Plank Shave radar on board a Pauk-class corvette. (U.S. Naval Institute)

A Matka-class hydrofoil shows her Plank Shave targeting radar at her masthead, with a Bass Tilt fire-control radar below, atop her bridge. (German Ministry of Defense)

◆ Plate Steer

The modified Top Steer/Top Plate combination operates in S-band in *Sovremennyy* units 4–5 and *Kiev* and *Baku*. It consists of 1 flat (canted) antenna and the 2D antenna of Top Steer.

◆ Pot Head/Pot Drum

Band: X (9275–9460 MHz) **Beam:** approx 3 deg
Peak Power: 100 kW **Pulse Width:** 0.25–1.0 microsec
PRF: 1600–1650, 3200–3300 pps
Scan Rate: circular at 2.5–4 or 5–6 rpm; sector at 7–8

Standard radar in SO.1-class submarine chasers and on many other patrol craft, Pot Head superseded Skin Head from about 1960 on. Pot Drum, which is externally very similar, entered service in 1958 and was carried by patrol craft such as the *Turya*,

A Soviet *Turya*-class hydrofoil torpedo boat shows a Pot Drum radar forward (with Square Tie IFF interrogator below it) and Drum Tilt aft. Some units have a new Peel Cone radar with a large reflector instead. The guns are twin 30-mm (AK 230). (U.S. Navy)

Stenka, *Shersten*, and *Pchela*. It appears that Pot Drum had a peak power of 150 kW and a pulse width of 0.5–1.0 microsec, whereas Pot Head, which would have needed more resolution (e.g., for periscope detection), had a shorter pulse width (1 source gives 0.3–0.5 microsec). These radars were succeeded by Square Tie (which has a somewhat different role) in missile boats and by Peel Cone in recent patrol craft; Square Tie in turn gave way to the current Plank Shave. However, Square Tie is still in production for export craft.

◆ Ship Bowl/Ship Globe/Ship Shell/Quad Series

These are probably space tracking or communications antennas on board some Soviet space-events instrumentation ships and also on board a few of the larger intelligence-gathering ships. Ship Bowl is a 12.5-m-diameter radome; Ship Globe is 30 m in diameter; Ship Shell is a 27-m-diameter dish. Ship Globe's dishes may be enclosed in radomes or they may be uncovered. Ship Shell is a large uncovered dish incorporating what appears to be a monopulse feed. Both the uncovered antennas (and presumably Ship Bowl as well) are stabilized. In some cases Ship Globe is described as a satellite-communications antenna, but in others it presumably receives missile telemetry (either friendly or in an intelligence role).

Quad Spring is a large stabilized dish with a double (side by side) feed, the Quad referring to the four (2 × 2) supports for the feeds. Other space-support ships have Quad Leaf, in effect 4 merged dishes each with its own large feed (presumably for super-monopulse tracking), Quad Rods, and Quad Wedge.

◆ Skin Head

Band: S (3000 MHz) **Beam:** 17 deg
Peak Power: 80 kW **Pulse Width:** 1 microsec
PRF: 400 pps **Antenna Dimensions:** radome: 0.8 × 1 m

This patrol craft surface-search radar is reportedly derived from the U.S. SO series, now in PRC service. Skin Head was developed in 1946–48 and tested in the Black Sea in April–June

Skin Head radar on a Soviet torpedo boat preserved as a memorial. Although the memorial is for World War II, the P-4 class boat and its equipment (including the twin 14.5-mm machine gun aft) are postwar. (U.S. Navy)

1948. Test results: destroyer detected at 7.5 nm; torpedo boat at 3.4 nm; aircraft at 100–300 m altitude detected at 9–17 nm. The Soviet name is Zarnitsa. This radar was manufactured in China during the 1960s.

◆ Sky Watch

The carrier *Baku*, the fourth of the *Kiev* class, emerged in mid-1988 with a new flat-sided 4-faced array radar on her superstructure; the same radar has also appeared on the newer carrier *Tblisi*. It replaces the Top Pair of earlier ships of the *Kiev* class and presumably operates at a similar frequency to achieve a similar range performance. Top Steer is retained as a backup. It is possible that the internal space required for the radar (and, presumably, for those maintaining it) precluded the installation of any long-range surface-to-air missile system; the other ships of the *Kiev* class all have SA-N-3. *Baku* is limited to the SA-N-9 point-defense system.

◆ "Pomornik" Search Radar (Positive E)

A new air- and surface-search radar, radome-enclosed, and as yet without any published NATO reporting name, appeared on board the large air-cushion vehicles of the "Pomornik" class, as well as on board East German-built "Parchim II" corvettes built for the Soviet Navy, and on the new Indian corvette *Khukri*. In the case of the Parchims, the East German version of the class has Strut Curve radar in the position occupied by the new radome. The new radar may have a secondary fire-control role, as the "Pomorniks" lack any specialized fire-control radar for their 30-mm guns (although 1 was photographed with Drum Tilt in place of its big radome).

Sky Watch electronically scanned arrays on the island of the Soviet carrier *Tblisi*. Above the arrays are Big Ball satellite-communications antennas and the big cylindrical Cake Stand, a Soviet equivalent of TACAN. The back-to-back antenna above Cake Stand is Top Plate. (SOVFOTO)

Sky Watch on board the Soviet carrier *Baku*. (U.S. Navy)

An account of the new Indian corvette *Khukri* calls this radar Positive E and credits it with a range of 70–75 nm; it is said to be effective against low fliers. The E may refer to the radar band in ECM notation (i.e., low S-band). Positive is presumably a translation of the Soviet name. Radome diameter is about 3 m.

◆ Slim Net

Band: S (2840 MHz) **Beam:** (est) 1×3 deg
Pulse Width: 1–1.5 microsec **PRF:** 420–425 pps
Antenna Dimensions: 5.5×1.8 m

This early (ca. 1957) S-band radar on some cruisers, destroyers, and frigates can be used for both air and surface search, varying rotation rate (data rate) for the 2 functions (slow rotation for surface targets, fast for air targets). This radar appeared on board all Kotlins as built and was eventually mounted on all but 1 Riga. Slim Net was a slightly modified Hair Net (1950, now obsolete).

Slim Net on board a Mirka-II-class corvette. (MoD Bonn)

◆ Snoop Head

This X-band submarine search radar has an ESM radome (Bald Head) on the same mast, above it. The reflector is slotted. This radar appeared in the late 1970s, on board Alfa- and Oscar-I-class submarines.

◆ Snoop Pair

This X-band submarine surface-search radar has back-to-back antennas for increased data rate. The 2 feeds appear to be somewhat different, so it may be a dual-beam (dual elevation, not vee-beam) set. The radar reflector is solid and resembles that of Snoop Slab (albeit with feed from above rather than from below,

A surfacing Alfa-class submarine shows its Snoop Head radar (with Bald Head ESM radome above it). It also shows 2 periscopes and a VHF whip, abaft the radar.

Snoop Pair (with its associated Rim Hat ESM antenna) is the second antenna from aft on this Sierra-class submarine; the cone abaft it is Pert Spring (satellite navigation). (Royal Norwegian Air Force, 1984)

as in other Soviet radars; this type of feed is probably necessary since the waveguide runs up the mast between the reflectors). This is the current standard nuclear-submarine radar, appearing in the early 1980s on board Typhoon-, Sierra-, Akula-, and Oscar-II-class submarines. The associated ESM antenna is Rim Hat, which includes a ring of intercept antennas (presumably for monopulse DF) around the base of the radar.

◆ Snoop Plate

Band: X (around 9370 MHz) **Peak Power:** 80 kW
Pulse Width: 1–2 microsec **PRF:** 1618 pps
Scan Rate: 10 or 20 rpm (but rotation can be manual or sector scan, and minimum rate is 4 rpm)

The first Soviet postwar submarine search radar was seen in 1953; Snoop Plate was standard through early Foxtrot-class boats. Many components duplicate those of Neptune, Don, and Post Lamp. Range scales are 2, 5, 10, and 40 nm, but maximum range is about 10 nm in practice. Snoop Plate was replaced by Snoop Slab in Foxtrot-class and later submarines. Snoop Slab was later retrofitted to many earlier submarines, although Snoop Plate remains in service.

◆ Snoop Slab

This X-band submarine surface-search radar replaced Snoop Plate from about 1957 on. Snoop Slab has a massive parabolic reflector and very noticeable motor housing. It is carried by Echo-II- and by some Juliett-class submarines.

Snoop Slab search radar on board an Echo-II-class submarine. Aft it is a Stop Light C ESM antenna, a hemispherical antenna atop a series of monopulse DF antennas operating in 4 bands. The Front Door/Front Piece missile-guidance antennas are forward of the windshield, submerged, and the after end of the sail carries a standard HF whip.

◆ Snoop Tray

This X-band submarine surface-search radar was introduced in 1962. It has a nearly flat and almost rectangular reflector, tipped over at an angle of about 25 deg. This radar succeeded Snoop Slab in production (initially on board Tango, Golf, November, Hotel, Echo classes). Snoop Tray 1 appeared in the early 1960s; it is carried by Charlie-, Echo-, some Tango-, Foxtrot-, Yankee-, Golf-, some Golf-II/III-, Juliett-, November-, Victor-I-, Yankee-I/II-, Lima-, Hotel-, Bravo-, and some Romeo-class submarines.

Snoop Tray search radar on board a Foxtrot-class submarine, 1982.

Snoop Tray 2 appeared in the mid 1970s and is carried by Delta-I/II/III/IV-, some Echo-II-, Charlie-II-, Victor-II/III-, some Tango-, Kilo-, India-, and Yankee-Notch-class submarines.

◆ Spin Trough

The X-band surface-search radar in Krivaks and in auxiliaries, small craft, etc., is an alternative to Don 2.

A Soviet ocean minesweeper (T-58 class) shows typical slotted-wave-guide surface-search radars (Spin Trough and Don-2) and a Muff Cob fire-control radar for her twin 57-mm guns. The long cylindrical object on deck under the after gun mount is presumably an acoustic sweep. This Soviet ship is missing the clutter that is typical of Western mine-countermeasures craft. [U.S. Navy]

◆ Square Tie/Type 331

This X-band surface-search/targeting radar for SS-N-2 missiles is now being superseded by Plank Shave. Square Tie is enclosed in the Band Stand radomes of export Nanuchka-class missile corvettes, which are equipped with SS-N-2C rather than SS-N-9 missiles.

The PRC designation for this radar is Type 331.

Square Tie search and missile-targeting radars at the mastheads of Chinese Osa-type missile boats, center and left. [U.S. Naval Institute]

◆ Strut Curve/Strut Pair

This S-band small-ship air-search radar, contemporary with the Head Net series, is installed on Petya and Mirka frigates and Poti and Grisha corvettes. Strut Curve reportedly operates at the high end of the S-band and is unusual in lacking a balancing vane behind its reflector. That lack might indicate that the antenna was not stabilized, the vanes on other Soviet antennas being used to reduce the load on the stabilizer.

Strut Pair is 2 Strut Curve antennas arranged back to back (for high data rate), using pulse compression. There are 2 versions. Strut Pair I appeared in the mid-1970s and is carried on board Mod Kildin- (*Bedovyy*), Udalo- (first 2 units), and some Grisha-V-class ships and on board the space-events ship *Marshal Nedelin*. Strut Pair II, with improved air-search capability, appeared in the early 1980s and is carried on board the carriers *Novorossiysk* and *Baku*, on board some Grisha-V-class ships, on board the *Marshal Nedelin*, and on some *Udaloy*s.

Strut Curve air-search radar on board an East German Koni-class frigate, 1978. (U.S. Naval Institute)

Strut Pair radar on board the *Udaloy*-class destroyer *Admiral Vinogradov* at Norfolk, July 1990. (S. Zaloga)

◆ Top Plate

Top Plate has back-to-back S-band planar-array antennas (1 shorter but apparently wider than the other) and is installed on the *Tbilisi*, *Kirov*, *Slava*, on 8 *Udaloy*-class and 5 *Sovremennyy*-class destroyers, as well as 2 *Krivak*-IIIs, and on the

Top Plate antenna on board the *Udaloy*-class missile destroyer *Admiral Vinogradov*, July 1990. The near plate shows the characteristic sinuous waveguide of a frequency-scanning radar on its left side, and the separate slotted waveguides of the other plate are clearly visible. (S. Zaloga)

new Bal-Aux 2 nuclear auxiliary. Top Plate seems to be the successor to Head Net C. Both arrays are canted to the horizontal, at opposite (i.e., analogous) angles. The conclusion that the arrays are in fact frequency-scanned would seem to flow from the replacement of Top Steer by Top Steer/Top Plate; that replacement also suggests the likely frequency.

The effect of canting would be to run the beam diagonally across the sky as the radar elevated. If the beam is relatively narrow, and the time between pulse trains of different frequencies relatively long, it might be argued that such operation would compensate for the rotation of the antenna. The advantage of such a design would be that the radar could dwell longer at each elevation angle, achieving a better probability of detection. Back-to-back construction might make for a better net data rate, the shorter antenna producing a somewhat broader beam (in elevation) intermediate between the fan beam of a 2D radar and the pencil beam of a true 3D radar.

◆ Top Sail/Top Pair

The large frequency-scanning 3D radar introduced in 1967 in the *Moskva* is the main search radar in all ships armed with SA-N-3 missiles. Top Sail probably operates at about the same frequency as Big Net, i.e., about 850 MHz, which is well below that used by the roughly analogous U.S. systems of a decade earlier (SPS-39/52 series). The typical U.S. flat serpentine waveguide is replaced by a waveguide twisted around a vertical pole in front of the reflector; very clear photographs show the twists, which are required to provide the greater length needed to operate at a longer waveguide. Presumably there are radiating slots on the pole where it faces the reflector. Antenna dimensions are about 6.1×7.5 m.

The Soviet name for Top Sail is Voskhod (Dawn), which would be particularly appropriate to a radar whose beam rises (like the sun).

Top Sail is invariably combined with a Head Net C secondary or backup 3D radar.

Top Sail on board a *Kresta-II*-class cruiser. The long straight element in front of the reflector is the twisted feed, which performs the same function as the sinuous feed in a U.S. frequency-scanning radar. The extra feed at the top is presumably for IFF. (U.S. Navy)

Top Pair radar on board the missile cruiser *Marshal Ustinov*, Norfolk, 1989. Note the interrogator (IFF) atop the array. (S. Zaloga)

Top Pair consists of Top Sail and Big Net antennas arranged back to back. Presumably that arrangement makes for better long-range coverage; the U.S. Navy has found that frequency-scanning radars do not dwell on any particular part of the sky long enough to provide the sort of detection probability achievable with a fan-beam (2D) radar. Top Pair first appeared in the *Kirov* and *Slava*. The usual backup radar is Top Steer.

◆ Top Steer

This 3D S-band radar consists of a frequency-scanned antenna arranged back to back with 1 Strut Pair antenna. There is no known example of the S-band frequency scanner alone (analo-

Top Steer radar on the missile destroyer *Otlichnyy* visiting Norfolk, 1989. The tube running up in front of the radar reflector carries the serpentine feed for frequency scanning. The array above the antenna is the Long Head IFF interrogator. (S. Zaloga)

Top Steer radar on the cruiser *Kirov*, 1981, with a Top Dome missile director on the left and Vee Tube HF radio antennas on the right. Below the radar are the box for a Fly Screen landing-control device and a Tin Man television camera. The small fire-control radar is Bass Tilt. (U.S. Naval Institute)

gous to Top Sail). The 2 antennas share a common feed. Since Strut Pair is known to have been the first Soviet pulse-compression radar, it is difficult to avoid concluding that the Soviets use a single frequency-scanned pulse in the height-finder, rather than changing frequency pulse by pulse as in most Western frequency-scanned radars.

This radar actually preceded Top Pair into service, the *Kiev* carrying Top Sail (not Top Pair) and Top Steer. It appeared as the secondary 3D radar of the *Kirov* and is the primary 3D radar on the first 3 *Sovremennyy*-class destroyers; it is also on board 2 *Kievs*, 2 *Kirovs*, 2 *Slavas*, and the experimental destroyer *Provornyy*.

Top Steer on the destroyer *Sovremennyy*, with Palm Frond surface-search radars. (U.S. Naval Institute)

Plate Steer is an analogous antenna, in which the 3D element of Top Steer is replaced by the planar array of Top Plate, canted to the vertical (as in other Top Plate installations), on the *Sovremennyy*-class destroyers *Osmotritel'nyy* and *Bezuprechnyy*.

FIRE-CONTROL RADARS

◆ Bass Tilt

This radar operates in C-band and is used with the Soviet AK 630 Gatling gun. In *Grisha*-III, Bass Tilt also controls the twin

A Bass Tilt radar director on board the missile cruiser *Marshal Ustinov* at Norfolk, 1989. The object tilted back alongside carries a microwave horn and may be used to cancel sidelobes. (S. Zaloga)

A Tarantul-II-class missile corvette shows her Light Bulb data link antenna at the top of her mast, with a Bass Tilt gunfire-control antenna below. The small slotted waveguide atop the bridge serves a Kivach-3 navigational radar. The 2 objects right aft are standard chaff launchers. (*Ships of the World*)

57-mm gun; and in *Nanuchka*-III, *Matka*, *Grisha*-III, *Tarantul*, and *Pauk*, Bass Tilt controls the 76.2-mm gun. As its name implies, this radar operates at a somewhat lower frequency than Drum Tilt, which it superficially resembles. Bass Tilt entered service about 1972. This radar is called *Vympal* in Indian service; that may be its Soviet name. It controls 2 separate guns, the single 76-mm and the AK-630, in the new Indian corvette *Khukri*.

◆ Cross Sword

Serving as the missile guidance for SA-N-9, which is the successor to SA-N-4, the Ku/X-band Cross Sword, like the Ku/C-band Pop Group, incorporates its own search antenna. In this case, however, there are no separate target and missile-tracking antennas, only a single flat face with a prominent illuminator. The antenna is not dished in any way and, therefore, cannot be a passive reflector for the feed. Nor is there sufficient depth for the flat plate to be merely a weather cover. Most probably the flat plate is an active reflector, in the sense that different elements change the phase of the incoming signal (from the feed) in different ways, so as to form 1 or more beams. Such a solution would square with the fact that Cross Sword is roughly contemporary with the phased-array Top Dome, and also that Cross Sword has apparently encountered serious manufacturing problems (a simple monopulse would not present any great difficulty). Presumably, the prominent pimple centered on the Top Dome radome is an analogous feed.

Such radars are quite different from Western phased arrays, in which the phase shifter is interposed directly between transmitter/receiver and antenna element. Presumably, they are simpler to wire and need not pass quite the same amount of power as in such Western radars as SPY-1.
